the robot to change from one behavior to another. Different inputs available to the behaviors could be used by the triggers to force a behavior change, such as the location of targets or through other events such as receiving a message from team members.

Consider the example behavior state machine, as shown in Fig. 71.3, which is used on this platform to perform a cooperative target search and detection mission. After the UAVs are safely at altitude and switched to autonomous operation, the UAVs enter the *Fly-Orbit* behavior. In this behavior, the UAV is in a “standby” mode and the mission processor simply gathers and logs data from the sensors but does not send commands to the autopilot. When the ground station mission operator sends a *Start-Mission* command, the behavior state machine switches to the *Fly-Search-Pattern* behavior. At this point the behavior commands the autopilot to follow a predetermined search pattern (defined by a set of waypoints.) However, a similar behavior could be written to provide low-level bank angle commands if desired. While the UAV performs the search pattern, the behavior is listening for messages from the other UAVs and UGV on the team (the *Help-Requested* message). It is also listening for messages from the sensors indicating that a target was found (*Target-Detected* message). If the computer vision process locates the target or one of the other UAVs locates the target and sends a request for help over the communications link, the current behavior becomes the *Survey-Target* behavior. At this point, the behavior will send new waypoints to the autopilot, dynamically commanding it to fly a new path around the target location.

Now, consider another example in which UAVs cooperatively negotiate task assignments with each other. In task assignment scenario, each available platform is assumed to be in a state where it can accept tasks. In some cases, these platforms may be autonomous vehicles or they may be manned or remotely operated assets. In either case, the vehicles may be in a holding pattern state, ready to be tasked with new requests. Once a request is assigned, the vehicle begins performing tasks, entering a *Perform Tasks* state, until either all tasks are complete or another event causes the vehicle to be removed from further consideration (such as a

low-fuel condition). If a vehicle has existing tasks to perform when it becomes unavailable, the system will reassign those tasks using the same agent-based negotiation mechanism.

71.3.1.1 High-Level Mission Planning

An important concept behind behavior-based autonomy is that these behaviors can be packed into reusable components that can be tested individually and combined into higher-level missions, such as the example described above. Therefore, for these systems to be useful, operators will need an interface for planning high-level missions, instead of low-level waypoint by waypoint routes.

Behavior-based autonomous systems will require a mission editor which allows operators to choose behaviors from a library of reusable behaviors and configure them into high-level missions. Each behavior is incorporated into a “state machine” plan that represents the event-based transitions between behaviors. There could be separate plans for multiple different missions, and these could be reused or combined into higher-level plans as well. An example of a graphical editor for allowing users to plan behavior-based missions is the MissionLab editor (Endo et al. 2004).

The behavior-based approach to mission planning and execution is a paradigm shift from the current approach to operations. Rather than sending a UAV to a particular location or set of locations, an operator would request that the UAV perform search and surveillance operations over a given area by loading the related behavior-based plan and inputting the specific areas to cover and flight constraints. The operator need not bother with low-level turn and waypoint commands, but allow the onboard planner to calculate them and notify the operator if there is a constraint violation. In addition, during flight, the operator would observe which state the UAV was operating in and be informed of any transitions between states. The next section describes how the behavior framework fits into an overall software architecture.

71.3.2 Behavior-Based Architecture

The recommended UAV autonomous control architecture consists of a layered control system that includes three layers, as shown in Table 71.1. These layers are (1) a deliberative, high-level mission executive, (2) a set of behaviors and state machines, and (3) a low-level reactive controller layer. The mission executive layer performs high-level planning and generates trajectories that can be executed by the UAV. The generated trajectories are segmented into local waypoints that are sent to the behaviors. The behaviors and state machine reflect the current state of the UAV autonomous operation. The behavior layer can request the generation of new plans and implement the behavior logic.

The reactive controller provides low-level control signals for the UAV, regardless of the mode of operation or current mission assignment, and provides for a fast response to ensure vehicle safety. The reactive layer should be tightly integrated with the autopilot and, in some cases, may fully reside within the autopilot. This architecture allows for a fast and responsive set of low-level reactive behaviors

Table 71.1 Control layers

| Layer | Description | Frequency | Outputs |
|-----------------------------------|--|----------------------------|----------------------------|
| Mission executive | Deliberative, high-level global planner | Low frequency | Candidate paths |
| Behaviors and state machine | Processes sensors and executes behaviors | Medium frequency | Waypoints, speed, altitude |
| Reactive controller and autopilot | Generates control signal | High frequency (fast loop) | Low-level control signals |

that allow the vehicle to navigate safely as perception is updated in a dynamic environment, while allowing for full deliberation and higher-level planning. The following sections discuss each of these modules in more detail.

71.3.2.1 Mission Executive

A low-frequency loop, the mission executive, generates trajectories based on mission goals, mission constraints (such as no-fly zones), and a priori knowledge. Global map information is used as an input to this layer. Additionally, regular updates from the perception modules can be incorporated to reflect changes in a dynamic environment. The planner also considers additional constraints for the vehicle, such as flight characteristics, fuel levels, and wind vectors to further refine the candidate path plans.

The high-level deliberative planner, running in a slower executing loop, considers the global environment of the robot to generate candidate path plans for the robot to follow. The planner uses the fused sensory information, stored in a global map as input. The global map is built from Perception module and contains far and near obstacles as well as mission waypoints and goals. The deliberative module runs planning algorithms to generate a candidate path plan that can be executed by the low-level reactive behaviors. The use of a high-level optimistic planner is necessary because perception data will change with additional exploration and is often less accurate from a distance. The high-level, optimistic planner generates candidate paths that encourage exploration and allow for a margin of error before closing off any path. As the robot navigates closer to obstacles, the mid-level deliberative planner will take additional perception inputs and constraints into account and refine the candidate paths. This level segments the candidate plan into a set of local waypoints that the low-level controllers can follow and these can be sent in sequence to the reactive module.

71.3.2.2 Behaviors and State Machine

This module takes as input dynamic obstacles and information about other vessels, such as vessel intent and heading vectors, and adjusts the candidate path to meet these constraints. It runs at a higher frequency than the planning loop and segments the candidate path into a series of local waypoints, which are sent to the low-level controller, for the UAV to follow.

Behavior-based architectures allow for robot developers to create separate and standalone behaviors for autonomous operations. Each behavior is encapsulated as a single unit and can be tested fully before being integrated into more complex sets of behaviors. In addition, behaviors can be extended and designed to operate together. Behavior arbitration schemes are used to determine which behaviors are allowed to run at a given time and which behaviors control the robot in the situation when there are conflicts. There are many existing behavior-based robot behavior frameworks and arbitration mechanisms that can be leveraged, including DAMN (Rosenblatt 1995), 4D/RCS (Albus 2002), MOOS IvP (Benjamin et al. 2009), and ROS (Quigley et al. 2009).

As described above, the behaviors and state machine reflect the current state of the system, and events trigger transitions between states. The behaviors may request that the planner generate a new plan when new information arrives or a state change occurs. In addition, the behaviors encapsulate the “mission logic.” In a cooperative UAV scenario, the behaviors would contain the task assignment and negotiation logic for cooperating with other UAVs and operators. The behaviors plan in the full configuration space of the robot and veto any operations that would cause the robot to violate safety constraints (such as navigating too close to obstacles or performing unsafe maneuvers).

Depending on the mission requirements and autopilot capabilities, it may be sufficient in the architecture to allow the behaviors to output higher-level commands including waypoints, altitude, and speed to the autopilot, while the autopilot sends the low-level, high-frequency control signals to the vehicle servos. However, in some mission scenarios, it may be desirable to exercise more low-level control over vehicle flight. An example of this might be when the vehicle is navigating in environments with obstacles or changing wind conditions. In that case, the lower-level reactive controller would exist external to the autopilot and send direct turn or bank commands.

71.3.2.3 Reactive Controller

The reactive controller consists of the final interface to the autopilot, which provides the control signal. It may also exist as part of the autopilot in some implementations. It should run in a fast loop, to ensure safe operations of the aircraft. It serves as the safety interface to the autopilot and ensures that if the state of the system has changed since the last behavior update that the UAV will react by sending the correct response to the autopilot to avoid a collision or other system failure.

71.4 Case Study: A UAV Cooperative Research Platform

71.4.1 Introduction

This case study describes an unmanned systems architecture and platform for performing cooperative autonomy research. The primary research aim of this system is to explore distributed, cooperative, and autonomy algorithms for controlling

Fig. 71.4 UAV-UGV team. The system includes multiple small UAVs and a UGV

multiple unmanned systems vehicles. The system consists of multiple small, unmanned aerial vehicles (UAVs) and an unmanned ground vehicle (UGV), shown in Fig. 71.4, that can operate autonomously and accept missions from a ground station. The system leverages open standards and off-the-shelf technologies and can be configured to carry different mission payloads. The vehicles communicate with each other and collaborate in a distributed manner. Real-time telemetry and sensor updates are displayed on the FalconView-based ground station. Over 60 flight demonstrations as well as UAV-UGV collaborative experiments have been performed using this system.

The Georgia Tech Research Institute (GTRI) Collaborative Unmanned Systems Technology Demonstrator (CUSTD) program involved multiple UAVs and a UGV working together in a collaborative, autonomous team. The research platform consists of multiple, tactical UAVs that perform onboard computer vision tasks and run autonomous behaviors. The UGV performs waypoint navigation and obstacle avoidance over a road network. The vehicles all operate autonomously and can exchange mission messages with each other using the JAUS standard. The vehicles perform air to ground teaming in a target detection and surveillance mission as well as distributed task allocation using market-based technologies. For a similar UAV to UGV cooperative mission, see the example in Grocholsky et al. (2006).

In a directed cooperation mission, multiple aerial vehicles search for a target, and once it is found, direct ground vehicles and other air vehicles to the target location to perform autonomous surveillance. This platform is part of our ongoing commitment to Unmanned Systems research at GTRI and can be used both internally and in externally sponsored research to study improvements to Unmanned Systems sensors, operations, and collaborative autonomy.

The CUSTD program also serves as a research platform for demonstrating autonomous task assignment using market-based algorithms. Ongoing work includes the ability for heterogeneous vehicles (vehicles with different capabilities

and different sensor characteristics) to collaborate on a shared mission to distribute tasks in dynamic and decentralized manner. In domains where there are a large number of tasks to be shared between a large number of vehicles with different characteristics, it will be important for vehicles to work together in a distributed and dynamic way to allocate tasks among themselves without (or perhaps in addition to) human direction.

71.4.2 UAV-UGV Teaming

In distributed, heterogeneous, multi-agent teams, agents may have different capabilities and types of sensors. Many real-world scenarios could benefit from having teams of robots with different capabilities working in a cooperative manner. An example is after an earthquake or hurricane disaster, in which multiple locations need to be searched and surveyed for survivors. Detection of forest fires or chemical spills is another example. In such dynamic environments, teams of heterogeneous agents will need to cooperate in real time to perform tasks efficiently.

A common theme explored in air-ground teaming missions is how to best leverage the differences between the UAV and UGV platforms. Small-sized UAVs may be flying at an altitude of 1,000 ft. or more and therefore have a broad field of view. They can cover areas quickly and are not constrained to road networks. However, it is often challenging to localize targets exactly from a moving airframe. Furthermore, because they are moving quickly and at altitude, they cannot get a detailed view of the target as easily as a ground vehicle can.

A UGV, on the other hand, can utilize better localization capabilities and get up close to take sensor readings of suspected targets. Furthermore, a UGV can carry additional payloads and sensors, beyond the weight and power limits of the UAV, and can easily perform long missions. However, the UGV in this case is restricted to navigation over road networks and does not have a full view of the environment at any given time.

The vehicles in this system work as a team and are able to leverage the characteristics of the different platforms: The UAVs are used for searching and surveillance, and the UGV is able to get a close-up view of a target. This work describes the architecture for the UAV research platform and mechanisms for communication between air and ground vehicles and the ground station. An example search and surveillance demonstration is also presented.

71.4.3 UAV Platform

The UAV platform, shown in [Fig. 71.5a](#), leverages off-the-shelf readily available components and is based on a quarter-scale Piper Cub airframe with a base model Piccolo avionics and autopilot system from Cloud Cap Technology (Vaglianti et al. 2009). The airframe has a wingspan of 104 in. Two airframes have been tested,

Fig. 71.5 UAV platform. (a) The UAV platform is configurable for different mission requirements, payloads, and sensors. (b) The basic research payload (on the *right*) includes a mission processor, datalink, and digital camera. The mission processor connects to the autopilot (small box on the *left*) over the serial port

one with a four-stroke 20 cc gasoline engine, and the other with a two-stroke 26 cc gasoline engine. The different engine configurations allow for either more power or endurance as the mission dictates. The flight duration is up to 90 min, depending on mission tasks and payload. There is room available onboard for scientific payloads and sensors, configurable to the missions; see [Fig. 71.5b](#). In addition to the autopilot package, each airframe can carry up to seven pounds of payload or sensors. Over 60 field tests of this platform were performed in 2010, including multi-UAV cooperative autonomy and UAV-UGV teaming demonstrations.

71.4.3.1 Flight Operations and Safety

During flight operations, a human pilot manually takes off and lands each UAV. A human operator also monitors the UAV health (GPS status, signal strength, speed, engine RPMs, etc.) using the autopilot operator interface component of the ground station. For safety, each UAV is flown at a separate altitude with sufficient separation. Once the vehicle is at the safe altitude, the human pilot switches the vehicle into autonomous operation. At this point the UAV will begin to track toward the first waypoint in its current route. At any time, the flight operator can change the waypoints and upload them to the vehicle. The operator can also send a command to

the autopilot to shut down any onboard payload should the need arise. Additionally, the pilot can take over manual control at any point during the flight. In the event that the autopilot system loses communication with the ground station, the UAV will automatically return to the safe waypoint and orbit. Lastly, the platform also includes a homing beacon for emergency recovery.

71.4.3.2 UAV System Architecture

The UAV system architecture consists of the autopilot system for low-level flight control and the autonomy payload for high-level mission control. The flight control modules and high-level autonomy modules have been logically and physically separated to provide for flight safety and ease of configuration. The autopilot system provides for low-level control of the platform and can be given a series of waypoints or control loops using the corresponding operator interface in the ground station. The UAV platform can be flown without the autonomy or other sensor payload, using only the autopilot to follow waypoints. This may be desirable if there is a mission requirement to carry a bulky sensor and gather data for offline analysis.

The autopilot module is self-contained and includes a dedicated communications link, power supply, and charging circuit. In addition the platform also carries a dedicated power supply for the engine's ignition. The autopilot system communicates with the ground station via a dedicated 2.4 GHz data-link. The avionics components include a flight control system (flight computer), a GPS/IMU and barometric altimeter sensor for localization, and a waypoint following autopilot for control. Position updates are sent to the ground station at 4 Hz and the core autopilot processes sensor data and controls airframe servos at a rate of 20 Hz. In addition a magnetometer is connected to the autopilot to provide for accurate heading estimates.

Higher-level mission control is provided by the autonomy payload and mission processor. The mission processor receives sensor data and sends new waypoint and turn rate commands to the autopilot. The mission processor communicates with the autopilot's flight control system over a serial port. The autonomy payload includes an onboard PC-104 Intel Atom 1.6 GHz mission processor running the Linux operating system, a USB digital camera with a 1/3" CCD sensor and interchangeable lenses (8, 16, and 25 mm for wide angle and zoom views), and a Digi 900 MHz radio. This radio serves as the mission-level communications link for and agent-agent communications. Each of the UAVs and UGV can use this link to send messages directly to each other or to the ground station. The autonomy payload is self-contained and can easily be removed to perform experiments with different sensor or payload configurations. For example, in other experiments an infrared camera payload was carried to gather sensor data from two different IR cameras for offline analysis.

The vehicle is also equipped with an analog color video camera that transmits video to the ground over a separate link. This video is captured by the ground station and stored in digital format for use by the base station operators and for after-action reports. An example video frame is shown in [Fig. 71.6a](#).

Fig. 71.6 Analog video feeds. (a) The UAV platform captures video during flights and transmits it to the ground station. (b) The UGV platform also streams video to the ground station operators

Fig. 71.7 The UAV simulation architecture can support the same autonomous behaviors in real flight or simulation

71.4.3.3 Simulation

The software architecture allows for full simulation of the flight control and mission processor as shown in Fig. 71.7. The Piccolo autopilot provides hardware-in-the-loop (HIL) and software-in-the-loop (SIL) simulation capabilities. This allows for the full simulation of the autopilot and groundstation over a given area. The mission computer is simulated on a Linux virtual machine (VM) and communicates with the simulated autopilot processes over the network. The same autonomous behaviors that execute during a real flight are used during simulation. The datalinks are also simulated by exchanging the hardware radios with a software process that sends the packets over the network. The mission messages and vehicle telemetry are also sent to FalconView™ over the simulated radio. Finally, the output from the autopilot simulation can be fed to a visualization and rendering engine, such as the MetaVR™ tool.

The UAV mission processor’s software architecture is open and extensible and includes the use of open-source technologies and tools. Software processes are loosely coupled and communicate using a publish-subscribe messaging architecture,

LCM (Huang et al. 2010). Some of the lower-level processes and libraries are written in C++, such as the computer vision processes, and high-level autonomous behaviors are written in Java. Both custom and 3rd party low-level libraries and drivers are used to encapsulate access to hardware and standards.

As an example of interprocess communication using LCM, the image processing software component uses pose information to stamp images with position and to perform target localization. The avionics process handles messages coming from the autopilot and publishes a pose message (containing position and attitude information). Other processes, such as filter or image processing, can subscribe to these messages and use them, while posting messages of their own. The use of a publish subscribe mechanism allows new processes and sensors to be more easily integrated onto the platform. For example, a new sensor could include a process that reads data from the sensor and consumes the pose messages from the existing system. The sensor could post new messages that additional behaviors could consume or replace existing message types (such as a target-found message).

71.4.3.4 Aerial Target Detection and Localization

An important component of the system is aerial target localization. The UAV platform currently uses a computer vision-based mechanism for target detection; although additional techniques or sensors could easily be integrated into the system. Aerial Target Detection and Localization combines the ability to capture images from the air, process them using computer vision to find a target in the image, and to calculate the location of that target on the ground, given the position of the UAV.

The UAV's onboard digital camera is affixed to the underside of the fuselage and points down at a target on the ground. The UAV and the camera each have their own coordinate frame. The vision system combines the ability to (1) capture images while in the air, (2) process them in real time using computer vision for target detection, and (3) compute the estimated GPS ground location of the detected target. Figure 71.8 displays a sample image of ground features from Ft. Benning. The image contains the colored tarps that are used as a sample target. Target detection is achieved using color-based recognition methods that rely on a trained model of color thresholds. The UAV's pose is recorded when the image is snapped and is defined by the UAV's position (latitude, longitude, elevation) and attitude (roll, pitch, yaw). In combination with the position and orientation of the camera's coordinate frame with respect to the UAV (extrinsic parameters) and knowledge of the camera's sensor size, lens configuration, and pixel resolution (intrinsic parameters), along with the detected target's pixel coordinates in the image, the target's estimated coordinates in the real world may be computed, i.e., localized.

71.4.3.5 Behavior-Based Autonomy

Mission-level autonomy is designed to work in a behavior-based framework, in which behavioral autonomy components are encapsulated into reusable modules

Fig. 71.8 UAV onboard computer vision. The mission processor processes images from the onboard digital camera in real time. The target location is at the colored tarps in the center of the images. The UGV navigated to the target location after the target was detected from the UAV. Images are shown from each of the 2 UAVs, with different camera lenses and flying at different altitudes (a) 8 mm lens at 300 m. (b) 16 mm lens at 250 m

or behaviors. Various sets of behaviors can be developed and unit tested before being incorporated into the system. Behaviors can encapsulate simple low-level control, such as flying a search pattern or commanding waypoints, or higher-level operations, such as performing a cooperative task.

71.4.4 UGV Platform

The UGV platform consists of a 2006 Porsche Cayenne SUV automobile that has been modified for autonomous operation, shown in Fig. 71.4. This vehicle was developed as Georgia Tech's entry into the DARPA Urban Challenge. (http://www.darpa.mil/grandchallenge/TechPapers/Sting_Racing.pdf). The vehicle is equipped with stereo vision for lane navigation and LIDAR and radar sensors for obstacle detection. The vehicle performs autonomous waypoint navigation using the filtered GPS and IMU sensor output. The system uses a standard D* algorithm for graph-based path planning over a list of ordered waypoints. The vehicle starts with a known map of the navigable environment, a Route Network Definition File (RNDF), which contains metadata about points that define road segments. The vehicle can be given a set of waypoints to visit in advance or can be sent a current waypoint using the JAUS standard messages. The LIDARs and radar are used to detect static and moving obstacles in the environment and provide 360° coverage around the vehicle. The UGV also is equipped with the same Digi 900 MHz radio as the UAVs for agent-agent communications. The vehicle also carries an analog video camera and transmitter. A sample video frame is shown in Fig. 71.6b. This platform can be configured to carry different sensors as mission requirements dictate. For example,

in one experiment, the UGV carried a chemical sensor as part of an ammonia detection mission and sent sensor readings back to the ground station.

The vehicle navigates using a hybrid approach of behavior-based reactive control which references an internal, local map, and a graph-based planner that references the RNDF road network. The reactive controllers, similar to the behavior-based controllers described in Wooden et al. (2007), keep the vehicle clear of obstacles, while the high-level planner provides a route to the waypoint locations.

71.4.5 JAUS Standard

In support of collaborative autonomy, the vehicles must have a common capability to request assistance from each other when a target of interest is located. The Joint Architecture for Unmanned Systems (JAUS) is a standard that allows for greater interoperability between unmanned systems. As an example, each of the vehicles in the system and also the base station can send JAUS GO-TO-WAYPOINT messages to the team or a specific vehicle to request that they navigate to a new area. The standard includes a message set, protocol, and was originally an initiative of the U.S. Department of Defense for facilitating open architectures for unmanned systems. Interoperability is an important focus area for future unmanned systems, as vehicles of different types and from different vendors will need to cooperate with each other.

The vehicles in this system can each exchange JAUS messages with the other vehicles and the ground station. The benefit of the JAUS messaging capability on this platform is that vehicles from other vendors that also implement JAUS may be easily integrated into this system for performing joint field tests. This project uses the OpenJAUS (<http://www.openjaus.com>) implementation for creating JAUS standard messages between the air and ground platforms.

71.4.6 Ground Station

The system also includes a FalconViewTM-based ground station, as shown in Fig. 71.9. FalconViewTM is widely used by the U.S. Department of Defense for its aircraft mission planning and mapping capabilities. The open-source version of FalconViewTM is now freely available (<http://www.falconview.org>). FalconViewTM provides for application extensions through a plug-in framework. The vehicles in this system communicate to the FalconViewTM application plug-in through a ground station mission server to display vehicle position and telemetry information in real time, using JAUS standard messages. The ground station can also be used to send JAUS messages to the vehicles and to send other waypoint and mission-based commands. As the vehicles in the system perform the mission, the vehicles' behavioral state (such as *Search* or *Survey*) is displayed on the FalconViewTM map, along with the vehicle positions. Detected target locations are updated on the map as well.

Fig. 71.9 Using the FalconView™-based ground station, multiple UAVs and UGVs can be displayed, with video overlays and system status. The FalconView™ plugin can also send mission-specific commands to the mission processor

71.4.7 Cooperative Target Detection and Surveillance

In one type of a cooperative scenario, all vehicles participate in a search, detection, and surveillance mission. For example, a team of UAVs and a UGV can perform target surveillance over a wide area by flying a set of predefined waypoints, with the UGV waiting in standby. When one of the UAVs locates the target, it sends a message to team members with the target location. At that time, the team members can all navigate to the target location and perform surveillance.

This field experiment was performed as part of the Army's Robotics Rodeo in October 2010, at the McKenna site at Ft. Benning, GA, shown in Fig. 71.6a. The test location includes a network of roads and a long runway, along with a village or Military Operations on Urban Terrain (MOUT) setting. The purpose of this experiment was to demonstrate air-ground cooperation. Two UAVs autonomously flew search patterns covering the road networks and the village, with the UGV in standby mode at the far end of the test site. A fixed target, consisting of colored tarps, was placed inside the village. The UAV mission computers processed 2–3 image frames per second onboard, using basic color thresholds, to detect the target, as shown in Fig. 71.8.

When the first UAV spotted the target on the ground, the mission processor sent new waypoint commands to the autopilot and it autonomously changed course to survey the target. It also requested help from the other UAV and UGV by sending a JAUS message to each vehicle. In this case, the vehicles were setup to resend the JAUS messages until an acknowledgement was received from each team member. The other UAV received the message and also autonomously changed course to survey the target. The UGV was given the target location and navigated autonomously to the target area to perform more detailed surveillance. After all of the vehicles jointly surveyed the target for several minutes, the mission was completed.

71.4.8 Case Study Summary

This case study presented the design of a reusable and configurable UAV-UGV research platform for performing joint air-to-air and air-to-ground cooperative missions. The system can process sensor data onboard and run high-level autonomy algorithms for performing collaborative, autonomous missions. This platform has been field tested in multiple flight configurations, including a demonstration of a cooperative detection and surveillance task involving two UAVs and a UGV.

71.5 Conclusion

This chapter presented desiderata for systems designers to consider when building autonomous UAV systems. These desiderata help support the increasing levels of autonomy in UAV systems through behavior-based autonomy, modular and loosely coupled components, and distributed architectures.

Also important to the design of autonomous UAVs is the ability to perform high-level mission planning and to observe the state of autonomous behaviors. In addition, a core concept is the ability to process and store as much of the sensor data onboard as possible to make it immediately available to the autonomous behaviors and to reduce the reliance on ground station operators and analysts.

From a testing and software maintenance viewpoint, by incorporating introspection, open standards, and architectures into the design, these approaches will make the certification process easier and decrease maintenance costs. Finally, these approaches will free operators to focus on high-level tasks and help to make UAV architectures more scalable as a result.

Abstract

This chapter considers problems where multiple autonomous UAVs cooperate to control their individual state so as to optimize a common objective while communicating with each other to exchange state information. Since communication costs can be significant, especially when the UAVs operate with limited energy, conditions are sought under which communication of state information among nodes can be restricted while still ensuring that the optimization process converges. An asynchronous, event-driven scheme is described which limits communication to instants when some state estimation error function at a node exceeds a threshold. This scheme guarantees convergence to an optimal

even in the presence of communication delays as long as they are bounded. This approach is applied to a UAV network coverage control problem where the objective is to maximize the probability of detecting events occurring in a given region, and it is shown that it may significantly reduce communication costs, hence also prolonging the system's lifetime, without any performance degradation.

72.1 Introduction

In this chapter, teams of autonomous UAVs cooperating toward a common objective are considered. What makes the UAVs “autonomous” is their ability to optimize their own actions while limiting communication with the remaining team members as much as possible. The cooperating UAVs define a dynamic system which may be thought of as a network with each UAV corresponding to a node maintaining its own state s_i , $i = 1, \dots, N$. The goal of each node is to control its state so as to optimize some system-wide objective expressed as a function of $\mathbf{s} = [s_1, \dots, s_N]$ and possibly the state of the environment. Clearly, to achieve such a goal in a dynamic and uncertain environment, the nodes must share, at least partially, their state information. However, this may require a large amount of information flow and becomes a critical issue when the UAVs operate with limited resources. Aside from energy required to move, communication is known to be by far the largest consumer of the limited energy of a node (Shnayder et al. 2004), compared to other functions such as sensing and computation. Moreover, every communication among nodes offers an opportunity for corruption or loss of information due to random effects or adversarial action. Therefore, it is crucial to reduce communication between UAVs to the minimum possible. This in turn imposes a constraint on the optimization task performed by each node, since it requires that actions be taken without full knowledge of other nodes' states. Standard synchronization schemes require that nodes exchange state information frequently, sometimes periodically, which can clearly be inefficient and, in fact, often unnecessary since it is possible that (i) system inactivity makes the periodic (purely time driven) exchange of information unnecessary, (ii) occasional state information is adequate for control and/or optimization mechanisms which do not require perfect accuracy at all times, and (iii) state information of other nodes can be estimated reasonably well and explicit communication is thus redundant. This motivates an effort to seek *asynchronous* optimization mechanisms in which a node communicates with others only when it considers it indispensable; in other words, each node tries to reduce the cost of communication by transmitting state information only under certain conditions and only as a last resort. This poses questions such as “what should the conditions be for a node to take such communication actions?” and “under what conditions, if any, can we guarantee that the resulting optimization scheme possesses desirable properties such as convergence to an optimum?”

The general setting described above applies to problems where the nodes are UAVs controlling their locations and seeking to maintain some desirable formation (Ögren et al. 2004; Lawton et al. 2000) while following a given trajectory.

The UAV team may also be operating as a sensor network with UAVs located so as to achieve objectives such as maximizing the probability of detecting events in a given region or maintaining a desired distance from targets or data sources that ensures high-quality monitoring (Meguerdichian et al. 2001; Cortes et al. 2004; Ganguli et al. 2006; Zou and Chakrabarty 2003; Mihaylova et al. 2002; Cassandras and Li 2005; Hussein and Stipanovic 2007; Hokayem et al. 2007); this is often referred to as a “coverage control” problem. In some cases, the state of a UAV may not be its location but rather its perception of the environment which changes based on data directly collected by this UAV or communicated to it by other UAVs; consensus problems fall in this category (DeGroot 1974; Vicsek et al. 1995; Jadbabaie et al. 2003; Moreau 2005; Nedić and Ozdaglar 2009).

In this chapter, a UAV team is viewed as a network of N cooperating nodes. The team’s goal is to minimize an objective function $H(\mathbf{s})$ known to all nodes with every node controlling its individual state $s_i \in \mathbb{R}^{n_i}$, $i = 1, \dots, N$. The state update scheme employed by the i th node is of the general form

$$s_i(k+1) = s_i(k) + \alpha_i d_i(\mathbf{s}(k)), \quad k = 0, 1, \dots \quad (72.1)$$

where α_i is a constant positive step size and $d_i(\mathbf{s}(k))$ is an *update direction* evaluated at the k th *update event* (see also Bertsekas and Tsitsiklis 1997). We often use

$$d_i(\mathbf{s}(k)) = -\nabla_i H(\mathbf{s}(k))$$

where $\nabla H(\mathbf{s}(k))$ is the gradient of $H(\mathbf{s}(k))$ and $\nabla_i H(\mathbf{s}(k)) \in \mathbb{R}^{n_i}$. In general, each state is characterized by dynamics of the form $\dot{s}_i(t) = f_i(s_i, u_i, t)$ where $u_i \in \mathbb{R}^l$ is a control vector; for our purposes, however, we treat s_i as a directly controllable vector. Thus, in (72.1) we view $s_i(k+1)$ as the *desired* state determined at the k th update event and assumes that the control u_i is capable of reaching $s_i(k+1)$ from $s_i(k)$ within a time interval shorter than the time between update events.

A key difficulty in (72.1) is that $\mathbf{s}(k)$ is in fact not fully known to node i . Thus, $d_i(\mathbf{s}(k))$ has to be evaluated by synchronizing all nodes to provide their states to node i at the time its k th update event takes place. This is extremely costly in terms of communication and assumes no delays so that the state information is accurate. Alternatively, node i can evaluate $d_i(\mathbf{s}(k))$ using estimates of s_j for all $j \neq i$ relying on prior information from node j and possibly knowledge of its dynamics. A key concern is to determine instants when a node j may communicate its state to other nodes through what are termed *communication events*. It should be noted that such communication events occur at different times for each node, as do each node’s state update events, so that the resulting mechanism is asynchronous. A distributed optimization framework is necessitated by the fact that nodes operate in a dynamic and uncertain environment and each node generally has local information not available to others. An example is the appearance of a random obstacle in the coverage control setting mentioned earlier, detected only by a single node.

A scheme is presented through which a node j maintains an *error function* of its actual state relative to its state as estimated by other nodes (which node j can evaluate). The node then transmits its actual state at time t only if this error function at t exceeds a given *threshold* δ_j . In other words, a node does not incur any communication cost unless it detects that the deviation of its state from the other nodes' estimate of its state becomes too large; this may happen due to the normal state update (72.1) accumulating noise, imperfect state estimation or through unexpected state changes (e.g., if a mobile node encounters an obstacle). First, assuming negligible communication delays, it was shown in Zhong and Cassandras (2010) that by varying this threshold appropriately and under certain rather mild technical conditions, the resulting optimization scheme converges and leads to a minimum of $H(\mathbf{s})$; this minimum may be local or global depending on the nature of the objective function. Our approach controls the asynchronous occurrence of communication events through the threshold-based scheme outlined above in a way that may drastically reduce the number of such events while still guaranteeing convergence. Our analysis can also be extended to cases where an explicit noise term is included in (72.1), as well as when we allow communication delays to be non-negligible, provided there exists an upper bound in the number of state update events that occur between the time of a communication event initiated by a node and the time when all nodes receive the communicated message.

In the second part of the chapter, this approach is applied to a coverage control problem in which a distributed optimization scheme based on (72.1) is used in order to deploy UAVs in a region (possibly containing polygonal obstacles) so as to maximize the probability of detecting events (e.g., unknown data sources) in this region. In earlier work (Cassandras and Li 2005), it was assumed that all nodes have perfect state information by synchronizing update events with communication events. This imposed significant communication costs. Here, this synchronization requirement is relaxed and communication events are limited to occur according to the new proposed event-driven policy leading to convergence to the optimum. Simulation results are included to show that the same performance is attained with only a fraction of the original communication costs.

Our work on asynchronous distributed optimization with event-driven communication was introduced in Zhong and Cassandras (2008a) with no communication delays in the convergence analysis. Such event-driven communication is also used in collaborative estimation (as opposed to optimization) (Shima et al. 2007) where a node transmits data to other nodes only when a computable estimation error exceeds some fixed threshold. In Wan and Lemmon (2009), an augmented Lagrangian method based on event-triggered message passing is developed to obtain an approximate solution of the network utility maximization problem.

The remainder of the chapter is organized as follows. Section 72.2 describes our asynchronous distributed optimization framework and the proposed scheme for communication events. The convergence analysis is reviewed in Sect. 72.3, including the case where communication delays are present. In Sect. 72.4, it is shown how our approach applies to a coverage control problem for UAV teams, and conclusions are given in Sect. 72.5.

Fig. 72.1 State update and communication processes for two nodes. *Dots* represent state update events at a node, and *triangles* represent state communication events

72.2 Asynchronous Distributed Optimization Framework

In a setting where N cooperating nodes (the UAVs) seek to optimize a common objective function, there are two processes associated with each node: a *state update process* and a *state communication process*. A discussion of the state update process comes first.

Let $t_k, k = 1, 2, \dots$, denote the time when any one node performs a state update, that is, it takes an action based on (72.1). No constraint is imposed on when precisely such an update event occurs at a node, and it is allowed to be either periodic or according to some local node-based policy. However, it will be assumed that every node performs an update with sufficient frequency relative to the updates of other nodes (this assumption will be stated precisely later).

Let C^i be the set of indices in $\{t_k\}$ corresponding to update events at node i . As an example, in Fig. 72.1, where nodes 1 and 2 perform state updates at $\{t_1, t_4, t_5\}$ and $\{t_2, t_3, t_6\}$, respectively, one can see that $C^1 = \{1, 4, 5\}$ and $C^2 = \{2, 3, 6\}$. For all $k \notin C^i, d_i(s(k)) = 0$ in (72.1), that is,

$$s_i(k+1) = s_i(k) \quad \text{if } k \notin C^i$$

Any state update at such $k \notin C^i$ is referred to as a *null step* at node i .

Next, the state communication process is discussed. Let τ_n^j be the n th time when node j broadcasts its true state to all other nodes, $n = 1, 2, \dots$ and $\tau_0^j = 0$ (a more general scheme which allows point-to-point communication will be introduced later in this section). Depending on the network connectivity at that time, it is possible that only a subset of nodes is reached. It is initially assumed that at all communication event times the state information broadcast by node j can reach any other node with negligible delay either directly or indirectly (in the latter case, through a sequence of transmissions), that is, we assume that the underlying network is connected. The negligible communication delay assumption will be relaxed in the sequel. The network connectivity assumption is preserved throughout, although it may be replaced by weaker conditions when the network has nodes that can be decoupled, that is, the local decision of a node is not affected by the state information of some other nodes in the network. For the range of applications that involve

UAV teams, there is usually a “base station” which maintains communication with all autonomous UAVs in the network, thus ensuring full connectivity. However, the existence of such a base station is not required for the general optimization framework proposed. If connectivity is lost by some node, then a related problem is to ensure that the node can control its state so as to reestablish such connectivity. This problem is discussed and resolved elsewhere (Zhong and Cassandras 2011).

Consider now a state update time t_k at node i , that is, $k \in \mathcal{C}^i$. Of interest is the most recent communication event from a node $j \neq i$. Define

$$\tau^j(k) = \max\{\tau_n^j : \tau_n^j \leq t_k, n = 0, 1, 2, \dots\} \quad (72.2)$$

as the time of the most recent communication event at node j up to a state update event at t_k . As an example, in Fig. 72.1 node 1 communicates its state to node 2 twice in the interval (t_2, t_3) ; in this case, $\tau^1(3) = \tau_2^1$. However, no further communication event takes place from node 1 until after the next state update event at node 2 at time t_6 , so that $\tau^1(6) = \tau^1(3) = \tau_2^1$. The policy used by node j to generate communication events is crucial and will be detailed later in this section, but it is emphasized that it is in no way constrained to be synchronized with update events or with the communication events of any other node.

In order to differentiate between a node state at any time t and its value at the specific update times t_k , $k = 0, 1, \dots$, $x_i(t)$ is used to denote the former and observe that

$$s_i(k) = x_i(t_k)$$

Thus, the state of node j communicated to other nodes at time $\tau^j(k)$ may be written as $x_j(\tau^j(k))$. Returning to the state update process, consider some t_k with $k \in \mathcal{C}^i$, and let $s^i(k)$ be a vector with node i 's estimates of all node states at that time, that is, an estimate of $\mathbf{s}(k)$. There are various ways for node i to estimate the state of some $j \neq i$. The simplest is to use the most recent state information received at time $\tau^j(k)$ as defined in (72.2), that is,

$$s_j^i(k) = x_j(\tau^j(k)) \quad (72.3)$$

Alternatively, node i may use a dynamic linear estimate of the form

$$s_j^i(k) = x_j(\tau^j(k)) + \frac{t_k - \tau^j(k)}{\Delta_j} \cdot \alpha_j \cdot d_{j,\tau^j(k)} \quad (72.4)$$

where Δ_j is an estimate of the average time between state updates at node j (e.g., a known constant if node j performs periodic updates) and $d_{j,\tau^j(k)}$ is the update direction communicated by node j at time $\tau^j(k)$ along with its state. Note that $[t_k - \tau^j(k)]/\Delta_j$ is an estimate of the number of state updates at j since its last communication event. More generally, if the precise local decision-making process of j is known to i , then i can evaluate $s_j^i(k)$ using this information with initial condition $x_j(\tau^j(k))$. In this case, the estimate is error-free except for noise that

may have affected the actual state evolution of node j in the interval $[\tau^j(k), t_k]$. In general, the value of an estimate $s_i^j(k)$ used by node i to estimate node j 's state depends on t_k , the most recent communication event time $\tau^j(k)$, and the actual state $x_j(\tau^j(k))$ of node j at that time.

Now consider what criterion a node i might use to generate its communication events, recalling that the goal is to reduce communication costs. If node i knows that node j uses a specific method to estimate its state, then node i can evaluate that estimate and hence the error in it at any time. If $x_i^j(t)$ is the estimate of $x_i(t)$ evaluated by node $j \neq i$ at time t , an estimation *error function* $g(x_i(t), x_i^j(t))$ is defined which measures the quality of the state estimate of node i with the requirement that

$$g(x_i(t), x_i^j(t)) = 0 \text{ if } x_i(t) = x_i^j(t) \quad (72.5)$$

Examples of $g(x_i(t), x_i^j(t))$ include $\|x_i(t) - x_i^j(t)\|_1$ and $\|x_i(t) - x_i^j(t)\|_2$. Let $\delta_i(k)$ be an error *threshold*, determined by node i after the k th state update event such that $k \in C^i$. Thus, $\delta_i(k) = \delta_i(k-1)$ if $k \notin C^i$. Let \tilde{k}_t^i be the index of the most recent state update time of node i up to t , that is,

$$\tilde{k}_t^i = \max \{n : n \in C^i, t_n \leq t\} \quad (72.6)$$

If different nodes use different means to estimate i 's state, then generally $x_i^j(t) \neq x_i^k(t)$ for nodes $j \neq k$, and communication may be limited to a node-to-node process. Let τ_n^{ij} be the n th time when node i sends its true state to node j . Let us also set $\tau_0^{ij} = 0$ for all i, j . Then, the communication event policy at node i with respect to node j is determined by

$$\tau_n^{ij} = \inf \left\{ t : g(x_i(t), x_i^j(t)) \geq \delta_i(\tilde{k}_t^i), t > \tau_{n-1}^{ij} \right\} \quad (72.7)$$

When a communication event is triggered by (72.7) at τ_n^{ij} , assuming negligible communication delay, x_i^j is instantaneously set to $x_i(\tau_n^{ij})$, that is, $x_i^j((\tau_n^{ij})^+) = x_i(\tau_n^{ij})$. Therefore, the error measure is reset to zero, that is, $g(x_i((\tau_n^{ij})^+), x_i^j((\tau_n^{ij})^+)) = 0$.

If, on the other hand, all nodes use the exact same estimation method, then $x_i^j(t)$ will have the same value for all $j \neq i$, and τ_n^{ij} in (72.7) can be replaced by τ_n^i . In other words, node i communicates its state to all other nodes only when it detects that its true state deviates from the other nodes' estimate of it by at least the threshold $\delta_i(\tilde{k}_t^i)$. Figure 72.2 shows an example of a trajectory of $g(x_i(t), x_i^j(t))$ where the threshold is decreasing over time and the error function is continuous over all intervals $(\tau_{n-1}^{ij}, \tau_n^{ij})$, $n = 1, 2, \dots$. Observe that the negligible communication delay assumption allows the value of $g(x_i(t), x_i^j(t))$ to be instantaneously reset to 0 at τ_n^{ij} , $n = 1, 2, \dots$.

Next, the way in which the threshold $\delta_i(k)$ should be selected is discussed. The basic idea is to use a large value at the initial stages of the optimization process and later reduce it to ultimately ensure convergence. One of the difficulties is in

Fig. 72.2 Trajectory of the error function $g(x_i(t), x_i^j(t))$ when the communication delay is negligible

selecting an appropriate initial value for $\delta_i(k)$ which, if too large, may prevent any communication. The approach followed is to control $\delta_i(k)$ in a manner which is proportional to $\|d_i(s^i(k))\|_2$, the Euclidean norm of the update direction at the k th update event henceforth denoted by $\|\cdot\|$. Thus, let

$$\delta_i(k) = \begin{cases} K_\delta \|d_i(s^i(k))\| & \text{if } k \in C^i \\ \delta_i(k-1) & \text{otherwise} \end{cases} \quad (72.8)$$

where K_δ is a positive constant. An initial condition is also imposed such that

$$\delta_i(0) = K_\delta \|d_i(s^i(0))\|, \quad i = 1, \dots, N \quad (72.9)$$

and

$$s_j^i(0) = x_j(0) \quad (72.10)$$

Note that (72.10) can be readily enforced by requiring all nodes to share their initial states at the beginning of the optimization process, that is, $\tau_0^{ij} = 0$ for all i, j ; since generally $g(x_i(0), x_i^j(0)) \geq \delta_i(0)$, this triggers (72.7) and results in $g(x_i((0)^+), x_i^j((0)^+)) = 0$ for all $i = 1, \dots, N$. Also note that since $s^i(k)$ is node i 's local estimate of $s(k)$ at t_k , the computation in (72.8) requires only local information.

Finally, it should be pointed out that the quality of the estimation method used may be critical for effective communication reduction in our event-driven optimization framework. Poor quality state estimation can potentially trigger communication events at a frequency that is higher than that of state updates, especially close to convergence when nodes have small $d_i(s^i)$. Interestingly, when the simplest method, that is, static estimation, is used, this issue does not arise because triggering estimation errors coincide with state update events. Therefore, a node will communicate its real state at most as often as it updates its state.

72.3 Convergence Analysis

In this section, the convergence properties of the asynchronous distributed state update scheme are discussed. For $k = 0, 1, \dots$,

$$s_i(k+1) = s_i(k) + \alpha d_i(s^i(k)) \quad (72.11)$$

is the scheme used by nodes $i = 1, \dots, N$, where $d_i(s^i(k))$ is an update direction which satisfies $d_i(s^i(k)) = 0$ for all $k \notin \mathcal{C}^i$. For simplicity, a common step size α is used, but each node may easily adjust its step size by incorporating a scaling factor into its own $d_i(s^i(k))$. Recall that $s^i(k)$ is the state estimate vector evaluated by node i at the k th update event using the most recent state updates from other nodes at times $\tau^j(k)$ defined by (72.2). The framework in Bertsekas and Tsitsiklis (1997) will be followed. The distinctive feature in our analysis is the presence of the controllable state communication process defined by (72.7)–(72.9) which imposes a requirement on the constant K_δ in order to guarantee convergence. Further, our analysis provides means to select this constant in conjunction with the step size parameter α in (72.11) in a way that may potentially drastically reduce the number of communication events while still guaranteeing convergence.

A number of assumptions are stated below, most of which are commonly used in the analysis of distributed asynchronous algorithms (Bertsekas and Tsitsiklis 1997). Recall that, for the time being, it is assumed that the communication delay is negligible whenever a node informs other nodes of its current states.

Assumption 1. There exists a positive integer B such that for every $i = 1, \dots, N$ and $k \geq 0$ at least one of the elements of the set $\{k - B + 1, k - B + 2, \dots, k\}$ belongs to \mathcal{C}^i .

This assumption imposes a bound on the state update frequency of every node in order to guarantee that the entire state vector will be iterated on. It does not specify a bound in time units but rather ensures that each node updates its state at least once during a period in which B state update events take place. It is worth pointing out that an update event time t_k may correspond to more than one node performing updates.

Assumption 2. The objective function $H(\mathbf{s})$, where $\mathbf{s} \in \mathbb{R}^m$, $m = \sum_{i=1}^N n_i$, satisfies the following:

- (a) $H(\mathbf{s}) \geq 0$ for all $\mathbf{s} \in \mathbb{R}^m$.
- (b) $H(\cdot)$ is continuously differentiable, and $\nabla H(\cdot)$ is Lipschitz continuous, that is, there exists a constant K_1 such that for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^m$, $\|\nabla H(\mathbf{x}) - \nabla H(\mathbf{y})\| \leq K_1 \|\mathbf{x} - \mathbf{y}\|$.

In what follows, all vectors shall be taken to be column vectors and $'$ will be used to denote a transpose. Let

$$d(k) = [d_1(s^1(k))', \dots, d_N(s^N(k))']'$$

For simplicity, $d_i(k)$ instead of $d_i(s^i(k))$ will henceforth be written.

Assumption 3. There exist positive constants K_2 and K_3 such that for all $i = 1, \dots, N$ and $k \in \mathcal{C}^i$,

$$(a) \quad d_i(k)' \nabla_i H(s^i(k)) \leq -\|d_i(k)\|^2 / K_3$$

$$(b) \quad K_2 \|\nabla_i H(s^i(k))\| \leq \|d_i(k)\|$$

Here, $\nabla_i H(s^i(k))$ denotes a vector with dimension n_i . Its j th component, denoted by $\nabla_{i,j} H(s^i(k))$, is the partial derivative of $H(\cdot)$ with respect to the j th component of s_i . This assumption is very mild and is immediately satisfied with $K_2 = K_3 = 1$ when an update direction given by $d_i(k) = -\nabla_i H(s^i(k))$ is used.

Assumption 4. The error function $g(x_i(t), x_i^j(t))$ satisfies the following:

$$(a) \quad \text{There exists a positive constant } K_4 \text{ such that } \|x_i(t) - x_i^j(t)\| \leq K_4 g(x_i(t), x_i^j(t)) \text{ for all } i, j, t.$$

$$(b) \quad g(x_i(t), x_i^j(t)) \leq \delta_i(\tilde{k}_i^j) \text{ where } \tilde{k}_i^j \text{ was defined in (72.6).}$$

In the common case where $g(x_i(t), x_i^j(t)) = \|x_i(t) - x_i^j(t)\|$, part (a) of this assumption is obviously satisfied with $K_4 = 1$. Part (b) may be violated if there is a discontinuity when $g(x_i(t), x_i^j(t))$ exceeds $\delta_i(\tilde{k}_i^j)$, in which case one can simply redefine the error function to take the value $\delta_i(\tilde{k}_i^j)$ at all such points, that is, an error function $\bar{g}(\cdot)$ is used instead such that $\bar{g}(x_i(t), x_i^j(t)) = \delta_i(\tilde{k}_i^j)$ if $g(x_i(t), x_i^j(t)) > \delta_i(\tilde{k}_i^j)$, otherwise $\bar{g}(\cdot) = g(\cdot)$. Alternatively, observe that if such a discontinuity occurs at t , then, by (72.7), node i generates a communication event, and, under the negligible delay assumption, node i receives node j 's state and sets $x_i^j(t) = x_i(t)$, hence $g(x_i(t), x_i^j(t)) = 0$ by (72.5); that is, the error is instantaneously reset to zero. Therefore, defining $g(\cdot)$ to be right-continuous guarantees that part (b) is always satisfied. With this understanding, the notation $g(x_i(t), x_i^j(t))$ will still be used, and this assumption is taken to be satisfied, though it is later relaxed.

Theorem 72.1. Under Assumptions 1–4, the communication event policy (72.7) and the state update scheme (72.11), if the error threshold $\delta_i(k)$ controlling communication events is set by (72.8) and (72.9), then there exist positive constants α and K_δ such that $\lim_{k \rightarrow \infty} \nabla H(s(k)) = 0$.

The proof of this theorem and all subsequent theoretical results in this chapter are omitted and can be found in Zhong and Cassandras (2010).

Corollary 72.1. If $0 < \alpha < 2/K_1 K_3$, then

$$K_\delta < \frac{1}{(1+B)K_4\sqrt{m}} \left(\frac{2}{K_1 K_3} - \alpha \right) \quad (72.12)$$

guarantees that $\lim_{k \rightarrow \infty} \nabla H(s(k)) = 0$.

Note that (72.12) provides an upper bound for K_δ that guarantees convergence under the conditions of Theorem 72.1. Obviously, there may be larger values of K_δ under which convergence is still possible.

As already mentioned, one often sets $d_i(s^i(k)) = -\nabla_i H(s^i(k))$ in (72.11) and uses $g(x_i(t), x_i^j(t)) = \|x_i(t) - x_i^j(t)\|$, in which case Assumption 3 is satisfied with $K_2 = K_3 = 1$ and Assumption 4(a) with $K_4 = 1$. It follows from Corollary 72.1 that $\alpha < 2/K_1$ can be chosen and (72.12) leads to a K_δ arbitrarily close from below to $(2/K_1 - \alpha)[(1 + B)\sqrt{m}]^{-1}$. Observe that, if node states are scalar, this value is inversely proportional to $\sqrt{m} = \sqrt{N}$. Thus, large networks require a smaller value of K_δ , implying that convergence is less tolerant to a node's state estimates evaluated by other nodes and communication needs to be more frequent. For vector node states, the same is true since $m = \sum_{i=1}^N n_i$. Along the same lines, note that K_δ is inversely proportional to B , which means that when there is a larger difference in the state update frequency between the fastest node and the slowest node (larger B), more communication is necessary in order to preserve convergence. Finally, a smaller step size α (slower change of states) allows one to choose a larger K_δ , which means greater tolerance to estimation errors.

72.3.1 Optimization with State Update Noise

As already mentioned, it has been assumed that each node executing (72.1) is capable of reaching a desired new state $s_i(k+1)$ from $s_i(k)$ within a time interval shorter than the time between update events. Thus, any noise present in this update step affects only the time required for $s_i(k+1)$ to be attained. If, however, a noise term $w_i(k)$ is explicitly included in (72.1), then a new state update process must be considered:

$$s_i(k+1) = s_i(k) + \alpha d_i(s^i(k)) + w_i(k) \quad (72.13)$$

The following assumption will be made regarding this added noise process:

Assumption 5. There exists a positive constant $K_w < 2/K_1 K_3$ such that $w_{i,j}(k) \leq K_w d_{i,j}(k)$, where $d_{i,j}(k)$ and $w_{i,j}(k)$ are the j th scalar component of $d_i(k)$ and $w_i(k)$, respectively.

This assumption requires the noise incurred during a state change to generally decrease with the magnitude of the state changes in the sense that it is bounded by $K_w d_{i,j}(k)$, which decreases with k . Then, Theorem 72.1 can be extended to the following result.

Theorem 72.2. Under Assumptions Assumption 1–5, the communication event policy (72.7) and the state update scheme (72.13), if the error threshold $\delta_i(k)$ controlling communication events is set by (72.8) and (72.9), then there exist positive constants α and K_δ such that $\lim_{k \rightarrow \infty} \nabla H(s(k)) = 0$.

72.3.2 Optimization with Non-negligible Communication Delays

Thus far, negligible communication delays have been assumed, that is, the transmission and reception of a message in a communication event has been treated as instantaneous. Under this assumption, when a communication event is triggered by node i at t according to (72.7), a copy of the true state of node i is sent to node j , and the error function $g(x_i(t), x_i^j(t))$ is reset to zero immediately. This was illustrated by the trajectory of $g(x_i(t), x_i^j(t))$ in Fig. 72.2. As a result, the upper bound $\delta_i(\tilde{k}_t^i)$ for $g(x_i(t), x_i^j(t))$ is at our disposal, which, due to Assumption 4(a), leads to a bound for $\|x_i(t) - x_i^j(t)\|$. This upper bound turns out to be instrumental in the proof of Theorem 72.1.

The case where communication delays are not negligible is now discussed, and the communication event policy is modified accordingly, leading to a convergence result similar to Theorem 72.1. The key to achieving this is to find another bound for $g(x_i(t), x_i^j(t))$ and $\|x_i(t) - x_i^j(t)\|$ without resorting to a negligible delay assumption. The first step is to observe that, as a consequence of non-negligible communication delays, after a communication event originates from nodes i to j at τ_n^{ij} , node j cannot set x_i^j to $x_i(\tau_n^{ij})$ immediately. Therefore, the error function $g(x_i(t), x_i^j(t))$ continues to grow until the message containing $x_i(\tau_n^{ij})$ is received by node j . This point is illustrated in Fig. 72.3 where the red curve is an example of the trajectory of $g(x_i(t), x_i^j(t))$ and σ_n^{ij} denotes the time when a message sent by node i at τ_n^{ij} is received at node j . Obviously, if messages sent by a node can take infinitely long to reach other nodes, there can be no cooperation among these nodes, and a distributed algorithm may never reach an optimal solution. If this happens, then the underlying communication network used to control the system is likely to be unstable, a case that must be excluded. In particular, if $\sigma_n^{ij} - \tau_n^{ij}$ for some $n = 1, 2, \dots$ in Fig. 72.3 is unbounded, then $g(x_i(t), x_i^j(t))$ may be unbounded, possibly leading to an infinitely large estimation error (for simplicity, the error bound $\delta_i(k)$ is treated as constant in all figures in this section). Thus, as a first step, the following assumption is added:

Assumption 6. There exists a nonnegative integer D such that if a message is sent before t_{k-D} from any node i to any other node j , it will be received before t_k .

In other words, it is assumed that at most D state update events can occur between a node sending a message and all destination nodes receiving this message.

An additional complication caused by non-negligible delays is in the triggering of communication events. Specifically, if the policy in (72.7) is still used, then between τ_n^{ij} and σ_n^{ij} the value of $g(x_i(t), x_i^j(t))$ generally remains above δ_i (as shown in Fig. 72.3). As a result, node i will continuously trigger communication events until σ_n^{ij} . To suppress this redundancy over the interval $[\tau_n^{ij}, \sigma_n^{ij}]$, it is necessary to modify (72.7). Doing so requires carefully differentiating between the way in which node j estimates the state of node i in the presence of communication delays as opposed to no delays (as assumed in the previous section). Thus, such a general-purpose estimate is expressed as follows:

Fig. 72.3 Trajectories of error functions with communication delays. In this case, every message sent by node i is received before a new communication event is triggered at node i

$$x_i^j(t) = \begin{cases} h_i^j(t; \tau_{n-1}^{ij}) & \rho_{n-1} < t < \rho_n, \quad n = 1, 2, \dots \\ x_n & t = \rho_n, \quad n = 1, 2, \dots \end{cases} \quad (72.14)$$

where $h_i^j(\cdot)$ denotes the specific functional form of the estimator used by node j to estimate the state of node i and τ_n^{ij} , $n = 1, 2, \dots$, is the time when the n th communication event from i to j is generated and viewed as a parameter of the estimator. The estimate is defined over an interval (ρ_{n-1}, ρ_n) , and ρ_n is the n th time when the estimate is reset to a given value x_n . This provides a formal representation of the estimation process in our optimization framework: At instants ρ_n , $n = 1, 2, \dots$, node j resets its estimate of node i 's state to some value x_n and then repeats the estimation process with this new initial condition over the next interval (ρ_n, ρ_{n+1}) . In the case of negligible communication delays (considered in the previous section),

$$\rho_n = \tau_n^{ij}, \quad x_n = x_i(\tau_n^{ij}) \quad (72.15)$$

that is, the n th reset time is the instant when a communication event is generated from nodes i to j , and the reset value is the corresponding actual state of i at that time. However, in the presence of communication delays, one must set

$$\rho_n = \sigma_n^{ij}, \quad x_n = h_i^j(\sigma_n^{ij}; \tau_n^{ij}) \quad (72.16)$$

where $\sigma_n^{ij} > \tau_n^{ij}$ is the time the n th message sent from node i is received by node j , and the reset value depends on the estimation method used by node j .

In view of this discussion, the new communication event policy is defined as

$$\tau_n^{ij} = \inf \left\{ t : g(x_i(t), h_i^j(t; \tau_{n-1}^{ij})) \geq \delta_i(\tilde{k}_t^i), \quad t > \tau_{n-1}^{ij} \right\} \quad (72.17)$$

with the initial condition $\tau_0^{ij} = 0$. Next, a new variable $\tilde{x}_i^j(t)$ is introduced, defined as

$$\tilde{x}_i^j(t) = \begin{cases} h_i^j(t; \tau_{n-1}^{ij}) & \tau_{n-1}^{ij} < t < \tau_n^{ij}, \quad n = 1, 2, \dots \\ x_i(\tau_n^{ij}) & t = \tau_n^{ij}, \quad n = 1, 2, \dots \end{cases} \quad (72.18)$$

with an initial condition $\tilde{x}_i^j(0) = x_i(0)$. In other words, $\tilde{x}_i^j(t)$ is the estimate of node i 's state used by node j as if there were no communication delays, consistent with (72.15). This variable is maintained by node i . If the estimation process is designed to have the property that $h_i^j(\tau_n^{ij}; \tau_n^{ij}) = x_i(\tau_n^{ij})$, (72.18) can be further simplified to

$$\tilde{x}_i^j(t) = h_i^j(t; \tau_{n-1}^{ij}), \quad \tau_{n-1}^{ij} \leq t < \tau_n^{ij}, \quad n = 1, 2, \dots$$

Figure 72.3 illustrates the difference between a trajectory of $g(x_i(t), \tilde{x}_i^j(t))$ (black curve) and a trajectory of $g(x_i(t), x_i^j(t))$ (red curve) under (72.17). Notice that if the communication delay is zero, then $g(x_i(t), \tilde{x}_i^j(t))$ and $g(x_i(t), x_i^j(t))$ will obviously follow the exact same trajectory. There is an additional reason for introducing $\tilde{x}_i^j(t)$ at node i : If communication delays are not negligible and are typically unknown, then node i does not know the exact value of $x_i^j(t)$ and hence cannot execute (72.7).

Regarding the possible forms that $h_i^j(t; \tau_n^{ij})$ can take, two cases are discussed. First, if node j uses a static state estimation method, that is, $h_i^j(t; \tau_n^{ij}) = x_i(\tau_n^{ij})$, it simply sets its estimate of i to the value contained in the received message:

$$x_i^j(\sigma_n^{ij}) = x_i(\tau_n^{ij}) \quad (72.19)$$

In this case, $\tilde{x}_i^j(t) = x_i(\tau_n^{ij})$ for all $t \in [\tau_n^{ij}, \tau_{n+1}^{ij})$, in accordance with (72.18). On the other hand, if node j uses a dynamic state estimation method, the value of $x_i^j(\sigma_n^{ij})$ depends on τ_n^{ij} as well. For example, if node j uses (72.4), then

$$x_i^j(\sigma_n^{ij}) = x_i(\tau_n^{ij}) + (\sigma_n^{ij} - \tau_n^{ij}) \cdot D_i \quad (72.20)$$

where $D_i = \alpha_i \cdot d_{i, \tau_n^{ij}} / \Delta_i$. Note that in this case evaluating the state estimate in (72.20) requires knowledge of τ_n^{ij} , that is, the message sent by node i must be time stamped (otherwise, in the presence of random delays, node j cannot infer the value of τ_n^{ij} when it receives a message at σ_n^{ij}). This, in turn, requires a clock synchronization mechanism across nodes (which is often not simple to implement).

Finally, the new communication event policy (72.17) and Assumption 6 provide bounds for $g(x_i(t), x_i^j(t))$ and $\|x_i(t) - x_i^j(t)\|$. For simplicity, first consider the case where every message from a node reaches its destination before the next communication event is triggered, that is, $\sigma_n^{ij} < \tau_{n+1}^{ij}$ for all $n = 1, 2, \dots$, as shown in Fig. 72.3. At each σ_n^{ij} , the state estimate $x_i^j(\sigma_n^{ij})$ is synchronized with $\tilde{x}_i^j(\sigma_n^{ij})$ defined in (72.18), and it follows that $g(x_i(\sigma_n^{ij}), x_i^j(\sigma_n^{ij})) \leq \delta_i(\tilde{k}_{\sigma_n^{ij}}^i)$. Due to Assumption 6, at most D state update events occur between τ_n^{ij} and σ_n^{ij} for all

Fig. 72.4 Trajectories of error functions with communication delays. In this case, additional communication events occur before a message is received

$n = 1, 2, \dots$, which guarantees that $g(x_i(t), x_i^j(t))$ will not exceed $\delta_i(k)$, for some k , augmented by the estimation error accumulated over these D state update steps.

If, on the other hand, $g(x_i(t), \tilde{x}_i^j(t))$ reaches $\delta_i(k_i^j)$ during $[\tau_n^{ij}, \sigma_n^{ij}]$, then a new communication message will be sent out by node i before the previous one is received. For example, in Fig. 72.4, $\tau_2^{ij} < \sigma_1^{ij}$ and $\tau_3^{ij} < \sigma_2^{ij}$. Although the trajectory of $g(x_i(t), x_i^j(t))$ becomes more complicated in this case, $g(x_i(t), x_i^j(t))$ (the red curve) still has an upper bound, which is given within the proof of Theorem 3, in Zhong and Cassandras (2010).

In light of this discussion, if an error function is chosen such that $g(x_i(t), x_i^j(t)) = \|x_i(t) - x_i^j(t)\|/K_4$, it is obvious that $\|x_i(t) - x_i^j(t)\|$ is bounded. Thus, if any error function is chosen such that $\|x_i(t) - x_i^j(t)\| \leq K_4 \cdot g(x_i(t), x_i^j(t))$ (according to Assumption 4(a), $\|x_i(t) - x_i^j(t)\|$ is also bounded. In Theorem 72.3, the static estimation case (72.19) is considered, which is the least costly in terms of estimation complexity. Moreover, static estimation, as already pointed out, does not require a synchronization mechanism which (72.20), for example, does. It is also important to point out that in Theorem 72.3, Assumption 4(b) is no longer used; instead, Assumption 6 allows the derivation of the bounds required to establish the desired convergence result.

Theorem 72.3. *Under Assumptions 1–4(a) and 6, the communication event policy (72.17), the state update scheme (72.11), and the static estimation method (72.19), if the error threshold $\delta_i(k)$ controlling communication events is set by (72.8) and (72.9), then there exist positive constants α and K_δ such that $\lim_{k \rightarrow \infty} \nabla H(s(k)) = 0$.*

In addition, if both the state update noise introduced in Sect. 72.3.1 and non-negligible communication delays are present in the optimization process, as long as Assumptions 5 and 6 are still satisfied, a convergence result (omitted here) similar to Theorem 72.2 can also be derived.

72.4 Asynchronous Distributed Coverage Control

In this section, the proposed distributed optimization framework with event-driven communication is applied to the class of coverage control problems mentioned in Sect. 72.1. Specifically, the problem of deploying a UAV team is considered so that the UAVs are located in a way that maximizes the probability of detecting events occurring in a given two-dimensional mission space. The goal is to show how an asynchronous algorithm may significantly reduce the energy expended on communication among nodes with no adverse effect on performance. The convergence of the objective function is also illustrated without and with communication delays, and the effect of K_δ on the convergence speed and the communication cost is examined.

72.4.1 Coverage Control Problem Formulation

A brief review of the coverage control problem is first given, following the formulation in Cassandras and Li (2005). An event density function $R(x)$ over the mission space $\Omega \subset \mathbb{R}^2$ is defined, which captures the frequency of random event occurrences at some point $x \in \Omega$. $R(x)$ satisfies $R(x) \geq 0$ for all $x \in \Omega$ and $\int_\Omega R(x) dx < \infty$. It is assumed that when an event takes place, it will emit some signal which may be observed by some UAVs equipped with sensing device. The cooperative system consists of N UAV nodes deployed into Ω to detect the random events. Their positions are captured by a $2N$ -dimensional vector $\mathbf{s} = (s_1, \dots, s_N)$.

The probability that node i detects an event occurring at $x \in \Omega$, denoted by $p_i(x, s_i)$, is a monotonically decreasing differentiable function of $\|x - s_i\|$, the Euclidean distance between the event and the UAV node. Since multiple nodes are deployed to cover the mission space, the joint probability that an event occurring at x is detected (assuming independent sensor detection processes), denoted by $P(x, \mathbf{s})$, is given by

$$P(x, \mathbf{s}) = 1 - \prod_{i=1}^N [1 - p_i(x, s_i)]$$

and the optimization problem of interest is

$$\max_{\mathbf{s}} H(\mathbf{s}) = \max_{\mathbf{s}} \int_{\Omega} R(x) P(x, \mathbf{s}) dx$$

in which the locations of the UAV nodes are used as decision variables to maximize the probability of event detection in Ω . As discussed in Zhong and Cassandras (2008b), this objective function aims at maximizing the joint event detection probability without considering the issue of maintaining a balance between a region

within Ω which may be extremely well covered and others which may not. Thus, a more general form of the objective function is

$$H(\mathbf{s}) = \int_{\Omega} R(x) M(P(x, \mathbf{s})) dx \quad (72.21)$$

where $M(P) : [0, 1] \rightarrow \mathbb{R}$ is a (possibly piecewise) differentiable concave nondecreasing function of the joint detection probability P . Clearly, $M(P)$ may be selected so that the same amount of marginal gain in $P(x, \mathbf{s})$ is assigned a higher reward at a lower value of P . A special case is $M(P) = P$ where coverage balance is not taken into account.

A *synchronous* gradient-based solution was obtained in Cassandra and Li (2005) in which the next waypoint on the i th UAV node's trajectory is determined through

$$s_i(k+1) = s_i(k) + \alpha \frac{\partial H(\mathbf{s})}{\partial s_i}, \quad k = 0, 1, \dots \quad (72.22)$$

The gradient is given by

$$\frac{\partial H(\mathbf{s})}{\partial s_i} = \int_{\Omega_i} R(x) \prod_{k \in \mathcal{B}_i} [1 - p_k(x, s_k)] \frac{dp_i(x, s_i)}{dd_i(x)} \frac{s_i - x}{d_i(x)} dx \quad (72.23)$$

where $d_i(x) \equiv \|x - s_i\|$ and $\Omega_i = \{x : d_i(x) \leq D\}$ is the node i 's region of coverage where D denotes the sensing radius of node i (i.e., $p_i(x, s_i) = 0$ for $d_i(x) > D$). In addition, $\mathcal{B}_i = \{k : \|s_i - s_k\| < 2D, k = 1, \dots, N, k \neq i\}$ is the set of neighbor nodes of i .

The state update rule (72.22) allows a fully distributed implementation based on node i 's local information and the state of its neighbors (instead of the state of all nodes). This eliminates the communication burden of transferring information to and from a central controller and the vulnerability of the whole system which would be entirely dependent on this controller. However, (72.23) shows that node i needs the exact locations of all nodes in \mathcal{B}_i in order to carry out (72.22) in a state update. As already mentioned, the communication involved to ensure such state synchronization has a high energy cost which is often unnecessary because the locations of neighboring nodes may be accurately estimated due to minor changes in their locations or update directions (see (72.3) and (72.4)).

Next, the asynchronous method developed above is applied to this problem, and the results with the synchronous approach are compared in terms of communication cost, performance, and convergence behavior. The asynchronous method is also applied to a nonsmooth version of the coverage control problem when the mission space contains obstacles (see also Zhong and Cassandra 2011).

72.4.2 Asynchronous Versus Synchronous Optimal Coverage Control

Numerical results are presented based on simulations of the coverage control setting using an interactive Java-based simulation environment (The interactive simulation environment used in all results shown in this section (along with instructions) is located at <http://codescolor.bu.edu/simulators.html>). We compare three versions of the optimal coverage control solution:

1. Synchronous iterations where all nodes perform state updates using state information from all other nodes
2. Asynchronous iterations performed by node i with fixed error threshold $\delta_i(k)$, that is, $\delta_i(k) = \delta_i$ for all k , where δ_i is a positive constant
3. Asynchronous iterations performed by node i using (72.8) and (72.9)

The coverage control problem considered here involves four UAVs deployed into a rectangular mission space (50 units by 60 units) from the lower left corner. All UAVs update their states at approximately the same frequency (one update in every ten simulation time steps augmented by some uniformly distributed noise) using the same step size in all three schemes. They all have identical sensing capabilities and $p_i(x, s_i) = e^{-0.08\|x-s_i\|}$ for all i , which means that, if deployed individually, a UAV can only effectively cover a relatively small portion of the mission space ($p_i(x, s_i) < 0.50$ when $\|x - s_i\| > 8.67$). For the asynchronous versions, (72.3) is used as a simple static state estimation scheme, and the error function is $g(x_i(t), x_i^j(t)) = \|x_i(t) - x_i^j(t)\|$.

In Figs. 72.5 and 72.6, these three algorithms are compared under both the negligible and non-negligible communication delay assumptions. When communication costs are compared in Fig. 72.5, every time a node broadcasts its state information, the total number of communications is increased by one. By looking at these figures, it is clear that the asynchronous method can substantially reduce the communication cost (hence, the energy consumption at all UAVs) while performance convergence is virtually indistinguishable from that of the synchronous method. The asynchronous algorithm with fixed $\delta_i(k)$ has the added advantage that it usually stops incurring communication cost earlier than the other two methods. However, it does not guarantee convergence to stationary points. In Figs. 72.5b and 72.6b, results are provided for a case with a fairly large communication delay (50 simulation time steps for every transmitted message). Comparing Fig. 72.6b to a, it is clear that introducing delays does not affect convergence but it does slow it down; in Fig. 72.6b, the optimal value of the objective function is attained approximately Assumption 5 time units later than the time seen in Fig. 72.6a.

Figure 72.7 shows the UAV trajectories for these three methods under the negligible communication delay assumption. Methods 1 and 3 converge to the same node configuration which is indicated by the squares, while method 2 converges to a configuration close to it (it is not possible to mark the configuration method 2 converges to due to the limited resolution of the figure).

Fig. 72.5 Communication cost comparison of three distributed optimization algorithms under different communication delay assumptions. (a) Negligible communication delay. (b) Non-negligible communication delay

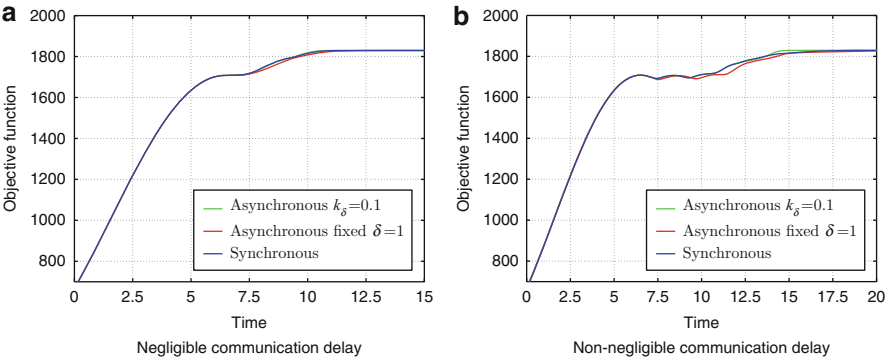

Fig. 72.6 Objective function trajectories of three distributed optimization algorithms under different communication delay assumptions. (a) Negligible communication delay. (b) Non-negligible communication delay

Fig. 72.7 Node trajectory comparison of three distributed optimization algorithms in a coverage control mission. See Fig. 72.6 for legend

Fig. 72.8 Communication cost comparison of asynchronous distributed algorithm with different K_δ

In Figs. 72.8 and 72.9, under the negligible communication delay assumption, the performance of the asynchronous method is compared under different values of the constant K_δ in (72.8) with the same coverage control setting as before. One can see that a larger K_δ leads to fewer communication events. But one can also notice in Fig. 72.9 that when $K_\delta = 5$, the objective function curve exhibits considerable oscillations before it converges. This suggests that K_δ is set too high and some “necessary” communications between nodes have been omitted at the expense of effective cooperation. In other words, when K_δ is increased, although convergence to a local optimum may still be guaranteed if (72.12) is satisfied, so is the risk of slower convergence.

Fig. 72.9 Objective function trajectories of asynchronous distributed algorithm with different K_δ

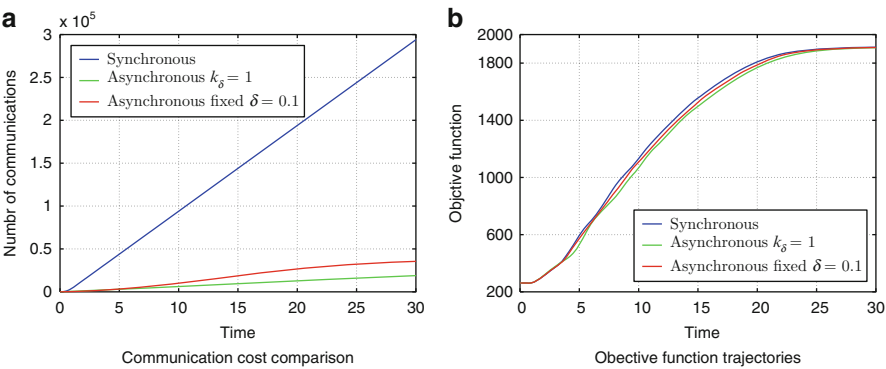

Fig. 72.10 Coverage control simulation result of a large network with 100 nodes. (a) Communication cost comparison. (b) Objective function trajectories

In Fig. 72.10, results are shown from a larger coverage control problem with 100 UAVs with no obstacle or communication delay and reduced sensing range. Similar communication savings are observed as in the smaller problem of Fig. 72.5 with only four UAVs.

Next, the asynchronous algorithm is applied to a problem with polygonal obstacles in the region to be covered and employs (72.4) as the state estimation method. Five UAVs are deployed into a mission space cluttered with obstacles as shown in Fig. 72.11. In this case, a nonsmooth optimization problem arises with gradients that are more complicated than (72.23) in order to account for discontinuities in the sensor detection probability functions $p_i(x, s_i)$; details on their derivation

Fig. 72.11 Initial and final deployment of an optimal coverage mission in an environment with polygonal obstacles. The *blue rectangles* represent obstacles. Areas covered with cyan color have joint detection probability $P(x, s) \geq 0.97$. Green areas have $0.50 \leq P(x, s) < 0.97$. Yellow and white areas have $0 \leq P(x, s) < 0.50$. If the image is viewed in *black and white*, a lighter color indicates lower event detection probability in that area. (a) Initial deployment. (b) Final deployment

Fig. 72.12 Communication cost comparison of three distributed optimization algorithms in a nonsmooth problem

are provided in Zhong and Cassandras (2011). Convergence under (72.22) cannot always be guaranteed, and there are multiple local optima which nodes can oscillate around. In order to achieve a more balanced coverage, the objective function in (72.21) is used. In Fig. 72.12, one can once again see the cost-cutting benefits of using asynchronous methods. Figure 72.13 shows that all three methods eventually achieve the same approximate level of coverage.

Fig. 72.13 Objective function trajectories of three distributed optimization algorithms in a nonsmooth problem

72.5 Conclusion

The issue addressed in this chapter is the extent to which communication among autonomous UAVs could be reduced in a cooperative optimization setting. This is crucial when the cooperating UAVs have limited energy resources. In addition, limiting communication reduces the possibility of jamming or other sources of information corruption that can damage the cooperative process. The main result is showing that frequent communication among cooperating UAVs (nodes in a network) is not necessary in order to guarantee convergence of a process seeking to optimize a common objective. Specifically, the scheme that has been developed limits communication events to “last resort only” when some state estimation error function at a UAV exceeds a threshold. Under certain technical conditions, the convergence of a gradient-based asynchronous distributed algorithm employing this communication policy is still provably guaranteed. In addition, the range of the two crucial parameters on which such convergence depends has been quantified. This important property applies to both cases where communication delays are negligible and where they are not. In the latter case, as expected, simulation results show convergence to be generally slower. Further, the convergence property still applies when noise is explicitly included in the UAV state update process, provided that some additional conditions hold which appropriately bound this noise term.

This approach has been applied to a coverage control problem common in the deployment of UAV teams and confirmed through numerical examples that limited asynchronous (event driven) communication results in substantial energy savings which can prolong the life of such a team with no adverse effect on the optimization objective. Thus, from a practical standpoint, the proposed method can significantly benefit teams of autonomous UAVs by reducing their use of energy with no compromise in performance. However, there is no guarantee that an event-driven

communication approach always provides energy savings relative to time-driven mechanisms. What this approach offers is the flexibility to exploit intervals over which there is no need for a UAV to unnecessarily communicate minimal errors in its state trajectory.

Abstract

The goal here is to design a path-planning algorithm to guide unmanned aerial vehicles (UAVs) for tracking multiple ground targets based on the theory of *partially observable Markov decision processes* (POMDPs). This study shows how to exploit the generality and flexibility of the POMDP framework by

incorporating a variety of features of interest naturally into the framework, which is accomplished by plugging in the appropriate models. Specifically, this study shows how to incorporate the following features by appropriately formulating the POMDP action space, state-transition law, and objective function: (1) control UAVs with both forward acceleration and bank angle subject to constraints, (2) account for the effect of wind disturbance on UAVs, (3) avoid collisions between UAVs and obstacles and among UAVs, (4) track targets while evading threats, (5) track evasive targets, and (6) mitigate track swaps.

73.1 Introduction

This study describes a dynamic path-planning algorithm that guides autonomous UAVs for tracking multiple ground targets based on the theory of *partially observable Markov decision processes* (POMDPs) (Chong et al. 2009; Miller et al. 2009). The algorithm collects measurements from the sensors (mounted on the UAVs), constructs the tracks, and computes the control commands for the UAVs.

In practice, POMDP problems are intractable to solve exactly. There are several approximation methods in the literature to solve a POMDP: heuristic ECTG (Kreucher et al. 2004), parametric approximation (Bertsekas and Tsitsiklis 1996; Sutton and Barto 1998), policy rollout (Bertsekas and Castanon 1999), hindsight optimization (Chong et al. 2000; Wu et al. 2002), and foresight optimization (Bertsekas 2007). This study uses an approximation method called the *nominal belief-state optimization* (NBO) (Miller et al. 2009) (explained later), which is computationally efficient. This study shows how to incorporate the following features of interest naturally into the POMDP framework: control UAVs with both forward acceleration and bank angle subject to constraints, account for wind disturbance on UAVs, avoid collisions between UAVs and obstacles and among UAVs, guide UAVs to track targets while evading threats, guide UAVs for tracking evasive targets, and guide UAVs for tracking targets while mitigating track swaps. These issues are addressed as explained below:

- Variable-speed UAVs are considered for the purpose of this study, where the speed and heading direction of a UAV are varied by appropriately controlling the forward acceleration and bank angle. These control variables are subject to certain constraints. These control variables are incorporated into the framework, which is accomplished by appropriately formulating the POMDP action space and state-transition law.
- Wind speeds are often comparable to UAV cruise speeds. As a result, the trajectory of a UAV gets deviated from its desired course (due to wind) leading to tracking performance degradation. The study addresses this problem by appropriately formulating the POMDP state-transition law. More precisely, the speed and direction of wind are incorporated into the UAV kinematic model.
- In a scenario where UAVs are tracking targets in the presence of obstacles and the UAV flying altitude is less than the height of these obstacles, a collision may happen between a UAV and an obstacle. This study designs the algorithm

in such a way that the UAVs track the targets while avoiding collisions with the obstacles. In a scenario where all UAVs fly at a same altitude, a collision may happen between a UAV and another UAV. The goal here is to design a path-planning algorithm while avoiding collisions among UAVs. A penalty metric is incorporated into the objective function used for optimizing the control commands to prevent collisions among UAVs.

- In this present study, a threat is a ground vehicle that pursues UAVs that are tracking it. The goal here is to design a method—in the context of the POMDP framework—to track targets while evading threats. A threat motion model is defined to represent the dynamics of a threat. A penalty metric is incorporated into the objective function to guide the UAVs to evade threats while tracking targets.
- In this present study, an evasive target is a ground vehicle that actively moves away from UAVs that are tracking it. The goal here is to design a method—in the context of the POMDP framework—to track evasive targets. An evasive target motion model is defined to represent the target dynamics. This motion model is incorporated into the NBO method.
- A *track swap* is an undesirable event that causes the swapping of target identities. The likelihood of a track swap depends on the location of the UAVs and the state of the tracker. Therefore, track swaps are mitigated by controlling the UAVs appropriately. This is accomplished by incorporating a metric—that represents the risk of a track swap – into the objective function.

In summary, this study shows how to incorporate a variety of features of interest naturally into the POMDP framework by simply plugging in the appropriate models. The organization of this chapter is as follows: Sect. 73.2 gives a brief overview of UAV guidance algorithms present in the literature and contrasts these methods with the method considered in this study; Sect. 73.3 presents a general description of the POMDP framework; Sect. 73.4 poses the UAV guidance problem as a POMDP and presents an approximation method to solve the POMDP problem; Sect. 73.5 shows how to incorporate a variety of features of interest naturally into the POMDP framework; and Sect. 73.6 summarizes this study.

73.2 Related Work

The literature is replete with motion planning algorithms for autonomous vehicles. A general survey of path-planning algorithms can be found in Dadkhah and Mettler (2012), Goerzen et al. (2010), and LaValle (2006). What makes this path-planning method for UAVs (presented in this chapter) worth studying is the combination of the following features naturally within the POMDP framework:

1. This method involves real-time calculation of guidance commands in response to continual feedback information.
2. This method has a “look-ahead” property, in that the guidance control at each time step takes into account the impact of the control over a time horizon into the future.

3. This method incorporates explicit dynamic constraints on the UAV motion.
4. The cost criterion is based on tracking error.

Many researchers have developed path-planning algorithms in the past while incorporating a few of these features. For example, the path-planning algorithms presented in Geyer (2008), Berger et al. (2009), He et al. (2010a), Tisdale et al. (2007), Park et al. (2009), He et al. (2010b), Kim et al. (2008), Saunders et al. (2005), and Cassandra and Li (2003) incorporated “look-ahead” and can be implemented in real time. However, only Tisdale et al. (2007) and Saunders et al. (2005) incorporated the dynamic constraints on UAV motion, and only He et al. (2010b) incorporated the tracking error as a cost criterion. This POMDP method is an integrated approach where all the above features are fused in a single framework—the guidance commands are calculated in real time (with look-ahead) while incorporating dynamic constraints on UAV motion in response to feedback information, where the cost criterion is tracking error.

There are many other methods in the literature that are not designed specifically for UAVs but are designed for autonomous robots in general, e.g., Kaneshige et al. (2004), Leven and Hutchinson (2002), Sud et al. (2008), Naveed et al. (2011), Bruce and Veloso (2002), LaValle (2000), Kavralu et al. (1996), Bry and Roy (2011), Yong and Barth (2006), Ma and Castanon (2006), McIntyre et al. (2005), Zu et al. (2004), Ousingawatt and Campbell (2004), Lu et al. (2011), Cowlagi and Tsotras (2007), Ren et al. (2005), and Li and Cassandra (2006). In the recent past, POMDPs have been used to design path-planning algorithms for UAVs, but they differ from the method in this study in that either the dynamic constraints on UAV motion are not incorporated (Sarunic et al. 2009) or the cost criterion is different (Sarunic et al. 2009; Bai et al. 2011). There are also methods in the recent literature (e.g., Capitán et al. 2011; Adiprawita et al. 2011; Du et al. 2010; Candido and Hutchinson 2010; Kurniawati et al. 2011) where POMDPs are used to develop path-planning algorithms for autonomous robots in general. There are many schemes in the literature for wind compensation (e.g., Jennings et al. 2008; McGee et al. 2005; Ceccarelli et al. 2007; McGee and Hedrick 2006; Lawrance and Sukkariéh 2011; Techy et al. 2010) and collision avoidance (e.g., Redding et al. 2007; Koren and Borenstein 1991; Kavraki et al. 1996; He et al. 2006; Dong et al. 2005; Khatib 1985; Tilove 1990; Krogh and Thorpe 1986; Borenstein and Koren 1989; Park et al. 2008; Nikolos et al. 2003). This study shows how to account for these naturally in the context of the POMDP framework.

73.3 Partially Observable Markov Decision Process

73.3.1 Definition

A *partially observable Markov decision process* (POMDP) is a controlled dynamical process in discrete time. A POMDP can also be interpreted as the controlled version of a hidden Markov reward process. This section provides a general description of the POMDP. The following are the key components of the POMDP:

- A set of states of the system that possibly evolve over time and an initial distribution specifying the random initial state. Let \mathcal{X} represent the set of states of the system and x_k is the state of the system at time k such that $x_k \in \mathcal{X}$.
- A set of actions, which are controllable aspects of the system. Let \mathcal{U} be the set of all possible actions and u_k is an action at time k such that $u_k \in \mathcal{U}$.
- A state-transition law that specifies the next state distribution given the current state and action, i.e., $x_{k+1} \sim p_k(\cdot|x_k, u_k)$, where p_k is a conditional probability distribution function given the current state x_k and the current action u_k .
- A set of observations and an observation law that specifies the distribution over the observation space given an action taken at a state. Let \mathcal{Z} represent the set of all observations and z_k be the observation at time k , which is given by $z_k \sim q_k(\cdot|x_k, u_k)$, where q_k is a conditional probability distribution function given the current state x_k and the current action u_k .
- A cost function that specifies the cost (real number) incurred given an action taken at a state, i.e., $C(x_k, u_k)$.

Figure 73.1a shows a symbolic representation of the POMDP process. The POMDP process begins at time $k = 0$ at a (random) initial state. As the process evolves, the state transitions to a (random) next state from the current state according to the state-transition law given the action. An action taken at a given state incurs a

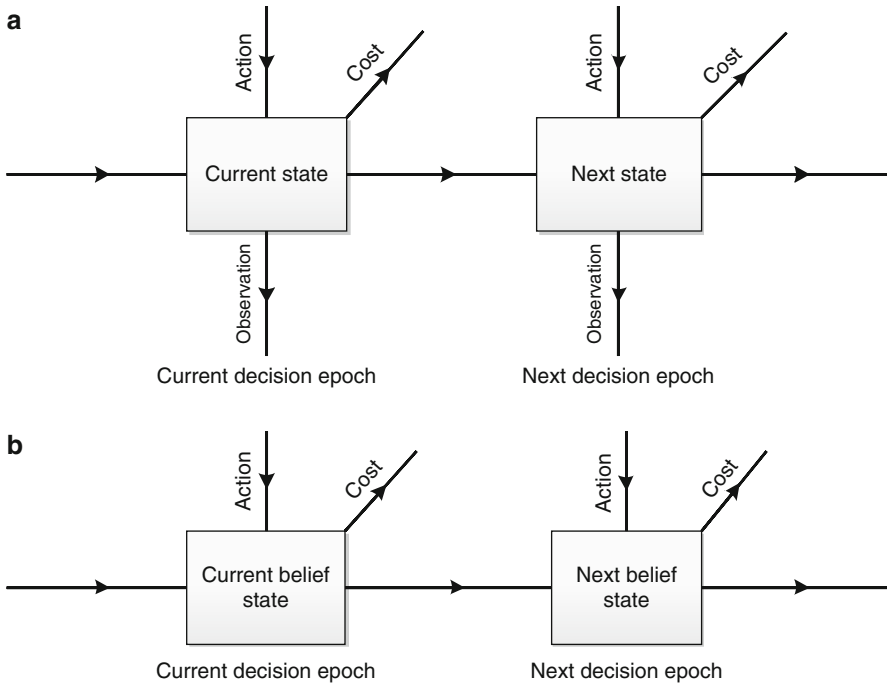

Fig. 73.1 Symbolic representations. (a) POMDP with state space \mathcal{X} and (b) fully observable MDP with state space \mathcal{B}

cost, which is given by the cost function. At every time step, the system generates an observation, which depends on the current state and the current action. At every time step, this observation is used to infer the actual underlying state. However, there will be some uncertainty in the knowledge of the underlying state; this uncertainty is represented by the *belief state*. The belief state is the posterior distribution over the underlying state, which is updated according to the Bayes' rule. Let \mathcal{B} represent the set of distributions over the state space \mathcal{X} . Let $b_k \in \mathcal{B}$ be the belief state at time k . A POMDP can be viewed as a fully observable Markov decision process (MDP) with state space \mathcal{B} as shown in Fig. 73.1b.

73.3.2 Optimization Objective

A POMDP problem boils down to an optimization problem, where the objective is to find actions over a time horizon H such that the expected cumulative cost is minimized. The expected cumulative cost, to be minimized over the action sequence u_0, u_1, \dots, u_{H-1} , is given by

$$J_H = \mathbb{E} \left[\sum_{k=0}^{H-1} C(x_k, u_k) \right]. \quad (73.1)$$

The action chosen at time k should be allowed to depend on the history of all observable quantities till time $k - 1$. If an optimal choice of such actions exists, then there exists an optimal sequence of actions that depend only on the “belief-state feedback” (Chong et al. 2009). Therefore, the objective function J_H can be written in terms of the belief states as follows:

$$J_H = \mathbb{E} \left[\sum_{k=0}^{H-1} c(b_k, u_k) \mid b_0 \right], \quad (73.2)$$

where $c(b_k, u_k) = \int C(x, u_k) b_k(x) dx$ and b_0 is the given initial belief state.

73.3.3 Optimal Policy

Given the optimization problem, the goal is to find, at each time k , the optimal policy $\pi_k^* : \mathcal{B} \rightarrow \mathcal{U}$ such that if the action $u_k = \pi_k^*(b_k)$ is performed at time k , the objective function (73.2) is minimized. According to the Bellman's principle of optimality (Bellman 1957), the optimal objective function value can be written in the following form:

$$J_H^*(b_0) = \min_u \{c(b_0, u) + \mathbb{E} [J_{H-1}^*(b_1) \mid b_0, u]\}, \quad (73.3)$$

where b_1 is the random next belief state, J_{H-1}^* is the optimal cumulative cost over the horizon $H - 1 : k = 1, 2, \dots, H - 1$, and $E[\cdot | b_0, u]$ is the conditional expectation given the current belief state b_0 and an action u taken at time $k = 0$. The Q -value of taking an action u given the current belief state b_0 is as follows:

$$Q_H(b_0, u) = c(b_0, u) + E[J_{H-1}^*(b_1) | b_0, u]. \quad (73.4)$$

The optimal policy (from Bellman's principle) at time $k = 0$ is given by

$$\pi_0^*(b_0) = \arg \min_u Q_H(b_0, u). \quad (73.5)$$

The optimal policy at time k is given by

$$\pi_k^*(b_k) = \arg \min_u Q_{H-k}(b_k, u). \quad (73.6)$$

In practice, the second term in the Q function (73.4) is hard to obtain exactly. There are several methods in the literature to obtain the Q -value approximately, which include heuristic ECTG (Kreucher et al. 2004), parametric approximation (Bertsekas and Tsitsiklis 1996; Sutton and Barto 1998), policy rollout (Bertsekas and Castanon 1999), hindsight optimization (Chong et al. 2000; Wu et al. 2002), and foresight optimization (Bertsekas 2007). This study adopts an approximation method called *nominal belief-state optimization* (NBO), which was introduced in Miller et al. (2009) specifically for the purpose of solving the POMDP in the context of the UAV guidance problem.

73.4 Formulation of the UAV Guidance Problem

73.4.1 Problem Specification

This study considers a specific UAV guidance problem, where the goal is to design an algorithm to control a fleet of UAVs for multitarget tracking. The guidance problem is specified as follows:

- *2-D motion*: The targets move in a plane on the ground. A simplified UAV motion model is used, where the altitude of a UAV is constant. The position coordinates of each UAV, i.e., (x, y) , are varied by applying the following UAV controls: forward acceleration and bank angle.
- *Noisy observations*: The UAVs are mounted with sensors that generate the position measurements of the targets. These measurements have random errors that are spatially varying, i.e., the measurement error covariance of a target depends on the locations of sensors (UAVs) and the target.

- *UAV controls*: A UAV is controlled by forward acceleration (controls the speed) and bank angle (controls the heading angle). The values of these control variables lie within certain minimum and maximum limits.
- *Obstacles*: The obstacles are modeled as circular regions in the surveillance region that act as occlusions and also block the path of UAVs.
- *Threats and evasive targets*: A threat is a ground vehicle that pursues the UAVs that are tracking it. An evasive target is a ground vehicle that actively moves away from UAVs to avoid being tracked.
- *Tracking objectives*: The objective is to minimize the mean-squared error between the tracks and the targets. In Sections 73.5.2, 73.5.3, and 73.5.5, the tracking objectives are modified to avoid collisions (between UAVs and obstacles and among UAVs), evade threats, and mitigate track swaps.

73.4.2 POMDP Formulation

This section poses the UAV guidance problem as a *partially observable Markov decision process* (POMDP). The key components of POMDP, in terms of the UAV guidance problem, are as follows:

- *States*. Here, three subsystems are defined as follows: the sensors, the targets, and the tracker. The state at time k is given by $x_k = (s_k, \chi_k, \xi_k, \mathbf{P}_k)$, where s_k represents the sensor state, χ_k represents the target state, and (ξ_k, \mathbf{P}_k) represents the tracker state. The sensor and the target states include the locations and velocities of the UAVs and the targets, respectively. The tracker state is a standard in the Kalman filter (Blackman and Popoli 1999; Bar-Shalom et al. 2001), where ξ_k is the posterior mean vector and \mathbf{P}_k is the posterior covariance matrix.
- *Actions*. The actions include the forward accelerations and the bank angles of all UAVs. More precisely, the action at time k is given by $u_k = [a_k; \phi_k]$, where a_k and ϕ_k are the vectors containing the forward accelerations and the bank angles, respectively, for all the UAVs.
- *State-transition law*. Since there are three subsystems, it is convenient to define the state-transition law for each subsystem separately. The sensor state evolves according to $s_{k+1} = \psi(s_k, u_k)$, where ψ is a mapping function (defined later). The target state evolves according to $\chi_{k+1} = f(\chi_k) + v_k$, where v_k represents an i.i.d. random sequence and f represents the target motion model (also defined later). Finally, the tracker state evolves according to the Kalman filter equations with a data association technique called *joint probabilistic data association* (JPDA) (Bar-Shalom and Fortmann 1988; Blackman and Popoli 1999).
- *Observations and observation law*. Let χ_k^{pos} and s_k^{pos} be the position vectors of a target and a sensor/UAV, respectively. Then the observation of the target's position is given by

$$z_k^\chi = \begin{cases} \chi_k^{\text{pos}} + w_k & \text{if the target is visible,} \\ \text{no measurement} & \text{if an obstacle blocks the} \\ & \text{line of sight,} \end{cases} \quad (73.7)$$

where w_k represents a random measurement error with a distribution that depends on the locations of the UAV (s_k^{pos}) and the target (χ_k^{pos}). The sensor and the tracker states are assumed to be fully observable.

- *Cost function.* The mean-squared error between the tracks and the targets is used as the cost function

$$C(x_k, u_k) = E_{v_k, w_{k+1}} [||\chi_{k+1} - \xi_{k+1}||^2 | x_k, u_k].$$

- *Belief state.* The belief state at time k is given by $b_k = (b_k^s, b_k^\chi, b_k^\xi, b_k^{\mathbf{P}})$, where $b_k^s = \delta(s - s_k)$, $b_k^\xi = \delta(\xi - \xi_k)$, $b_k^{\mathbf{P}} = \delta(\mathbf{P} - \mathbf{P}_k)$ (since the sensor and the tracker states are fully observable), and b_k^χ is the posterior distribution of the target state.

73.4.3 NBO Approximation Method

A linearized target motion model with zero-mean noise is considered, as given below:

$$\chi_{k+1} = \mathbf{F}_k \chi_k + v_k, \quad v_k \sim \mathcal{N}(0, \mathbf{Q}_k), \quad (73.8)$$

and the observations are given by

$$z_k^\chi = \mathbf{H}_k \chi_k + w_k, \quad w_k \sim \mathcal{N}(0, \mathbf{R}_k(\chi_k, s_k)),$$

where \mathbf{F}_k is the target motion model and \mathbf{H}_k is the observation model (73.7). The *constant velocity* (CV) model (Blackman and Popoli 1999; Bar-Shalom et al. 2001) is considered for target dynamics (73.8), which defines \mathbf{F}_k and \mathbf{Q}_k . Since the probability distributions are assumed to be Gaussian, the target belief state can be expressed (or approximated) as $b_k^\chi(\chi) = \mathcal{N}(\chi - \xi_k, \mathbf{P}_k)$, where ξ_k and \mathbf{P}_k evolve according to the JPDA algorithm (Bar-Shalom and Fortmann 1988; Blackman and Popoli 1999).

According to the *nominal belief-state optimization* (NBO) method, the objective function is approximated as follows:

$$J_H(b_0) \approx \sum_{k=0}^{H-1} c(\hat{b}_k, u_k),$$

where $\hat{b}_1, \hat{b}_2, \dots, \hat{b}_{H-1}$ is a *nominal* belief-state sequence and the optimization is over an action sequence u_0, u_1, \dots, u_{H-1} . The nominal target belief-state sequence can be identified with the nominal tracks $(\hat{\xi}_k, \hat{\mathbf{P}}_k)$, which are obtained from the Kalman filter equations (Blackman and Popoli 1999; Bar-Shalom et al. 2001) with exactly zero-noise sequence as follows:

$$\begin{aligned}\hat{b}_k^\chi(\chi) &= \mathcal{N}(\chi - \hat{\xi}_k, \hat{\mathbf{P}}_k), \\ \hat{\xi}_{k+1} &= \mathbf{F}_k \hat{\xi}_k, \\ \hat{\mathbf{P}}_{k+1} &= \left[\hat{\mathbf{P}}_{k+1|k}^{-1} + \mathbf{H}_{k+1}^T \left[\mathbf{R}_{k+1} (\hat{\xi}_{k+1}, s_{k+1}) \right]^{-1} \mathbf{H}_{k+1} \right]^{-1},\end{aligned}$$

where $\hat{\mathbf{P}}_{k+1|k} = \mathbf{F}_k \hat{\mathbf{P}}_k \mathbf{F}_k^T + \mathbf{Q}_k$ and $s_{k+1} = \psi(s_k, u_k)$ (ψ is defined in the next subsection). The cost function, i.e., the mean-squared error between the tracks and the targets, can be written as

$$c(\hat{b}_k, u_k) = \text{Tr} \hat{\mathbf{P}}_{k+1}.$$

Therefore, the goal is to find an action sequence $(u_0, u_1, \dots, u_{H-1})$ that minimizes the cumulative cost function (with truncated horizon Miller et al. 2009)

$$J_H(b_0) = \sum_{k=0}^{H-1} \text{Tr} \hat{\mathbf{P}}_{k+1} = \sum_{k=0}^{H-1} \left(\sum_{i=1}^{N_{\text{targs}}} \text{Tr} \hat{\mathbf{P}}_{k+1}^i \right), \quad (73.9)$$

where N_{targs} represents the number of targets and $\hat{\mathbf{P}}_{k+1}^i$ represents the nominal error covariance matrix of i th target at time $k + 1$. When there are multiple UAVs, the nominal covariance matrix for i th target at time $k + 1$ can be expressed (based on data-fusion techniques) as

$$\hat{\mathbf{P}}_{k+1}^i = \left[\sum_{j=1}^{N_{\text{sens}}} (\hat{\mathbf{P}}_{k+1}^{i,j})^{-1} \right]^{-1},$$

where N_{sens} represents the number of sensors/UAVs and $\hat{\mathbf{P}}_{k+1}^{i,j}$ is the nominal covariance matrix of the i th target computed at the j th sensor. See Miller et al. (2009) for a detailed description of the NBO method.

73.4.4 UAV Kinematics

In this subsection, the mapping function ψ is defined, which was introduced in Sect. 73.4.2 to describe the evolution of the sensor (UAV) state given an action, i.e., $s_{k+1} = \psi(s_k, u_k)$. The state of the i th UAV at time k is given by $s_k^i = (p_k^i, q_k^i, V_k^i, \theta_k^i)$, where (p_k^i, q_k^i) represents the position coordinates, V_k^i represents the speed, and θ_k^i represents the heading angle. Let a_k^i be the forward acceleration (control variable) and ϕ_k^i be the bank angle (control variable) of the UAV, i.e., $u_k^i = (a_k^i, \phi_k^i)$. The mapping function ψ can be specified as a collection of simple

kinematic equations that govern the UAV motion. The kinematic equations of the UAV motion (Geiger et al. 2006) are as follows:

1. Speed update:

$$V_{k+1}^i = [V_k^i + a_k^i T]_{V_{\min}^{V_{\max}}}, \quad (73.10)$$

where $[v]_{V_{\min}^{V_{\max}}} = \max \{V_{\min}, \min(V_{\max}, v)\}$,

2. Heading angle update:

$$\theta_{k+1}^i = \theta_k^i + (gT \tan(\phi_k^i) / V_k^i), \quad (73.11)$$

3. Location update:

$$p_{k+1}^i = p_k^i + V_k^i T \cos(\theta_k^i),$$

$$q_{k+1}^i = q_k^i + V_k^i T \sin(\theta_k^i),$$

where V_{\min} and V_{\max} are the minimum and the maximum limits on the speed of the UAVs, g is the acceleration due to gravity, and T is the length of the time step.

73.4.5 Empirical Study of NBO

The NBO method is implemented in MATLAB, where the optimization problem discussed in Sect. 73.4.3 is solved using the command *fmincon* (gradient-based search algorithm). The measurement error, i.e., w_k , in (73.7) is distributed according to the normal distribution $\mathcal{N}(0, \mathbf{R}_k(\chi_k, s_k))$, where \mathbf{R}_k reflects 10 % range uncertainty and 0.01π radian angular uncertainty. In all the simulations in this study, the time horizon in (73.9) is set to $H = 6$. The goal of this empirical study is to illustrate the flexibility of the POMDP framework in being able to incorporate features of interest simply by “plugging in” the appropriate feature model into the framework and to compare the quantitative performance over varying parameter values.

This subsection provides the simulation of a few scenarios to demonstrate the coordinated behavior among the UAVs and the ability of the planning algorithm to track multiple targets with a single UAV. This subsection also provides empirical results to compare the tracking performance of variable-speed UAVs with that of the fixed-speed UAVs. In these simulations, a sequence of red circles represents the trajectory of a target, and a curve joining the arrows represents the trajectory of a UAV, where the size of an arrow is proportional to the instantaneous speed of the UAV and the arrow points toward the instantaneous heading direction of the UAV.

73.4.5.1 Coordinated UAV Motion

Figure 73.2 shows the simulation of a scenario with three UAVs and two targets, which depicts the scenario at the end of the simulation. Both targets start at the bottom, and as the simulation progresses, one target moves toward the northeast and the other moves toward the northwest. The UAVs start at the bottom and move according to the kinematic equations in Sect. 73.4.4, with controls obtained from the command *fmincon*, which minimize the cumulative cost function (73.9). The UAVs

Fig. 73.2 Three UAVs (*blue*) tracking two targets (*red*)

coordinate to maximize the coverage of the targets as shown in Fig. 73.2. To evaluate how the agility in UAV motion affects the quantitative tracking performance, the scenario in Fig. 73.2 is simulated for 1,000 Monte Carlo runs with variable-speed UAVs and then with fixed-speed UAVs. Figure 73.3 shows the cumulative frequency of the average target-location errors for both fixed-speed and variable-speed UAVs. It is evident from Fig. 73.3 that variable-speed UAVs give better performance over fixed-speed UAVs.

73.4.5.2 Weaving Between Targets

Figure 73.4 shows the simulation of a scenario with one UAV and two targets, which depicts the scenario at the end of the simulation. Both targets start from the left and move toward the right. The UAV weaves between the targets as shown in Fig. 73.4, so that the average speed of the UAV toward the right is close to the speed of the targets. Also, the tracks get refined by looking at the targets from different angles, which is achieved by weaving between the targets. This scenario demonstrates the ability of the planning algorithm to maximize the coverage of multiple targets with a single UAV.

73.5 Model Enhancements and Additional Features

This section shows how to incorporate a variety of features of interest naturally into the POMDP framework. Specifically, the following features are incorporated by appropriately formulating the state-transition law and the objective function: (1) account for the effect of wind disturbance on UAVs, (2) avoid collisions between

Fig. 73.3 Performance comparison: variable-speed UAVs (speed 11–26 m/s) vs. fixed-speed UAVs (speed: 15 m/s)

Fig. 73.4 One UAV (*blue*) tracking two targets (*red*)

UAVs and obstacles and among UAVs, (3) track targets while evading threats, (4) track evasive targets, and (5) mitigate track swaps.

73.5.1 Wind Compensation

If unaccounted for, wind drags the UAVs from their planned paths, which results in tracking performance degradation. In this subsection, a wind-compensation method is discussed in the context of the POMDP framework. More precisely, the speed and direction of wind are incorporated into the framework to nullify the effect of wind on UAVs.

The NBO method requires a nominal belief-state sequence of future states of the targets and the sensors (UAVs) given the actions. Since the planning algorithm in this study has a *look-ahead* property, it is important to have a UAV motion model that correctly predicts the trajectory of each UAV. [Figure 73.5a](#) shows the simulation of a scenario with one UAV and one target in the presence of wind. A simple

Fig. 73.5 UAV (blue) tracking a target (red) in the presence of wind. (a) No wind compensation; wind speed = 15 knots (north) and (b) wind compensation; wind speed = 15 knots (north)

wind model is used, i.e., wind blowing in the north direction at a constant speed. Figure 73.5a shows a plot at the end of the simulation where wind was unaccounted for, which resulted in drifting of the UAV from its desired course. As a result, the tracking performance (measured in average target-location error) gets deteriorated. To nullify the effect of wind, the speed and direction of wind are incorporated into the state-transition law corresponding to the sensor subsystem, i.e., the kinematics of the UAV motion. The information on wind (i.e., the speed and direction of wind) is assumed to be available (e.g., via measurements from a pitot tube). The modified location update equations are given below:

$$\begin{aligned} p_{k+1}^i &= p_k^i + V_k^i T \cos(\theta_k^i) + w_x T, \\ q_{k+1}^i &= q_k^i + V_k^i T \sin(\theta_k^i) + w_y T, \end{aligned} \quad (73.12)$$

where w_x and w_y are the average wind speeds in x and y directions. The speed and bank angle update equations remain the same as in (73.10) and (73.11). This wind-compensation method is not limited to constant wind scenarios (as in the above example); any wind model can be incorporated into the framework.

Figure 73.5b shows the simulation of the same scenario as in Fig. 73.5a, but with modified UAV kinematic model (73.12). With wind compensation, the UAV trajectory stays close to that of the target's, which improves the tracking performance. These scenarios (with and without wind compensation) are simulated for 2,000 Monte-Carlo runs; at the end of every run, the average target-location error is calculated. Figure 73.6 shows the cumulative frequency of average target-location errors for various wind speeds, which also demonstrates the advantage of having wind compensation. From Fig. 73.6, it is evident that the tracking performance deteriorates with increasing wind speed when wind is not compensated for, and

Fig. 73.6 Tracking performance under various wind speeds: 10 knots (*red*), 15 knots (*blue*), and 20 knots (*green*)

with wind compensation, the tracking performance does not deteriorate even with increasing wind speed.

73.5.2 Collision Avoidance

73.5.2.1 Collision Avoidance Between UAVs and Obstacles

Suppose that the targets are moving on the ground in the presence of obstacles where the UAV flying altitude is lower than the height of the obstacles. A collision between the UAVs and the obstacles may happen if the obstacles are unaccounted for. These obstacles also act as occlusions, i.e., a sensor cannot generate the measurement of a target if it is occluded. This section shows how to avoid collisions between UAVs and obstacles in the context of the POMDP framework. To avoid collisions, a penalty term (that increases as the UAVs come close to obstacles) is included in the objective function. Let N_{targs} represent the number of targets and N_{sens} represent the number of UAVs. The new objective function is written as follows:

$$J_H = \sum_{k=0}^{H-1} \left(\sum_{i=1}^{N_{\text{targs}}} \text{Tr} \hat{\mathbf{P}}_{k+1}^i + \gamma \sum_{j=1}^{N_{\text{sens}}} P_{k+1}^{\text{coll},j} \right), \quad (73.13)$$

where $P_{k+1}^{\text{coll},j}$ is a collision penalty function corresponding to the j th UAV and γ is a scaling factor. For the purpose of the 2-D simulation environment, the obstacles

Fig. 73.7 UAV tracking a target while evading obstacles: UAV (blue), target (red), and obstacles (black). (a) No obstacles and (b) obstacles in the path of the UAV

are modeled as circular regions in the plane (surveillance region). Any continuous function can be used as the collision penalty function provided that the function increases as a UAV approaches an obstacle. For the purpose of the simulation, a simple linear function is used as the penalty function as given below:

$$P_{k+1}^{\text{coll},j} = \begin{cases} D - d_{k+1}^j & \text{if } d_{k+1}^j < D, \\ 0 & \text{otherwise,} \end{cases} \quad (73.14)$$

where d_{k+1}^j is the distance between the j th UAV and the closest obstacle from its location at time $k + 1$ and D is a constant such that the penalty function is nonzero only when d_{k+1}^j is less than D (i.e., the obstacles do not affect the planning algorithm when the UAVs are far from the obstacles). The UAV can detect its distance from the surrounding obstacles. Therefore, d_{k+1}^j ($\forall j$) in (73.14) is available at all times.

Figure 73.7b shows the simulation of a scenario with one UAV and one target, where the target moves on the ground in the presence of obstacles. Both the target and the UAV start at the left, and as the target moves toward the right, the UAV tracks the target while evading the obstacles, demonstrating the effectiveness of the inclusion of the penalty term in the objective function (73.13). If there were no obstacles, the UAV trajectory would have been close to that of the target as in Fig. 73.7a. When the UAV goes far from the target (when avoiding obstacles), the trace objective increases. However, the penalty from the collision penalty function is reduced (the parameter γ in (73.13) is set to a sufficiently large value to induce this behavior).

73.5.2.2 Collision Avoidance Among UAVs

Consider a multi-UAV scenario, where all UAVs are flying at the same altitude. To avoid collisions among the UAVs, a penalty term is incorporated into the objective function similar to (73.13), as given below:

$$J_H = \sum_{k=0}^{H-1} \left(\sum_{i=1}^{N_{\text{targs}}} \text{Tr} \hat{\mathbf{P}}_{k+1}^i + \gamma \sum_{j=1}^{N_{\text{sens}}} P_{k+1}^{\text{coll},j} \right), \quad (73.15)$$

where

$$P_{k+1}^{\text{coll},j} = \begin{cases} D - d_{k+1}^j & \text{if } d_{k+1}^j < D, \\ 0 & \text{otherwise,} \end{cases} \quad (73.16)$$

where d_{k+1}^j is the distance between the j th UAV and the closest neighboring UAV at time $k + 1$, i.e.,

$$d_{k+1}^j = \min_{i, i \neq j} d_{k+1}^{ji},$$

where d_{k+1}^{ji} is the distance between the j th UAV and the i th UAV.

The significance of D in (73.16) is as follows: a UAV contributes to the penalty function only if it approaches another UAV such that the distance between them becomes less than D . This penalty function penalizes those actions (over time) that cause any two UAVs to come close to each other, which effectively avoids collisions among the UAVs. Suppose that the safe distance (minimum spacing between two aircrafts, which is maintained to avoid midair collisions) between two aircrafts is 100m. The value of D in (73.16) is set equal to the safe distance, i.e., $D = 100$. Figure 73.8 shows the simulation of a scenario, where two UAVs are tracking one target with enhancement to the objective function (73.15). Figure 73.9 shows the plot of the distance between the two UAVs (in the scenario Fig. 73.8) as a function of time for $\gamma = 10$. From Fig. 73.9, it is evident that, with the enhancement to the objective function (73.15), the distance between the UAVs is greater than D , i.e., the safe distance, at all times. This shows that the enhancement to the objective function enables the planning algorithm to guide the UAVs for tracking a target while avoiding collisions among the UAVs by keeping a safe distance (D) between them.

A performance metric called *collision threat index* (CTI) is introduced for the scenario in Fig. 73.8, which is defined as the fraction of time the distance between the UAVs is less than D . The scenario in Fig. 73.8 is simulated for 1,000 Monte Carlo runs for various values of γ in (73.13). Figure 73.10a shows the plot of the cumulative frequency of CTI for various values of γ . It is evident from Fig. 73.10a that the performance with respect to CTI can be improved by increasing the value of γ . Table 73.1 shows that the inclusion of the collision penalty function in the objective function has significantly improved the performance in terms of CTI. However, increasing the value of γ reduces the tracking performance with respect to the average target-location error, which is evident from Fig. 73.10b. Figure 73.10b

Fig. 73.8 Two UAVs tracking a target while avoiding collisions among themselves: UAVs (blue, magenta) and target (red)

Fig. 73.9 Distance between the UAVs as a function of time (for scenario in Fig. 73.8)

shows the plot of the cumulative frequency of average target-location errors for various values of γ . In summary, γ can be used as a parameter to tune the trade-off between the performance with respect to CTI and the performance with respect to average target-location error.

73.5.3 Evading Threats

For the purpose of this section, a *threat* is a ground vehicle that actively pursues UAVs that are tracking it. Each threat knows the locations of all UAVs at all times

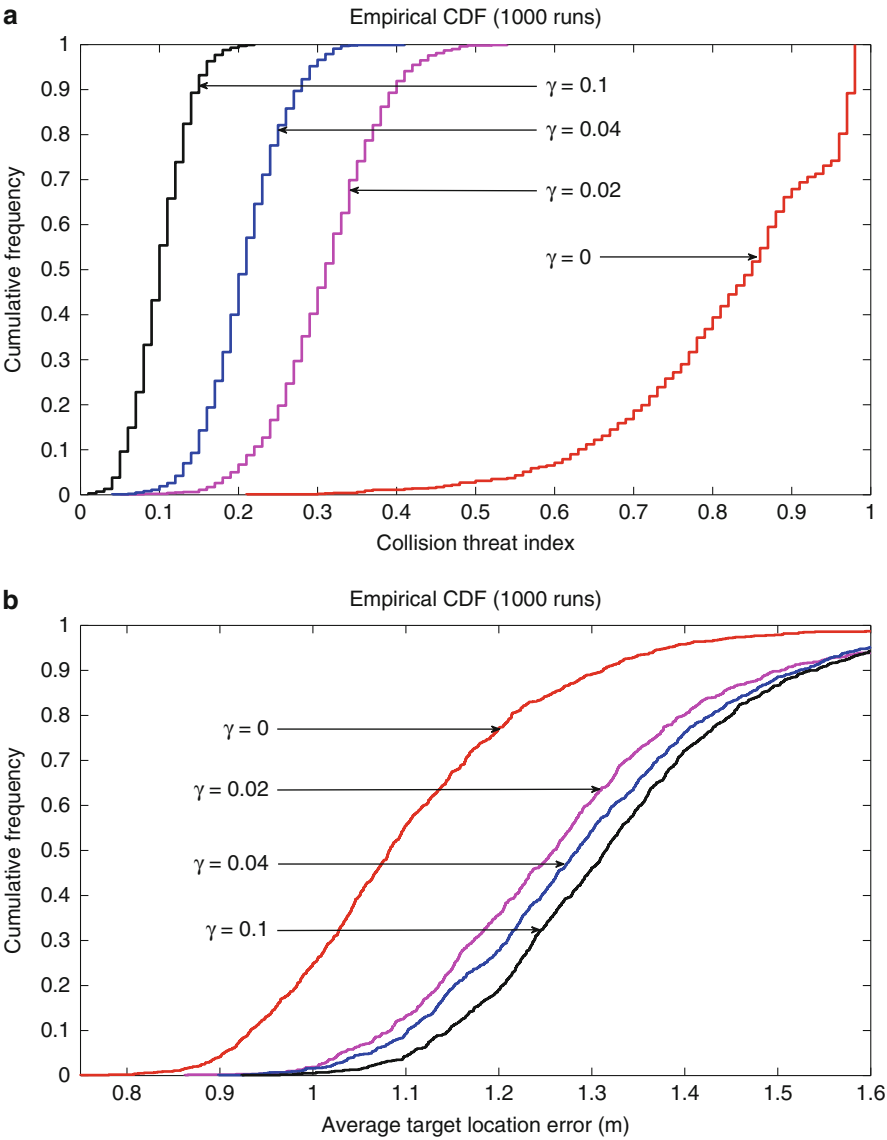

Fig. 73.10 Cumulative frequency of performance measures for various values of γ in (73.13). (a) CTI and (b) Avg. target-location error

and aligns its direction of motion toward the closest UAV at every time step. The goal here is to design the guidance algorithm in such a way that the UAVs track targets while avoiding threats by keeping a safe distance from them. The next subsection introduces a threat motion model that describes the evolution of the threat state.

Table 73.1 Average CTI (averaged over 1,000 runs) with and without the collision penalty function in the objective function

| Objective function | CTI (average) |
|---|---------------|
| $\text{Tr } \mathbf{P}$ | 0.823 |
| $\text{Tr } \mathbf{P} + 0.1 (P^{\text{coll}})$ | 0.102 |

73.5.3.1 Threat Motion Model

Let χ_k^t represent the state of a threat at time k , which includes the position coordinates (x_k and y_k) and speed (v_k) of the threat, i.e.,

$$\chi_k^t = [x_k, y_k, v_k]^T.$$

The threat state evolves according to the following equation:

$$\chi_{k+1}^t = \Phi_k \chi_k^t + n_k, \quad n_k \sim \mathcal{N}(0, \mathbf{Q}_k^t), \quad (73.17)$$

where \mathbf{Q}_k^t represents the process noise covariance matrix and

$$\Phi_k = \begin{bmatrix} 1 & 0 & \cos(h_k)T \\ 0 & 1 & \sin(h_k)T \\ 0 & 0 & 1 \end{bmatrix},$$

where h_k is the heading angle of the threat, which is given by

$$h_k = \tan^{-1} \left(\frac{y_k^{\text{closest UAV}} - y_k}{x_k^{\text{closest UAV}} - x_k} \right), \quad (73.18)$$

where $(x_k^{\text{closest UAV}}, y_k^{\text{closest UAV}})$ represent the position coordinates of the closest UAV from the threat at time k and (x_k, y_k) represent the position coordinates of the threat at time k . The heading angle Eq. (73.18) captures the pursuing property of the threat.

73.5.3.2 Threat Belief-State Evolution

The observation of the threat state is given by

$$z_k^t = \mathbf{H}_k \chi_k^t + w_k, \quad w_k \sim \mathcal{N}(0, \mathbf{R}_k).$$

Since the threat state evolves according to (73.17), i.e., $\chi_{k+1}^t = f(\chi_k^t) + n_k$, the Kalman filter or the extended Kalman filter cannot be used to evaluate the threat state estimate because the function $f(\cdot)$ is nonlinear and not differentiable. Therefore, a heuristic approach is used to write the Kalman filter equations. The threat belief state can be expressed (or approximated) as $b_k^t(\chi) = \mathcal{N}(\chi - \xi_k^t, \mathbf{P}_k^t)$, where ξ_k^t and \mathbf{P}_k^t evolve according to a heuristic Kalman filter (differs from the Kalman filter only in the prediction step), where the prediction step is written as follows:

$$\begin{aligned}\xi_{k|k-1}^t &= \hat{\Phi}_k \xi_{k-1}^t, \\ \mathbf{P}_{k|k-1}^t &= \hat{\Phi}_k \mathbf{P}_{k-1}^t \hat{\Phi}_k^T + \mathbf{Q}_k^t,\end{aligned}$$

where $\hat{\Phi}_k$ is an approximation of Φ_k in (73.17), which is evaluated as follows:

$$\hat{\Phi}_k = \begin{bmatrix} 1 & 0 & \cos(\hat{h}_k)T \\ 0 & 1 & \sin(\hat{h}_k)T \\ 0 & 0 & 1 \end{bmatrix},$$

where

$$\hat{h}_k = \tan^{-1} \left(\frac{\hat{y}_k^{\text{closest UAV}} - \hat{y}_k}{\hat{x}_k^{\text{closest UAV}} - \hat{x}_k} \right), \quad (73.19)$$

where $(\hat{x}_k^{\text{closest UAV}}, \hat{y}_k^{\text{closest UAV}})$ are the position coordinates of the estimated closest UAV from the threat at time k and (\hat{x}_k, \hat{y}_k) are the estimated position coordinates of the threat at time k . The closest UAV from the threat can be found by evaluating the Euclidean distances between the threat and each UAV. The location of the threat is known only with uncertainty, which is given by the posterior distribution of the threat state. Therefore, the exact Euclidean distance between the threat and a UAV cannot be calculated. So, the Mahalanobis distance (Mahalanobis 1936) is evaluated, which is a statistical distance, between the threat and a UAV. The closest UAV from the threat is estimated as follows:

1. The Mahalanobis distance (Mahalanobis 1936) of the position coordinates of each UAV i ($s_k^{i,\text{pos}}$) from the probability distribution (Gaussian) of the threat's location given by $\mathcal{N}(\xi_k^{t,\text{pos}}, \mathbf{P}_k^{t,\text{pos}})$ is evaluated, where $\xi_k^{t,\text{pos}}$ represents the first two elements of the threat state estimate ξ_k^t and $\mathbf{P}_k^{t,\text{pos}}$ represents a 2×2 sub-matrix of the threat state error covariance matrix \mathbf{P}_k^t , such that

$$\mathbf{P}_k^t = \begin{bmatrix} \mathbf{P}_k^{t,\text{pos}} & \mathbf{A}_k \\ \mathbf{A}_k^T & \mathbf{B}_k \end{bmatrix}.$$

The Mahalanobis distance of the i th UAV from the probability distribution of the threat's location is given by

$$D_M^i = \sqrt{[s_k^{i,\text{pos}} - \xi_k^{t,\text{pos}}]^T [\mathbf{P}_k^{t,\text{pos}}]^{-1} [s_k^{i,\text{pos}} - \xi_k^{t,\text{pos}}]}. \quad (73.20)$$

2. The closest UAV I from the threat is estimated as follows:

$$I = \arg \min_i D_M^i.$$

The *nominal* threat belief state ($\hat{b}_k^{\chi,t}$) is identified with the *nominal* tracks of the threat ($\hat{\xi}_k^t, \hat{\mathbf{P}}_k^t$) as follows:

$$\begin{aligned}\hat{b}_k^{\chi,t}(\chi) &= \mathcal{N}\left(\chi - \hat{\xi}_k^t, \hat{\mathbf{P}}_k^t\right), \\ \hat{\xi}_{k+1}^t &= \hat{\Phi}_k \hat{\xi}_k^t, \\ \hat{\mathbf{P}}_{k+1}^t &= \left[(\hat{\mathbf{P}}_{k+1|k}^t)^{-1} + \mathbf{H}_{k+1}^T \left[\mathbf{R}_{k+1} \left(\hat{\xi}_{k+1}^t, s_{k+1} \right) \right]^{-1} \mathbf{H}_{k+1} \right]^{-1},\end{aligned}$$

where $\hat{\mathbf{P}}_{k+1|k}^t = \hat{\Phi}_k \hat{\mathbf{P}}_k^t \hat{\Phi}_k^T + \mathbf{Q}_k^t$. The *constant velocity* (CV) model (73.8) is incorporated for target dynamics into the NBO method (as in the previous subsection). The next subsection provides an enhancement to the objective function to guide UAVs for tracking targets while evading threats.

73.5.3.3 Enhancement to the Objective Function

Let N_{targs} represent the number of targets and N_{sens} represent the number of UAVs. To guide the UAVs for tracking targets while avoiding threats, a penalty metric is included in the objective function. This penalty term increases whenever a UAV comes close to a threat. Therefore, the Euclidean distance between the locations of a UAV and the closest threat from the UAV can be used as a penalty metric. As mentioned in the previous section, the exact Euclidean distance between a UAV and a threat cannot be evaluated because of the uncertainty in the location of the threat. Therefore, as before, the Mahalanobis distance (Mahalanobis 1936), which is a statistical distance, between a UAV and its closest threat is used as the penalty metric. The new objective function can be written as follows:

$$J_H(b_0) = \sum_{k=0}^{H-1} \left(\sum_{i=1}^{N_{\text{targs}}} \text{Tr} \hat{\mathbf{P}}_{k+1}^i + \gamma \sum_{j=1}^{N_{\text{sens}}} G_{k+1}^j \right), \quad (73.21)$$

where γ is a scaling constant and

$$G_{k+1}^j = \begin{cases} D - d_{k+1}^j & \text{if } d_{k+1}^j < D, \\ 0 & \text{otherwise,} \end{cases} \quad (73.22)$$

where

$$d_{k+1}^j = \min_m D_M^m(s_{k+1}^{j,\text{pos}}),$$

where $s_{k+1}^{j,\text{pos}}$ represents the position coordinates of the j th UAV and $D_M^m(s_{k+1}^{j,\text{pos}})$ represents the Mahalanobis distance (73.20) of $s_{k+1}^{j,\text{pos}}$ from the probability distribution of the location of m th threat, i.e., $\mathcal{N}(\hat{\xi}_{k+1}^{t,\text{pos},m}, \hat{\mathbf{P}}_{k+1}^{t,\text{pos},m})$, where $\hat{\xi}_{k+1}^{t,\text{pos},m}$ represents the first two elements of $\hat{\xi}_{k+1}^{t,m}$ and $\hat{\mathbf{P}}_{k+1}^{t,\text{pos},m}$ represents the top-left-corner 2×2

Fig. 73.11 UAV tracking a target while evading a threat: UAV (*blue*), threat (*red*), and target (*green*)

sub-matrix of $\hat{\mathbf{P}}_{k+1}^{t,m}$. The next subsection provides an empirical study to demonstrate the effectiveness of this enhancement.

73.5.3.4 Empirical Study

Figure 73.11 shows the simulation of a scenario with one UAV, one threat, and one target. In this simulation, the value of D in (73.22) is set to 100. Figure 73.12 shows the plot of the distance $D_{\text{threat-UAV}}$ between the UAV and the threat (in the scenario Fig. 73.11) as a function of time. It is evident from Fig. 73.12 that the UAV tracks the target while maintaining a safe distance, $D_{\text{safe}} (= D)$, from the threat. This demonstrates the effectiveness of the enhancement to the objective function (73.21).

A performance metric called the *threat index* is introduced for the scenario in Fig. 73.11, defined as the fraction of time the distance between the UAV and the threat is less than D . The scenario in Fig. 73.11 is simulated for 1,000 Monte Carlo runs for various values of γ used in (73.21). Figure 73.13a shows the plot of the cumulative frequency of threat indices for various values of γ . From Fig. 73.13a, it is evident that the performance with respect to *threat index* can be improved by increasing the value of γ . However, the performance with respect to average target-location error degrades with increasing γ , which is evident from Fig. 73.13b. In summary, the parameter γ can be used to tune the trade-off between the performance with respect to *threat index* and the performance with respect to average target-location error.

73.5.4 Tracking Evasive Targets

An evasive target is a ground vehicle that actively moves away from UAVs that are tracking it to avoid being tracked. In this section, all targets are evasive.

Fig. 73.12 Distance between the UAV and the threat as a function of time in the scenario Fig. 73.11

Each target knows the locations of all UAVs at every time step. The state of a target evolves according to the evasive target motion model as described in the following subsection.

73.5.4.1 Evasive Target Motion Model

The evasive target motion model described here is very similar to the threat motion model presented in the previous section. Let χ_k represent the state of a target at time k , which includes the position coordinates (x_k and y_k) and speed (v_k), i.e.,

$$\chi_k = [x_k, y_k, v_k]^T.$$

The target state evolves according to the following equation:

$$\chi_{k+1} = \Phi_k \chi_k + n_k, \quad n_k \sim \mathcal{N}(0, \mathbf{Q}_k^{\text{Evas}}),$$

where $\mathbf{Q}_k^{\text{Evas}}$ represents the process noise covariance matrix and

$$\Phi_k = \begin{bmatrix} 1 & 0 & \cos(h_k)T \\ 0 & 1 & \sin(h_k)T \\ 0 & 0 & 1 \end{bmatrix},$$

where h_k is the heading angle of the target, which is given by

Fig. 73.13 Cumulative frequency of performance measures for various values of γ in the scenario Fig. 73.11. (a) Threat index and (b) Avg. target location error

$$h_k = \pi + \tan^{-1} \left(\frac{y_k^{\text{closest UAV}} - y_k}{x_k^{\text{closest UAV}} - x_k} \right), \quad (73.23)$$

where $(x_k^{\text{closest UAV}}, y_k^{\text{closest UAV}})$ are the position coordinates of the closest UAV from the target at time k and (x_k, y_k) are the position coordinates of the target at time k . Equation (73.23) differs from (73.19) in that the former induces an addition of π radians, representing motion away from the closest UAV.

73.5.4.2 Target Belief-State Evolution

As before, the observation of the target state is given by

$$z_k = \mathbf{H}_k \chi_k + w_k, \quad w_k \sim \mathcal{N}(0, \mathbf{R}_k).$$

The target belief state b_k^χ and the *nominal* target belief state \hat{b}_k^χ evolve according to the heuristic Kalman filter equations as in Sect. 73.5.3.2. However, the heading angle estimate (used in $\hat{\Phi}_k$) is evaluated according to the following equation:

$$\hat{h}_k = \pi + \tan^{-1} \left(\frac{\hat{y}_k^{\text{closest UAV}} - \hat{y}_k}{\hat{x}_k^{\text{closest UAV}} - \hat{x}_k} \right),$$

where $(\hat{x}_k^{\text{closest UAV}}, \hat{y}_k^{\text{closest UAV}})$ are the position coordinates of the estimated closest UAV from the target at time k (the closest UAV from the target is estimated in the same way the closest UAV from a threat was estimated in the previous section) and (\hat{x}_k, \hat{y}_k) are the estimated position coordinates of the target at time k . The nominal target belief-state update equations (described above) are incorporated into the NBO method. The objective function is given by

$$J_H(b_0) = \sum_{k=0}^{H-1} \left(\sum_{i=1}^{N_{\text{targs}}} \text{Tr} \hat{\mathbf{P}}_{k+1}^i \right),$$

where $\hat{\mathbf{P}}_{k+1}^i$ is the nominal error covariance matrix corresponding to the i th target at time $k+1$, which is obtained from the nominal target belief-state update equations (described above).

73.5.4.3 Empirical Study

To demonstrate the effectiveness of incorporating the evasive target motion model into the NBO method (as described in Sect. 73.5.4.2), its performance is compared with the use of a target motion model that does not account for the evasive property of the target (in particular *constant velocity* model). First, a scenario is simulated with one UAV and an evasive target while adopting the *constant velocity* model (henceforth referred to as the CV model) (Bar-Shalom et al. 2001; Blackman and Popoli 1999) for evasive target dynamics (which means the target is evasive, but the evasive property of the target is unaccounted for) (73.8). Second, the previous scenario is simulated while adopting the evasive target motion model (presented in Sect. 73.5.4.2) for target dynamics. Figure 73.14a and b shows the plots of one UAV tracking an evasive target with the CV model and with the evasive target motion model (Evas model), respectively. These scenarios are simulated for 1,000 Monte Carlo runs, and the cumulative frequency of average target-location errors is plotted, as shown in Fig. 73.15. From Fig. 73.15, it is evident that by adopting the Evas model over the CV model for the dynamics of an evasive target, the performance with respect to average target-location error can be improved significantly.

Fig. 73.14 UAV tracking an evasive target: UAV (*blue*) and target (*red*). (a) NBO with CV model and (b) NBO with Evas model

Fig. 73.15 Performance comparison of Evas model and CV model for the scenarios in Fig. 73.14

73.5.5 Track Swap Avoidance

A track swap is a switch in the association between the tracks and the targets. The identities of the targets are interpreted through the association between the tracks

and the targets. Therefore, a track swap switches the identities of targets, which is undesirable. The likelihood of a track swap depends on the tracker state, which in turn depends on the locations of UAVs relative to the targets. Therefore, track swaps can be mitigated by appropriately controlling the UAVs. This is achieved by incorporating a metric into the objective function that represents the risk of a track swap (this idea was first introduced in Miller et al. 2009).

73.5.5.1 Problem Description

Suppose that a UAV is tracking three targets as shown in Fig. 73.16. In this scenario, the bottom two targets come in close proximity to each other periodically, and the topmost target remains far from the bottom two targets. The planning algorithm discussed in Sect. 73.4 maximizes the coverage of the targets by guiding the UAV to weave between the topmost target and the bottom targets (as shown in Fig. 73.16), which is achieved by minimizing the overall trace objective. The likelihood of a track swap is high when the measurement sources are ambiguous. In the scenario of Fig. 73.16, when the UAV is far from the bottom targets, i.e., when the UAV is close to the topmost target, the likelihood of a track swap (corresponding to the bottom targets) is high because the chance that the sources of the measurements from the bottom two targets becoming ambiguous is high. The following subsection provides an enhancement (Miller et al. 2009) to mitigate track swaps.

73.5.5.2 Enhancement for Mitigating Track Swaps

The similarity between the target state distributions is a good predictor for a track swap because the likelihood of the measurement sources becoming ambiguous is high when the similarity between the target state distributions is high. The target state distributions depend on the tracker states and the locations of the UAVs over

Fig. 73.16 UAV tracking three targets: UAV (*blue*), targets (*red*), and error concentration ellipses of target's location (*green*)

time. Therefore, the UAVs can be controlled appropriately such that the target state distributions are less similar. The similarity between the probability distributions can be measured as the inverse of a statistical distance between the distributions. To minimize the likelihood of a track swap, a term that is inversely proportional to a statistical distance (between the target state distributions) is incorporated into the objective function. The new objective function is written as

$$J_H = \sum_k \left(\sum_{i=1}^{N_{\text{targs}}} \text{Tr} \mathbf{P}_{k+1}^i + \gamma(1/D_{k+1}) \right), \quad (73.24)$$

where γ is a scaling factor, N_{targs} represents the number of targets, and

$$D_{k+1} = \min_{p \neq q; p, q \in S} D(\chi_{k+1}^p || \chi_{k+1}^q),$$

where $S = \{1, 2, \dots, N_{\text{targs}}\}$ and $D(\chi_{k+1}^p || \chi_{k+1}^q)$ is a statistical distance between the distributions of the p th target and the q th target.

There are several statistical distances defined in the literature: KL divergence (Kullback and Leibler 1951), Bhattacharyya distance (Bhattacharyya 1943), Hellinger distance (Cam and Yang 2000), and worst-case chi-square distance (see Miller et al. 2009 for a description of the worst-case chi-square distance). Figure 73.17 shows the simulation of a scenario with three targets and one UAV (similar to the scenario in Fig. 73.16) with the new objective function (73.24) (where the worst-case chi-square distance is used to measure the similarity between distributions). Figure 73.17 shows that, with enhancement to the objective function (73.24), the UAV stays close to the bottom two targets in contrast to the behavior in Fig. 73.16. This reduces the similarity between the probability distributions of the bottom targets, which in turn reduces the chance of a track swap.

KL divergence, Bhattacharyya distance, and Hellinger distance are average-case measures of how often the state values from the distributions fall in a small neighborhood of each other, whereas worst-case chi-square distance is a

Fig. 73.17 UAV tracking three targets while mitigating track swaps

worst-case measure. Miller et al. (2009) explain that a worst-case measure is more suited to track swap prediction than an average-case measure. The next subsection provides an empirical study to show that the worst-case chi-square distance is an appropriate metric in predicting track swaps, which corroborates the claim in Miller et al. (2009).

73.5.5.3 Empirical Study

The scenario where a UAV tracks three targets (as described in Sect. 73.5.5.1) is simulated for 2,000 runs with and without the enhancement in the objective function. In every run, the fraction of track swaps—a metric to evaluate the tracking performance—is calculated according to the following method.

Fraction of Track Swaps: Let N_{TS} represent the number of track swaps, defined as follows. The tracks are checked for a track swap only at instances when the bottom targets are the farthest apart. These instances occur periodically, as can be seen in Figs. 73.16 and 73.17. At each of these instances, the associations between the tracks and the targets are evaluated. Whenever the association at a particular instance differs from the association in the previous instance, N_{TS} is incremented by one. At the end of the simulation, the fraction of track swaps is evaluated as follows:

$$\text{fraction of track swaps} = \frac{N_{TS}}{N},$$

where N represents the total number of instances the track associations are evaluated.

For the purpose of simulations, the following notation is used to represent the statistical distances: (1) KL divergence, D_{KL-div} ; (2) Hellinger distance $D_{Hell-dist}$;

Fig. 73.18 Performance comparison for various statistical distances

Table 73.2 Fraction of track swaps (averaged over 2,000 Monte Carlo runs) for various statistical distances

| Objective function | Fraction of track swaps (average) |
|--|-----------------------------------|
| $\text{Tr } \mathbf{P}$ | 0.48 |
| $\text{Tr } \mathbf{P} + (\gamma/D_{\text{KL-div}})$ | 0.17 |
| $\text{Tr } \mathbf{P} + (\gamma/D_{\text{Hell-dist}})$ | 0.12 |
| $\text{Tr } \mathbf{P} + (\gamma/D_{\text{Bhatt-dist}})$ | 0.11 |
| $\text{Tr } \mathbf{P} + (\gamma/D_{\chi^2})$ | 0.08 |

(3) Bhattacharyya distance, $D_{\text{Bhatt-dist}}$; and (4) worst-case chi-square distance, D_{χ^2} . Figure 73.18 shows the plot of the cumulative frequency of the fraction of track swaps for various statistical distances. From Fig. 73.18 and Table 73.2, it is evident that the enhancement to the objective function improves the performance (in terms of the fraction of track swaps) significantly for all candidate statistical distances. It is also evident that D_{χ^2} is the best among other statistical distances in mitigating track swaps. This shows that the worst-case chi-square distance is an appropriate metric for predicting track swaps—which corroborates the claim in Miller et al. (2009).

73.6 Conclusion

In this study, a dynamic path-planning algorithm was designed to guide autonomous UAVs for multitarget tracking based on the theory of POMDPs. The key features of this study are summarized as follows:

- Variable-speed UAVs are considered for the purpose of this study. The UAVs are controlled by forward acceleration and bank angle. This study described how to incorporate these controls into the framework by appropriately formulating the POMDP action space and state-transition law. The results show that the variable-speed UAVs give better tracking performance over fixed-speed UAVs, which demonstrates that higher the agility in UAV motion better the tracking performance.
- A wind-compensation method is discussed in the context of POMDP framework. The speed and direction of wind are incorporated into the UAV kinematic model to nullify the effect of wind disturbance on UAVs. The results from the Monte Carlo simulations show that the performance remained good even with increasing wind speed when wind was accounted for, whereas the performance deteriorated significantly when wind was unaccounted for.
- To avoid collisions between UAVs and obstacles and among UAVs, a penalty term (scaled appropriately) is included in the objective function. The penalty function penalizes the actions that bring UAVs close to the obstacles or bring two UAVs close to each other (these two scenarios are addressed separately). In the first scenario, the simulation results show that by incorporating the penalty term into the objective function, a UAV tracks a target while safely evading the obstacles. In the second scenario, the inclusion of the penalty term in the objective function ensured that the UAVs track the targets while avoiding collisions among themselves. In this scenario, the Monte Carlo simulation results

show that, by varying a certain parameter (γ), one can trade off between the performances with respect to *collision threat index* (CTI) and average target-location error.

- This study presented a method to guide UAVs for tracking targets while evading threats. First, the threat motion model is defined while incorporating the pursuing property of threats. Second, the threat belief-state update equations are written based on the threat motion model. Third, a penalty term is included in the objective function, which penalizes the actions that bring the UAVs close to the threats. The results show that the enhancement to the objective function ensured that the UAVs track the targets while evading the threats. The results also show that the trade-off between the performances with respect to *threat index* and average target-location error can be tuned with a parameter γ .
- This study presented a method to guide UAVs to track evasive targets. The evasive property of targets is incorporated into the NBO method, which is accomplished by appropriately defining the evasive target motion model. First, the evasive target motion model (Evas model) is defined while incorporating the evasive property of targets. Second, the target belief-state update equations are written using the Evas model. Third, an empirical study is conducted to demonstrate the effectiveness of incorporating the evasive property of targets into the NBO method.
- To reduce the likelihood of a track swap, a term that is proportional to the inverse of the statistical distance (between the target state distributions) is included in the objective function. The simulation of the scenario with one UAV and three targets shows that the modified objective function successfully enabled the UAV to track the targets while reducing the similarity between the target state distributions, which effectively reduced the chance of a track swap. The performances of various statistical distances are compared, and the results support the argument that D_{χ^2} is an appropriate metric in predicting track swaps.

The above-mentioned features are incorporated into the framework by simply plugging in the appropriate models, showing the generality and flexibility of the framework.

UAV Sense, Detect and Avoid Systems

Lennaert Speijker

Kimon P. Valavanis and George J. Vachtsevanos

The absence of a pilot onboard the UAV may endanger the life of the UAV itself and that of other flying objects, as well as endanger the life of human personnel on the ground when crashing, on top of other collateral damage. Safe UAV flying in the national airspace is a major concern of regulatory agencies, OEMs, and UAV users. UAVs flying in the national airspace must be capable of sensing and identifying the world around them, deciding upon potential collision risks, and taking appropriate actions to avoid such collisions.

However, UAS have emerged as a viable, operational technology for potential civil and commercial applications in the National Airspace System (NAS). Although this new type of technology presents great potential, it also introduces a need for a thorough inquiry into its safety impact on the NAS. The FAA, ICAO, and other regulatory agencies, worldwide, are stipulating requirements for safe UAV flight and their integration into the national airspace, which may be summarized in *one* statement: “UAVs should fly as if there were a human pilot onboard.”

Sense and avoid (SAA) remains one of the key enabling capabilities required for the safe airspace integration of UAS into the global airspace system. Very little has been done to satisfy the technical and operational requirements necessary for allowing the unfettered access to civil airspace, domestically and internationally, projected to be needed by the U.S. DoD and the civil/commercial market. Although standard organizations like RTCA and EUROCAE are focusing on the problem,

the current lack of specific UAS standards is clearly slowing the progress of the defense and commercial development of this exploding technology. In addition, as it relates to SAA, the impact of the lack of an SAA-focused “program of record” within one or all of the federal agencies and the associated funding that will be required and/or the lack of existing technical capability to move toward an autonomous solution believed by many to be necessary for complete, unfettered access to the national airspace appears to be slowing progress. Regardless, it looks like 2013 is the turning point year as roadmaps have been published for integration of unmanned aviation into the national airspace.

This section of the handbook introduces the reader to those sensing, processing, and control-enabling technologies that constitute the “sense-detect-and-avoid” technical foundations. Requirements, technologies, and future trends in sense, detect, and avoid are covered thoroughly.

► *Development of a Regulatory Safety Baseline for UAS Sense and Avoid* by Oztekin and Wever presents a systems-level approach to analyze the safety impact of introducing UAS into the NAS. Utilizing Safety Management Systems (SMS) principles and the existing regulatory structure, a methodology is outlined to determine a regulatory safety baseline for a specific area of interest regarding a new aviation technology, such as UAS Sense and Avoid (SAA). The presented methodology is then employed to determine a baseline set of hazards and causal factors for the UAS Sense and Avoid problem domain and associated regulatory risk controls.

► *Achieving Sense and Avoid for Unmanned Aircraft Systems: Assessing the Gaps for Science and Research* by Davis and Cook focuses on the efforts by the Office of the Under Secretary of Defense (OUSD) for Acquisition, Technology, and Logistics (AT&L) to make progress in solving the SAA problem by the establishment of the SAA Science and Research Panel (SARP) in February 2011. The SARP consists of a panel of experts in technologies necessary to provide UAS with the ability to sense and avoid other aircraft. The panel’s primary purpose is to promote partnerships between the U.S. DoD and the broader academic and scientific community on UAS NAS Integration science and research initiatives in order to identify open questions and challenges in research and science efforts that must be addressed to provide UAS with an effectual SAA capability. Further, this chapter describes the methods of identifying and closing the science and research gaps that have been identified to date.

► *Automatic Traffic Alert and Collision Avoidance System (TCAS) Onboard UAS* by Meyer, Gottken, Vernaleken, and Scharer reports on the SAA capabilities of the Barracuda UAS demonstrator, on which Cassidian installed a cooperative collision avoidance system based on Traffic Alert and Collision Avoidance System (TCAS). The demonstration is intended as a risk mitigation measure to support future UAS development efforts. The demonstration steps involve laboratory tests with real equipment in a closed-loop demonstration and the automatic execution of a collision avoidance maneuver in-flight. The in-flight demonstration takes place in segregated air space involving the Barracuda demonstrator platform and a real intruder. The chapter outlines the setup of the cooperative collision avoidance

system demonstrator, including the interface with the flight control system of the Barracuda and the control authority granted to the cooperative collision avoidance system demonstrator. It summarizes the Human-Machine Interface (HMI) layout and situation awareness provided to the UAS operator and illustrates how the potential loss of data link connection is covered by the system design. The development process is detailed, including requirements definition, validation, and verification steps as well as hardware-in-the-loop demonstration in support of the in-flight demonstration. It illustrates the demonstration scenarios utilized in the flight demonstration and the results achieved. Conclusions are drawn regarding the potential of such cooperative collision avoidance systems based on TCAS, the operational implications, and the certification aspects to be solved.

► *Test Flights to Demonstrate Effectiveness of a Ground-Based Detect and Avoid Integration Concept* by Udovic, de Jong, and Vielhauer presents and reports on the VUSIL program (*Validierung von UAS zur Integration in den Luftraum*) that has developed a concept for integrating UAS into uncontrolled nonsegregated airspace, which is also used by manned civil aviation. The surrounding traffic is indicated on a display in the pilot ground control station (GCS), based on radar data provided by the Air Navigation Service Provider (ANSP). In addition, the pilot is supported by means of a “detect and avoid” tool in detecting potential conflicts. This tool shows conflicts and possible avoidance maneuvers on a separate display. To validate the integration concept, two flight campaigns with two different UAS (helicopter and fixed-wing UAS) and several intruders were conducted. In the first flight campaign, the intruders for the real flying UAS were simulated. In the second flight campaign, the intruder was a manned helicopter. The concept has been validated by the results of both flight campaigns and by a safety analysis. The latter has addressed demonstrating the equivalent level of safety (ELOS) of “see and avoid” in manned aviation and “detect and avoid” as developed in the VUSIL program.

► *Scalable RADAR-Based Sense-and-Avoid System for Unmanned Aircraft* by Moses, Rutherford, and Valavanis presents one possible solution for addressing the midair collision problem in addition to increasing the levels of autonomy of UAS beyond waypoint navigation to include preemptive sensor-based collision avoidance. The proposed solution goes beyond the current state of the art by demonstrating the feasibility and providing an example of a scalable, self-contained, RADAR-based, collision avoidance system. The RADAR hardware and collision avoidance algorithms are presented in detail. The technology described herein can be made suitable for use on a miniature (maximum takeoff weight <10 kg) UAS platform. This is of paramount importance as the miniature UAS field has the lowest barriers to entry (acquisition and operating costs) and consequently represents the most rapidly increasing class of UAS.

► *Assessment of Detect and Avoid Solutions for Use of Unmanned Aircraft Systems in Nonsegregated Airspace* by Verstraeten, Stuij, and Birgelen summarizes and assesses the most promising candidate solutions for Detect and Avoid (DAA) for use of UAS in nonsegregated airspace against a set of DAA requirements. A DAA solution is the combination of the sensor suite, the avoidance algorithms, and the method of operation. The functions of a DAA solution are collision avoidance and,

in uncontrolled airspace, separation provision. The chapter focuses on the detection of conflicting traffic by the sensor suite. The sensor suite needs to be able to detect different classes of conflicting traffic in varying environments. Requirements for DAA solutions have to be set, and DAA systems must then be developed to meet these requirements. ATM requirements for use of UAS in nonsegregated airspace have been drafted by EUROCONTROL, including a subset of requirements that are directly or indirectly of influence on the sensor suite used to DAA other traffic. This subset is used as baseline for the establishment of DAA requirements and expanded by the development of five additional generic requirements based on the main tasks of a DAA solution: (1) detection of other traffic, (2) tracking of other traffic, (3) assessing if there is a conflict, (4) determining which evasive maneuver is to be executed, and (5) executing the selected maneuver. Five candidate solutions are assessed against the requirements: a noncooperative solution, a cooperative solution, and three solutions mixing cooperative and noncooperative sensors. Overall it is concluded that it is a great challenge to develop a collision avoidance solution for UAS with a satisfactory level of safety. It is even more difficult to develop a DAA system that is capable of both collision avoidance and separation provision.

Collectively, this section informs but also alerts the reader about challenges that need to be overcome in order for UAS to function safely in the global airspace system. It is expected that standards will soon be introduced that will accelerate the development of sense, detect, and avoid systems.

Abstract

Unmanned Aircraft Systems (UAS) emerge as a viable, operational technology for potential civil and commercial applications in the National Airspace System (NAS). Although this new type of technology presents great potential, it also introduces a need for a thorough inquiry into its safety impact on the NAS. This study presents a systems-level approach to analyze the safety impact of introducing a new technology, such as UAS, into the NAS. Utilizing Safety Management Systems (SMS) principles and the existing regulatory structure, it outlines a methodology to determine a regulatory safety baseline for a specific area of interest regarding a new aviation technology, such as UAS Sense and

Avoid. The proposed methodology is then employed to determine a baseline set of hazards and causal factors for the UAS Sense and Avoid problem domain and associated regulatory risk controls.

75.1 Introduction

Unmanned Aircraft Systems (UAS) present great potential for civil and commercial applications in non-segregated airspace. Unrestricted UAS access into the National Airspace System (NAS) of the United States requires a thorough examination of its safety impact on the current operations in the NAS. In addition, a lack of regulatory guidance is considered an obstacle against achieving the full potential that UAS has to offer (FAA Flight Plan 2009–2013; Weibela and Hansman 2005). Recognizing the need for regulations and guidance material, aviation regulators initiated efforts to develop policies and establish requirements, procedures, and standards that will support UAS technology development and certification to enable safe operations of UAS. In the United States, Federal Aviation Administration (FAA) is working closely with the UAS community through RTCA Special Committee 203 (SC-203) to define the Minimum Aviation System Performance Standards (MASPS). Similarly, EUROCAE Working Group 73 (WG-73) is coordinating European efforts to deliver standards and guidance that will ensure the safety and reliability of unmanned aircraft missions operating in non-segregated airspace (EUROCAE 2009). These efforts are also being informally coordinated to facilitate harmonization (RTCA 2010).

The integration of UAS into the NAS presents various unique challenges, which will require novel and mostly platform-specific technological solutions. However, it can be argued that demonstration of airworthiness of these technologies will not present the only barrier to the introduction of UAS in the NAS. The difficulty that UAS is currently facing arises in obtaining authorization to enter and use civil airspace. This originates from the legitimate concern that unmanned aircraft may collide with other aircraft. Given the consensus that there will be no dedicated airspace for UAS operations, some authorities place the primary role of avoiding any collision between UAS and manned aircraft solely to the UAS. For all practical purposes, the UAS is, therefore, expected to have full responsibility to sense other aircraft and take effective evasive action. In this context, “see and avoid” or “sense and avoid” (SAA) emerges as one of the areas, which introduces new challenges and technologies compared to manned aviation and raises attention of regulators as well as the UAS manufacturers and future operators.

The body of current research projects on sense and avoid in the UAS domain mainly focuses on technology development and demonstration to provide a portfolio of workable technological solutions for the see and avoid concept. As compared to technology development, research on UAS safety risk analysis with an emphasis on SAA is still in its infancy. Most current UAS safety studies perform the risk analysis at a very detailed level based, on limited event or occurrence data. Examples of such research are preliminary functional hazard assessments (Hayhurst et al.

2007), event-based safety models of UAS (Weibel 2005), and simulation-based encounter models (Kochenderfer et al. 2008). However, a systems-level safety analysis focusing on the regulatory aspects of the SAA concept for UAS operations with an emphasis on future NAS access is lacking.

This study outlines a systems-level safety risk analysis framework for the SAA concept. Within the context of this study, a system-level perspective refers to looking at the air transport system as a whole from a high-level of abstraction as a system, or a system of subsystems. Thus, NAS may be considered as the system and UAS as a subsystem. In particular, the proposed framework presents a novel regulatory-based and integrated approach to understand hazards associated with midair collision risk and SAA and provides an analysis of current regulatory controls related to this topic. Utilizing Safety Management Systems (SMS) principles, the proposed framework establishes a systems-level safety analysis approach based on the FAA regulatory requirements to support the safe integration of UAS into the NAS with a particular focus on “sense and avoid.” The framework is intended to provide insight in risks and risk controls in current regulations when integrating new and complex technologies into the NAS while meeting the FAA’s SMS mandates. This study divides potential operations in the NAS into two main subgroups: flights conducted under Visual Flight Rules (VFR) and Instrument Flight Rules (IFR). The analysis and results presented here were developed for IFR operations.

In this study, the terms “hazard” and “causal factor” are used within the following context: A hazard is a condition, object, or activity with the potential of causing injuries to personnel, damage to equipment or structures, loss of material, or reduction of ability to perform a prescribed function. Hazards occur usually due to several causal factors. In general, hazards are considered at a higher level of abstraction, whereas causal factors are of a more detailed level.

The research presented here is based on the concepts and ideas that have been introduced in (Luxhøj et al. 2009, 2010; Oztekin and Luxhøj 2008, 2009). The next section provides background information on these concepts that are instrumental to the analysis, results, and discussion presented. Consequently, the proposed approach is illustrated by using a causal model for midair collision as the basis to develop a safety baseline for the SAA concept. Finally, an analysis on the SAA safety baseline is presented along with some concluding remarks.

75.2 Defining a Safety Baseline

In order to regulate a new technology that is to operate within an already-established and well-regulated infrastructure, such as NAS, without risking stifling its potential, one needs to understand existing safety criteria required to achieve the level of safety associated with the current operations. Within the context of the NAS, the existing safety criteria are the applicable aviation rules and regulations governing everyday manned flight and flight support and management operations of commercial or noncommercial nature. In this context, aviation rules and regulations act as controls

against potential risks and provide a baseline for safe operations in the NAS. More specifically, regulations are risk controls that constitute a safety baseline for all operations in the NAS. All aircraft operating in the NAS have to satisfy requirements set by Title 14 Code of Federal Aviation Regulations (14 CFR) and follow supporting guidance material. 14 CFR provides the risk controls for safe operations and establishes a baseline for all prospective operation in the NAS. For UAS technology and operations in nonsegregated airspace, current regulations (14CFR) apply. Thus, understanding the risk controls as defined by 14 CFR and outlining a baseline set of hazards and underlying causal factors that existing regulations control lie at the crux of the regulatory safety baseline concept (Oztekin and Lee 2011; Oztekin et al. 2011).

75.3 Challenge with the UAS

Limited availability of data on emergent nature of UAS operations introduces a challenge for the safety analysis and assessment of UAS operations. Conventional quantitative safety risk analysis techniques, essentially event-driven and largely built upon past experience and vast amount of historical data, may not provide adequate information for risk controls necessary for emerging technologies such as UAS. In the absence of operational data, it becomes very difficult to perform a systems-level safety analysis of UAS using conventional quantitative safety analysis methodologies. However, this situation can be considered as typical for any new technology with a limited accumulation of historic operational data. In this context, it is argued that a new approach may add valuable insight to understand the safety impact of emerging UAS operations on NAS. This new approach should not rely on historic data about the new technology, therefore would not be hindered by the lack of it. Furthermore, it should also assume a systems-level perspective while performing the safety analysis. Thus, a successful attempt to understand the safety impact of emerging UAS operations of civil/commercial nature can be achieved through a higher systems-level approach, which takes into account the problem domain as a whole. In this case, the problem domain in question is the NAS and it should be treated as a single complex system. Subsystems, such as Air Traffic Control (ATC), Airmen, Aircraft, Flight Operations, and Airspace constituting the NAS are interdependent and their interactions determine safety that permeates the whole system and defines minimum mandatory safety requirements for the NAS. These minimum set of requirements constitute a mandatory baseline for conducting safe operations in the NAS. A systematic approach for the identification of such a safety baseline will provide guidance to understand systems-level safety impact of a new technology, such as UAS, onto the NAS. Utilizing the safety baseline concept, Regulatory-based Causal Factor Framework (RCFF) (Luxhøj et al. 2009, 2010; Oztekin and Luxhøj 2008, 2009; Oztekin and Lee 2011; Oztekin et al. 2011, 2012), provides such a systematic approach. Although RCFF is a new and intuitive approach, one should make it clear that it does not replace but complements existing qualitative and quantitative methods by recognizing existing rules and regulations

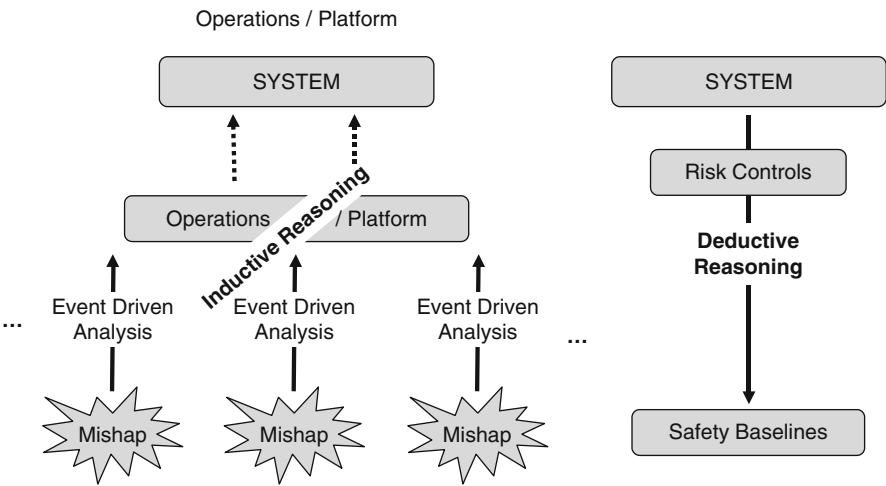

Fig. 75.1 Inductive reasoning versus deductive reasoning

covering the problem domain as key components of a system-level qualitative safety risk analysis framework.

Data-centric methodologies benefit from *inductive reasoning* when modeling the problem domain and the system in question. Although inductive reasoning has been successfully employed for data-rich systems for which extensive collections of case studies exist, due to similar reasoning outlined above, inductive frameworks may not be a good fit to understand and model new technology with limited accident/incident data. In this context, this study adopts *deductive reasoning* to understand the problem. Figure 75.1 illustrates deductive approach as compared to inductive reasoning. Deductive reasoning is a top-down approach, which puts emphasis on modeling the system based on its higher and more general components. When applied to the area of safety analysis, contrary to inductive approach where the analysis would be based on individual accident/incident cases and related data, a deductive approach will study the system as a whole and focus on its higher-level components and their interactions. Thus, a deductive approach will concentrate on understanding the safety minimums and, using an engineering term, determine the boundary conditions for conducting safe operations within the system.

75.4 Regulatory-based Causal Factor Framework

The study presented in this chapter utilizes concepts introduced by the RCFF. In very broad terms, RCFF is a qualitative, systems-level approach to safety assessment based on deductive reasoning to construct a safety baseline for operations in the

NAS in the United States. The basic concept relies on two fundamental premises: Aviation rules and regulations “Title 14 Code of Federal Regulations (14 CFR)” provide minimum mandatory requirements (i.e., risk controls) for safe operations in the NAS and various unrelated regulations interact to provide risk controls for hazards.

14 CFR can be considered as the culmination of efforts by the larger aviation community to provide an inherent minimum level of safety for every single operation to be conducted within the NAS. This notion of minimum safety is outlined as rules and requirements by the 14 CFR, and every aircraft in the NAS has to operate above the minimums of this mandatory safety baseline. In this sense, regulations act as minimum controls for potential risks associated with operating in the NAS.

However, individual regulations do not operate in a vacuum. When a specific aircraft or operation is concerned, a diverse collection of rules regulating different areas of the NAS interact to provide minimum requirements for safety as they apply to the specifics of the operation/aircraft in question. For example, issues related to certification of aircraft, aircraft engine, or propeller are regulated by 14 CFR Part 21, whereas airworthiness standards for the aircraft and its components are outlined in Parts 21–33. Subchapter D of 14 CFR focuses on the issues of certification and training of airmen and Subchapter E defines and partitions airspace, within which the proposed operation is set to take place. Thus, every single operation in the NAS, whether that particular type of operation has been conducted routinely for many years or it is the implementation of a new technology, is enveloped by a mandatory minimum safety baseline created collectively by various interacting rules regulating potential sources of various different hazards.

The notion of interactions between various parts of the 14 CFR to provide a minimum mandatory safety risk controls is a simple yet powerful idea, which brings forth a new approach to understand and study safety in aviation. This intuitive idea, in fact, borrows from the fundamental principle of the interdisciplinary field Systems Analysis. Formally, systems analysis is the dissection of a system into its component pieces for purposes of studying how those component pieces interact. In complex systems such as NAS, safety is the product of these interactions. However, a closer look at various current research efforts on UAS integration in the NAS reveals that such studies rarely explore potential interactions between their respective area of interest and various other components of the NAS, in a systematic fashion.

The regulatory-based approach of RCFF takes cues from FAA’s own Safety Management System (SMS) process. FAA Policy Document on SMS Guidance (FAA 2008) states that

...regulations will serve as risk control, if correctly applied in the context of the unique operational environments of service providers. Rule making process therefore should apply the concepts of safety risk management ...They [regulations] should identify hazards ... Compliance with the regulations would thus move beyond viewing them on as administrative requirements and into an environment where compliance entails effective control of clearly identified hazards. This would enhance the value of regulations as effective instruments of safety management. Regulations and subsequent oversight activities must be part of a strategy of risk control.

This understanding of regulation's role coincides with the fundamental concepts that RCFF is built upon; namely, use regulations as risk controls, identify hazards based on risk controls, identify causal factors underlying hazards, determine potential interactions between causal factors (thus between risk controls). Within the context outlined in the FAA SMS Guidance, RCFF can also be used as part of an exploratory risk-based rule-making process as a future research initiative, where the impact of the current regulations as risk controls are evaluated on the safety baseline and shortcomings are identified and corrected.

RCFF adopts a deductive, top-down approach to identify systems-level hazards and associated causal factors using regulations (i.e., 14 CFR) as risk controls. This approach is especially a good fit for providing a system-level qualitative safety risk analysis of emerging technologies, such as UAS, where limited availability of case data poses a challenge. RCFF also proposes a methodology to determine connections between potentially related causal factors, thereby creating an interlinked safety baseline. Ultimately, the RCFF safety baseline can be explored to understand the interactions between causal factors, as well as the dependencies between regulations (i.e., risk controls).

The outcome of the RCFF process is the safety baseline: hazards, causal factors, and regulations as risk controls. The context and scope of the safety baseline is determined by the set of regulations included in the RCFF analysis. Hazards and causal factors are identified based on risk controls outlined by these regulations. The scope of an RCFF analysis and the extent of the resulting safety baseline can be adjusted both depth-wise and breadth-wise in terms of detail and coverage.

Conceptually, the RCFF hierarchy closely follows the current regulatory structure. At the very top of this hierarchy, covering the entire NAS, Federal Aviation Regulations (14 CFR) provide minimum risk controls for safe operations. Thus, an RCFF top-down modeling process starts with regulations, or rather, it accepts regulations as input. However, risk controls can also be found beyond 14CFR: orders, technical manuals, guidance material, even prior safety studies are among the source materials that can be used as risk controls to initiate the process for an RCFF-based analysis.

The RCFF hierarchy including risk controls, hazards, causal factors, and linkages between them are stored in a database. A detailed discussion on the methodology used to construct an RCFF hierarchy based on the existing set of regulations and to populate the RCFF database is provided in Oztekin and Lee (2011) as part of a proof-of-concept study, where a potential utilization of the database is outlined. The high-level implementation of RCFF utilizes 14 CFR Parts as the basis to develop its hierarchy and the resulting system-level safety baseline (Oztekin and Lee 2011).

75.5 Approach to Construction of a Safety Baseline for SAA

Current regulations prescribe generic risk controls against midair collision and near midair collision risk. Under provisions that regulate operations near other aircraft, FAR Sect. 91.111 (b) states that “no person may operate an aircraft so close to

another aircraft as to create a collision hazard.” Additionally, FAR Sect. 91.113 (b) quoted below, explicitly uses language that includes the terms “see and avoid” and “well clear”: “When weather conditions permit, regardless of whether an operation is conducted under instrument flight rules or visual flight rules, vigilance shall be maintained by each person operating an aircraft so as to see and avoid other aircraft. When a rule of this section gives another aircraft the right-of-way, the pilot shall give way to that aircraft and may not pass over, under, or ahead of it unless well clear.” Obviously, the need for UAS to comply with the SAA concept in the NAS extends well beyond these two 14 CFR sections and a more detailed analysis of regulations with a particular emphasis on current risk controls for hazards related to (near) midair collision is needed.

See and Avoid can be used to assure separation from other aircraft and to avoid collisions in case separation failed. The SAA concept can be divided into two areas, namely, separation assurance and collision avoidance (Lacher et al. 2008). Separation assurance covers topics ranging from airspace structure and procedures to onboard alert systems such Traffic Collision Avoidance System (TCAS). On the other hand, collision avoidance entails the act of sensing and avoiding traffic conflicts or executing the collision avoidance maneuver once all preceding protective layers fail to provide the separation required. Most of the UAS SAA-related research focus on technology development that falls within the domain of collision avoidance. When it comes to understanding the safety impact of various interacting components of the NAS on the UAS SAA, there is more to it than sensor technology and algorithm development. Therefore a more integrated approach is needed to conduct a safety analysis of UAS SAA.

The objective of this study is to define a safety baseline for (near) midair collisions and the SAA concept. In this study, the RCFF concept has been applied to identify risk controls that the current regulations provide to mitigate the hazards and causal factors related with (near) midair collisions and the SAA concept. The result is a set of risk controls derived from existing regulations that will not only be applicable to manned operations in the NAS but will also provide a minimum, but possibly not sufficient set of risk controls to mitigate (near) midair collision risk for potential UAS operations. Operations conducted under instrument flight rules (IFR) and visual flight rules (VFR) have to be considered to develop a minimum mandatory baseline for SAA which applies to a wide range of traffic encounters under all operational environments. The current study is focused on IFR operations only. It is planned to expand the scope of the study by including VFR operations as part of future research.

In this context, the study presented in this chapter is composed of the following three phases:

1. Identify a baseline set of hazards and underlying causal factors for (near) midair collisions and the SAA concept. A causal model developed and validated specifically for this topic is used as the starting point to identify a baseline set of regulatory risk controls.
2. Identify risk controls for the causal factors. The risk controls are derived from existing regulations. The risk controls along with the hazards and causal factors constitute the safety baseline for preventing (near) midair collisions;

3. Perform an analysis of existing regulatory controls. The objective of the analysis is to quantify and understand the coverage that the identified regulatory risk controls provide to potentially mitigate the hazards and causal factors associated with the SAA safety baseline. Such an analysis also focuses on interactions between different domains of regulatory controls and helps to determine the coverage or gaps in regulatory material concerning regulating the new system, operation, etc.

Since the RCFF exists conceptually and not yet as a full-scale application, it is not possible to apply RCFF directly to the SAA concept, as the set of associated causal factors, hazards, and risk controls is not available yet. Instead, a detailed causal model developed specifically for the issue at hand provided a good starting point to identify a set of hazards and causal factors and associated regulatory controls that could form the safety baseline for the midair collision risk and SAA concept.

Considering that RCFF is a top-down framework, this “bottom-up” approach may seem inconsistent. However, the basic idea behind the RCFF is that regulations provide a set of risk controls for hazards (and causal factors); these regulations interact and their interactions can be identified through identifying dependencies between hazards (or between causal factors). The ultimate goal of RCFF is to determine risk controls and their interactions for the problem domain in question. Using existing knowledge about hazards and causal factors (i.e., a causal model) to identify the regulatory risk controls and their dependencies is still consistent with the RCFF concept.

75.6 Causal Model for Midair Collision

A causal model explains the functional and quantitative relationship between the various factors affecting risk in the Air Transport System (or NAS) or major parts of it. Generally speaking, such models allow the user to understand how, and how much, changes in a particular part of the ATS change the local as well as the overall safety risk of the ATS.

The hazards and causal factors in relation to (near) midair collision and SAA for IFR operations were identified by means of an existing causal model, which was developed as part of the Causal Model for Air Transport Safety (CATS) study (Ale et al. 2005; CATS 2008). The CATS study was a major effort sponsored by the Dutch government and developed by a consortium of parties including the NLR-Air Transport Safety Institute. The aim of CATS was to understand the causal factors underlying the risks of commercial air transport. It is an integrated quantitative causal model that can be used for safety risk analysis and assessment in civil air transport. The backbone of CATS consists of 33 generic accident scenarios. Each accident scenario was modeled as an Event Sequence Diagram (ESD), a flowchart which starts with an initiating event and progresses through pivotal event toward a set of possible outcomes (e.g., accident, incident, and continued flight). Each path through the flowchart is a scenario. Along each path, pivotal events are identified as

either occurring or not occurring. Fault Trees connect to the events in the ESD and represent the deeper, underlying causes of these events.

The causal model is composed of a qualitative as well as a quantitative part. The qualitative part is formed by the ESD and Fault Tree structure defining the accident scenario and causal pathways leading to different outcomes. In other words, event names and descriptions and the relationships between events, the model structure, constitute the qualitative model. The model was quantified using accident, incident, and occurrence data as well as expert judgments. It is crucial to maintain the context of the ESD and Fault Trees and avoid drastically revising language and model structure; otherwise the quantified model elements would no longer be valid.

This study utilizes (near) midair collision ((N)MAC) as the system-level hazard to define the SAA problem domain. (N)MAC as an event has been fully studied to understand underlying hazards and causal factors using available occurrence data from aviation safety databases. Analysis indicated that the SAA problem domain in the NAS can be decomposed into two main operational sub-domains, namely, operations conducted under instrument flight rules (IFR) and under visual flight rules (VFR). All potential scenarios need to be studied to fully cover the problem domain and develop a minimum mandatory baseline for SAA which applies to all encounters under all operational environments. The resulting safety baseline for SAA will not only be applicable to manned operations in the NAS but will also provide a minimum, but possibly not sufficient, set of risk controls to govern potential UAS-specific hazards.

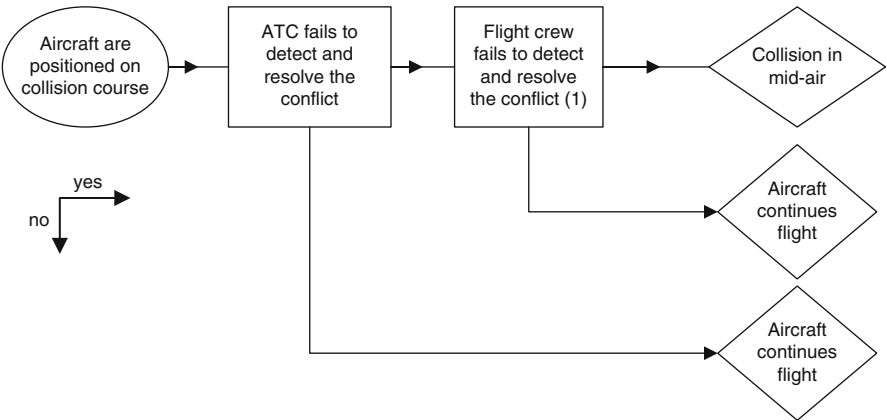

In this context, the study presented here is based on the MAC/NMAC encounters involving two aircraft-operated under IFR, thereby partially covering the operational domain of the NAS, as the current scope of this research.

The ESD for midair collision is one of the 33 generic accident scenarios modeled in CATS and describes generically hazards and causal factors in relation to (near) midair collision and SAA for IFR operations. The initiating event is “aircraft are positioned on collision course” and the end states are “collision in midair” or “aircraft continues flight.” The detailed specific or possible causes or contributing factors of the pivotal events in the ESD are added by Fault Trees underneath each pivotal event. The ESD models two layers of conflict detection and resolution: ATC and the flight crew (supported by, e.g., collision avoidance systems and SAA). The models were developed by a combination of retrospective and prospective analysis. The retrospective analysis consisted of a detailed and structured analysis of aviation accidents, which demonstrate typical accident patterns. The prospective analysis is based on engineering knowledge and aviation operational domain experts to identify potential hazards and hazardous combinations of causal factors that may have not (yet) resulted in an accident.

The ESD is representative for Part 121 operations with Part 25 aircraft and entails the encounter of two aircraft operating under IFR. It is composed of the initiating event and two pivotal events, and together with the associated Fault Trees, it has 29 intermediate events and 61 base events, see Fig. 75.2.

The ESD for midair collision is used as the basis to develop a minimum mandatory safety baseline for SAA. However since the scope of the midair collision

Accident type: mid-air collision.
Flight phases: initial climb, en-route and approach.
Initiating event: aircraft are positioned on collision course.

(1) This pivotal event includes the execution of ‘see-and-avoid’ principle and the response to a Traffic Collision Avoidance System alert.

Fig. 75.2 Event sequence diagram used to develop the components of the SAA safety baseline

model is limited to IFR, only the portion of the SAA safety baseline that covers IFR operations within the NAS is modeled by the study presented here.

The events constituting the Fault Tree supporting the ESD were originally defined using short descriptive texts which outline the intended scope of the event within the context of the accident scenario in question. The causal model elements were reviewed by a group of subject matter experts (SMEs) to identify causal factors and hazards that will constitute the safety baseline for SAA in the NAS. During the course of the review process, the original language used to describe the events was also revised by the SMEs so as to fit the terminology currently prevalent in the NAS. The review process resulted in 3 “system-level” hazards and 60 causal factors constituting the SAA safety baseline for IFR operations in the NAS.

The set of hazards and causal factors are generic and applicable to both manned and unmanned aviation operations. Some causal factors may have a minor different interpretation in case of unmanned aircraft, without affecting the cause-effect relationship. For example, some causal factors may refer to “pilot” which can be interpreted as “UAS operator” without changing its cause-effect relationship. However, the identified set of causal factors should be reviewed in more detail to identify potential missing causal factors related to UAS-specific operations and technology.

The original causal model for midair collision is composed of a qualitative as well as a quantitative part. The qualitative part is comprised of the ESD and Fault Tree structure defining the accident scenario and causal pathways leading to different outcomes. In other words, event names and descriptions and how they

are placed in the model structure constitute the qualitative model. The model was quantified using accident, incident, and occurrence data as well as expert judgments. Thus, the causal model for midair collision, as a whole, represents a certain probability distribution. However, if it becomes necessary to include additional UAS-specific hazards as part of a future study, associated Fault Trees may also need to be revised quantitatively resulting in a new probability distribution representing the revised causal model.

75.7 Approach to Identifying Regulatory Risk Controls for SAA

Once a baseline set of hazards and causal factors was determined from the causal model, the next step was the identification of existing regulations that provide potential controls to prevent and mitigate hazards and causal factors related to midair collision and SAA for IFR operations in the NAS.

The SAA safety baseline presents a simple hierarchical structure. The regulation that explicitly mentions SAA as a safety requirement for conducting operations in the NAS (i.e., FAR Sect. 91.113-b) is at the very top of this hierarchy. Hazards identified for SAA branch out from Sect. 91.113(b), and individual causal factors are listed for each hazard. In this context, risk controls for hazards are identified through individual causal factors. In other words, risk controls are identified for individual causal factors, thus their connections to hazards are indicated through causal factors. Regulations (i.e., 14 CFR) also present a hierarchical structure. Fourteen CFR is grouped into subchapters. Subchapters are partitioned into Parts and Parts into subparts. Subparts are divided into sections. Specificity of information that a regulation provides increases as one moves toward the next lower level in the regulatory hierarchy. Since the safety baseline is comprised of a collection of very detailed causal factors, pertaining risk controls should also present a level of detail that is comparable with the information content of the safety baseline. Thus, for each causal factor, specific 14 CFR sections were identified as potential risk controls. Notional representation of the SAA safety baseline hierarchy based on the structure of the NMAC ESD is illustrated in Fig. 75.3.

Due to resource constraints, this study limited the scope of the risk control identification to 13 FAR Parts representing three major subchapters of 14 CFR as sources for potential risk controls. The FAR Parts and corresponding subchapters included in this study are listed below:

Subchapter C – Aircraft:

Part 21 – Certification Procedures for Products and Parts

Part 23 – Airworthiness Standards: Normal, Utility, Acrobatic, and Commuter Category Airplanes

Part 25 – Airworthiness Standards: Transport Category Airplanes

Part 27 – Airworthiness Standards: Normal Category Rotorcraft

Part 33 – Airworthiness Standards: Aircraft Engines

Part 34 – Fuel Venting and Exhaust Emission Requirements for Turbine Engine Powered Airplanes

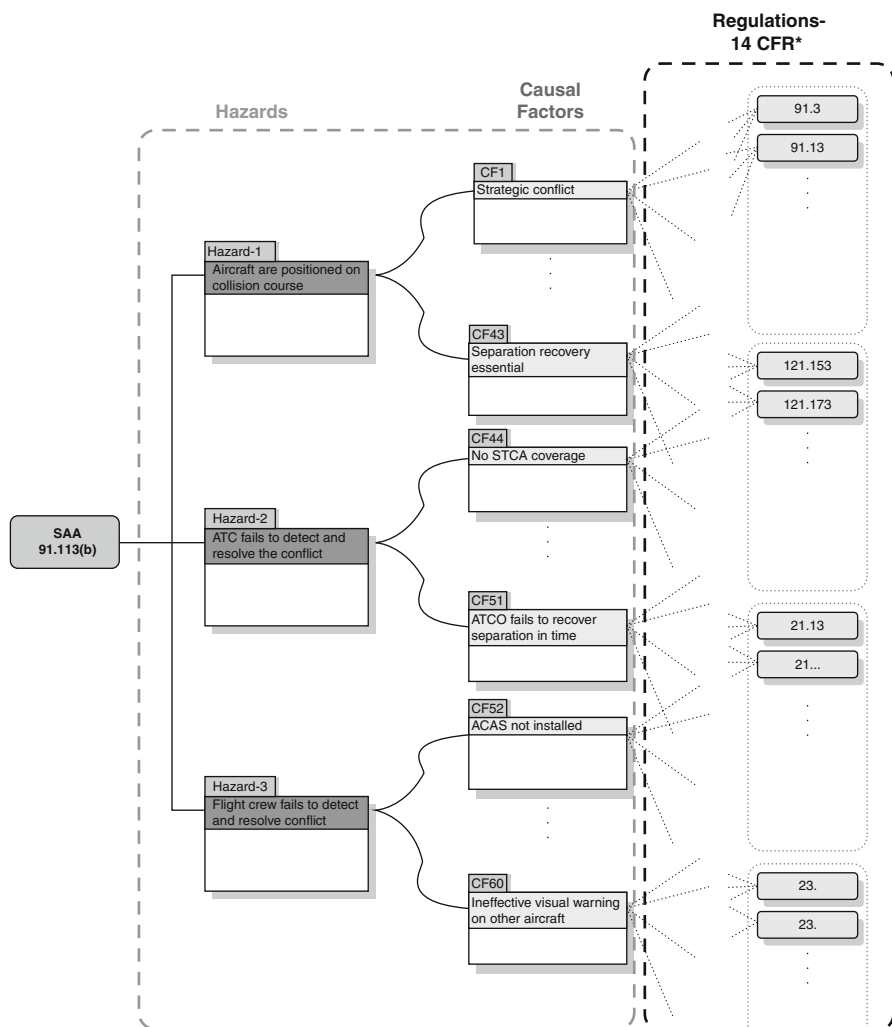

Fig. 75.3 Notional illustration of the SAA safety baseline

Part 43 – Maintenance, Preventive Maintenance, Rebuilding, And Alteration

Subchapter D – Airmen:

Part 61 – Certification: Pilots, Flight Instructors, and Ground Instructors

Part 65 – Certification: Airmen Other Than Flight Crewmembers

Subchapter F – Air Traffic and General Operations:

Part 91 – General Operating and Flight Rules

Subchapter G – Air Carriers and Operators for Compensation or Hire: Certification and Operations:

- Part 121 – Operating Requirements: Domestic, Flag, And Supplemental Operations
- Part 135 – Operating Requirements: Commuter and On Demand Operations and Rules Governing Persons OnBoard Such Aircraft
- Subchapter H – Schools and Other Certificated Agencies:*
- Part 145 – Repair Stations

Note that the Parts listed above are some of the most prominent rules regulating aviation safety. Thus they provide extensive coverage in terms of risk controls for the NAS.

The process of identifying section-level risk controls for the identified hazards and causal factors involved multiple knowledge elicitation sessions with Subject Matter Experts (SMEs), with extensive background and expertise on aviation-related rulemaking, regulatory oversight, as well as operations. The sessions were moderated in a structured manner with the participation of multiple SMEs and an aggregate approach was employed to determine potential risk controls for individual causal factors across the 13 FAR Parts mentioned before. The data sample provided below in Table 75.1 illustrates the type and content of the data that has been compiled as the result of the elicitation process to identify risk controls for the SAA safety baseline.

Table 75.1 Risk controls identified for CFs #4 and #5 of Hazard #1. Only risk controls from Parts 65, 91, 121, and 135 are shown

| Hazard #1 | | | | | | | |
|---|---|---|--------------------------------|------------------|--|---------------------------|--------------|
| Aircraft are positioned on collision course | | | | | | | |
| | | | Risk controls | | | | |
| # | Causal factor | Definition | Part 91 | Part 135 | Part 65 | Part 121 | Part 61 |
| 4 | Inadequate strategic surveillance picture | The radar picture is inadequate to allow the Planning Controller to identify the pre-tactical conflict, e.g., incomplete traffic picture, picture with overlapping labels, or too much traffic for the display system | N/A | 135.18 | N/A | 121.357, 121.356, 121.360 | N/A |
| 5 | Inadequate flight plan data | Flight plan data is inadequate to allow the Planning Controller to identify the pre-tactical conflict, e.g., incorrect flight plan, flight plan insufficient to identify conflicts, flight plan strips obtained too late, or aircraft not following flight plan | 91.173, 91.111, 91.113, 91.123 | 135.345, 135.347 | 65.31, 65.33, 65.35, 65.37, 65.39, 65.45, 65.49, 65.50 | 121.395 | 61.87, 61.93 |

75.8 Analysis of Regulatory Risk Controls

This section presents the analysis of risk controls that were identified according to the methodology outlined above. First, the identified risk controls are analyzed from a higher systems-level perspective and its interaction with the NAS as a whole. Next, individual causal factors are analyzed to achieve a more in-depth understanding of the SAA safety baseline and its interaction with the NAS.

The reader should bear in mind that the scope of this study includes only the 13 FAR Parts listed in the preceding section and this fact should be taken into consideration when reviewing the result presented here. Even though a set of regulations were identified in this study as applicable risk controls for a certain hazard or causal factor, there is still a need for further analysis to determine the extent to which these controls mitigate the risks associated with that hazard.

Potential system-level hazard sources underlying midair collision can be analyzed according to the Hazard Classification and Analysis System (HCAS) (Oztekin and Luxhøj 2008; Luxhøj et al. 2009, 2010). HCAS identifies four system-level hazard sources, namely, Aircraft, Operations, Airmen, and Environment, whose interactions impact any potential hazards within the context of the NAS. These system-level hazard sources are also in line with the 14 CFR subchapters.

The causal factors identified in the SAA safety baseline can be allocated to these four system-level hazard sources. Likewise the risk controls derived from the review of 13 FAR Parts can be categorized under the four main categories of interest: Aircraft, Airmen, Operations, and Certification. The distribution of risk controls over those categories is shown in Fig. 75.4 for the SAA safety baseline (IFR case only).

Note that Fig. 75.4 indicates a distribution over the total count of risk controls identified according to the methodology outlined in this chapter. Thus, 31 % of the risk controls identified originates from Part 91 corresponding to Air Traffic Control and General Operations Rules. Risk controls from Operational Certification–related Parts, namely, Parts 121 and 135, also provide 31 % of all the risk controls identified.

Fig. 75.4 Distribution of risk controls for the SAA safety baseline according to the four major categories of interest (IFR only)

While 28 % of the risk controls are Airmen related, only 6 % can be attributed to Aircraft certification–related regulations. Thus, one can conclude that, for the SAA safety baseline, existing rules regulating operational aspects of the NAS provide the majority of controls, whereas only a minority of the controls originate from current regulations governing aircraft certification. However, one should bear in mind that the analysis presented throughout this chapter is based only on the 13 Parts included in this study.

The SAA safety baseline includes three system-level hazards, namely, Loss of Separation, Failure by ATC, and Failure by Flight Crew. The hazard “Loss of Separation” represents the case that two aircraft are on a collision course/lost separation. The hazard “Failure by ATC” depicts a situation where, given that loss of separation occurs, ATC fails to detect and resolve the conflict. The hazard “Failure by Flight Crew” refers to a case where, given that Loss of Separation and Failure by ATC have occurred, the flight crew fails to detect and resolve the conflict. The distribution of risk controls identified for these three hazards over the categories Aircraft, Airmen, Operations, and Certification are shown in Figs. 75.5–75.7, respectively.

The system-level hazard “Loss of Separation” contains 43 causal factors for which 11 separate FAR Parts provide risk controls. Figure 75.5 indicates that 36 % of the risk controls for Loss of Separation are provided by sections of Part 91, which provides ATC and general operations rules for the NAS. Operation certification–related Parts (i.e., Parts 121 and 135) and Airmen-related Parts (61 and 65) each provide 26 % of the risk controls for Loss of Separation respectively. Considering how closely the hazard is associated with operational and ATC-related issues, this sort of a distribution is to be expected. Regulations such as Parts 21, 23, and 25 that govern aircraft and component certification provide a small portion of the risk controls (7 %) for the identified hazards/causal factors.

The system-level hazard “Failure by ATC” has eight causal factors. Three separate FAR Parts provide risk controls as shown in Fig. 75.6. Half of the risk controls are provided by Parts 61 and 65, whereas 44 % of the controls come from

Fig. 75.5 Distribution of risk controls for the system-level hazard loss of separation

Fig. 75.6 Distribution of risk controls for the system-level hazard failure by ATC

Fig. 75.7 Distribution of risk controls for the hazard failure by flight crew

operation certification–related regulations. Only 6 % of the controls originate from Part 91.

Figure 75.7 presents the distribution of the risk controls for the third and the last system-level hazard constituting the safety baseline: Failure by Flight Crew. Nine causal factors were identified under this hazard and three FAR Parts provide potential risk controls. Among the 13 FAR Parts included in the scope of this study, only Parts 91, 121, and 135 provide risk controls for the causal factors grouped under this hazard. Operation certification–related regulations, namely, Parts 121 and 135, present the overwhelming majority of the risk controls, whereas Part 91 provides only 11 % of the total controls for this hazard and underlying causal factors.

A more detailed analysis of the risk controls can also be performed at the level of causal factors constituting the SAA safety baseline for the IFR operations. Such an analysis is presented below with a particular emphasis on individual causal factors.

Fig. 75.8 Top causal factors in the SAA safety baseline with the highest number of 14 CFR sections acting as risk controls

Certain causal factors in the safety baseline receive relatively better coverage by 14 CFR sections acting as potential risk controls. The top five causal factors for which existing regulations provide the highest number of risk controls are presented in Fig. 75.8.

The causal factor “Loss of Communication” is defined as “communication between ATC and pilot is lost during a conflict in uncontrolled airspace due to technical failure or human error.” Forty-six regulatory sections are identified as potential risk controls for this factor. A closer look at these risk controls reveals that 10 different FAR Parts out of the 13 investigated by this study provide controls for mitigating or preventing potential risk associated with loss of communication. However, note that even though a set of regulations was identified as applicable risk controls for this causal factor, there is still a need for further analysis to determine that these controls fully mitigate the risks associated with the factor.

The lower end of the coverage spectrum, on the other hand, provides a glimpse of causal factors for which review regulations presents little to no coverage on the identified hazards/causal factors. Table 75.2 shows the causal factors that are potentially covered by only one or no section-level risk control.

Figure 75.7 and Table 75.2 help by illustrating the value of the proposed approach, which provides an analysis regarding to what extent the hazards and causal factors identified for the SAA are covered by existing regulations. Thus, the proposed approach facilitates the identification of gaps in the current regulations for a specific problem domain, in this case for SAA. These gaps indicate areas of potential risk within the SAA baseline, for which current regulations do not provide proper mitigation.

From the study results, the coverage and gaps in the current regulatory structure as potential risk controls for the identified hazards and causal factors related to midair collisions and SAA are presented in Figs. 75.9 and 75.10.

Table 75.2 SAA safety baseline causal factors with the least coverage in terms of risk controls that existing regulations provide

| Causal factor | Description | # of risk controls |
|--|---|--------------------|
| Other aircraft effectively invisible | The other aircraft cannot be seen from the cockpit. (other aircraft may not be visible due to glare, weather (rain), obstruction of view by wings, window frame, poor contrast, etc.) | 0 |
| Inadequate tactical surveillance picture | The radar picture is inadequate to allow the Tactical Controller to maintain separation in a plannable conflict, e.g., incomplete traffic picture or picture with overlapping labels | 0 |
| ATCO failure to recognize conflict | Tactical Controller obtains adequate flight information but fails to recognize the conflict | 1 |
| Conflict due to military traffic | Unauthorized penetration of civilian controlled airspace by military traffic | 1 |
| Weather induced level bust | Vertical deviation resulting from weather conditions | 1 |
| Level bust results in conflict | Given a level bust occurs, the aircraft has separation infringement with another aircraft | 1 |
| ACAS avoidance invalidated by other aircraft | ACAS avoidance action is canceled out by incorrect action from the other aircraft | 1 |
| Flight crew fail to observe visible aircraft in time | Pilots fail to observe visible aircraft in time to make avoidance action | 1 |
| Pilot fails to take avoidance action in time | Pilots fail to make appropriate avoidance action, having observed the other aircraft with sufficient time to take the necessary action | 1 |
| Visual avoidance invalidated by other aircraft | Pilot's response is canceled out by opposing maneuver from the other aircraft | 1 |
| Ineffective visual warning on other aircraft | Pilots on the conflicting aircraft fail to resolve the conflict using see and avoid techniques, given similar failure on the subject aircraft | 1 |

Figure 75.9 presents 14 CFR sections that act as potential risk controls for causal factor #16 “loss of communication between ATC and pilot.” Within the hierarchy of the SAA safety baseline, CF16 is associated with Hazard #1 “loss of separation.” A closer inspection of Fig. 75.10 shows that CF16 is controlled by four distinct grouping (i.e., subchapter) of 14 CFR Parts. In other words, to address hazards related to loss of communication between ATC, the applicability of the individual sections covering these four separate domains of interest need to be investigated to demonstrate that a baseline level of safety is achieved regardless of whether the operation is manned or unmanned. Not all the causal factors of the SAA baseline are

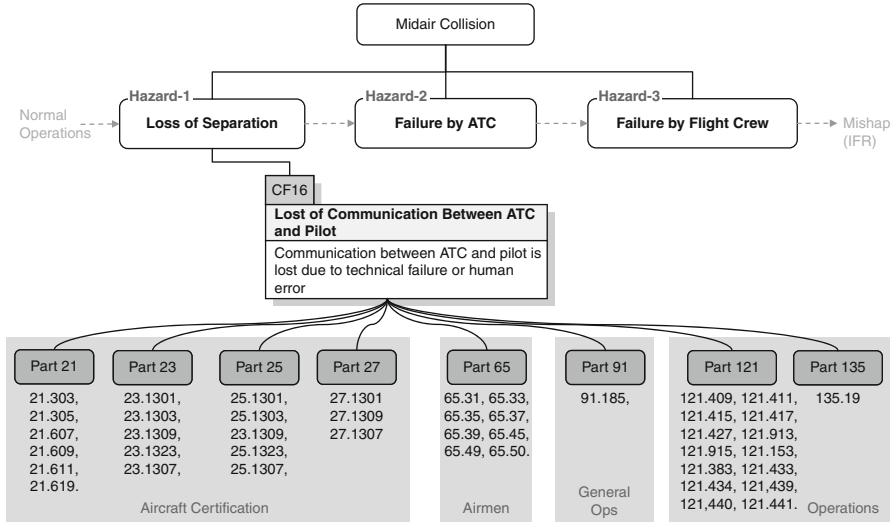

Fig. 75.9 Section level regulatory risk controls identified for CF 16 in the SAA safety baseline

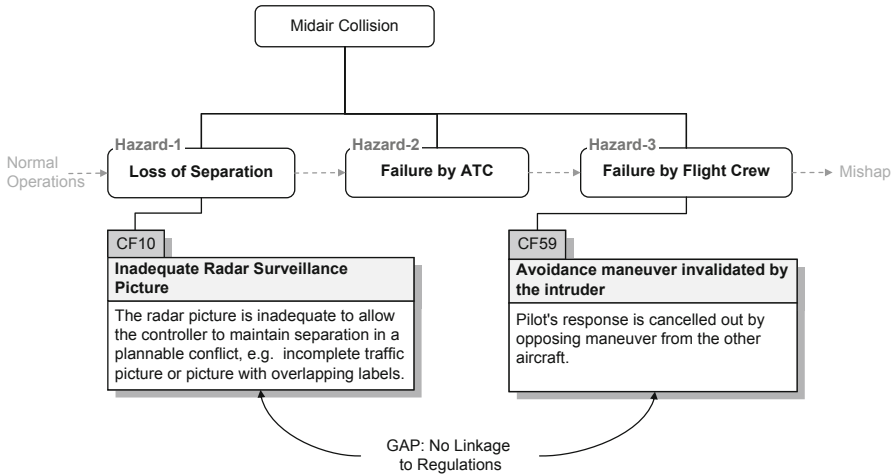

Fig. 75.10 Potential gap in the existing regulations. No risk controls were identified for CF 10 and CF 59 in the SAA safety baseline

covered by an existing regulation acting as risk control, indicating a potential gap in the existing regulatory structure. For example, Fig. 75.10 provides two causal factors in the IFR SAA baseline, for which no regulatory risk controls were identified from within the 13 FAR Parts included in this study.

75.9 Concluding Remarks

Ongoing efforts to develop rules and requirements for UAS SAA underlines the need to understand to what extent existing regulations cover SAA related hazards. In this context, this study presents a methodology that can be used to define a minimum set of risk controls based on current rules and regulations to control or mitigate hazards and causal factors related to a certain operation or technology. The value of the presented approach lies in the structured analysis to identify the existing regulatory coverage for the risks present in a certain domain. In particular, it provides an analysis regarding the extent to which hazards and causal factors identified for that domain are covered by existing regulations. Thus, the proposed approach facilitates the identification of gaps in the current regulations for a specific risk or domain.

The regulatory-based methodology (Regulatory-based Causal Factor Framework, RCFF) was applied to the domain of midair collision and See and Avoid (SAA). The study provided the identification of a set of hazards and underlying causal factors for (near) midair collision and SAA concept based on a causal model. The midair collision scenario was modeled as an Event Sequence Diagram with underlying Fault Trees that further detail the underlying causal factors within the context of IFR-only commercial air transport operations. The causal model provided an initial set of hazards and causal factors for the near midair collision and the SAA concept, which was consequently employed to identify a minimum set of risk controls for the SAA baseline using current rules and regulations.

The resulting SAA safety baseline is comprised of three hazards, 60 underlying causal factors, and a large number of applicable regulatory risk controls. While studying aviation regulations as potential risk controls for the identified hazards and causal factors, an initial set of FAR Parts representative of all major areas of interest in 14 CFR was selected and included in the scope of this study. Risk controls defined in the reviewed set of regulations were identified at the sections level. Finally, a systems-level analysis of risk controls was presented along with a more detailed look at the distributions with respect to the individual hazards and causal factors within the SAA safety baseline.

Although this study concentrates on the SAA problem domain, the proposed approach, coupled with the RCFF concept, is intended to be used for system-level safety analysis and assessment of other core areas of interest such as command, control, and communication for UAS integration into the NAS.

The outcome and the potential value of this study can be surmised as follows:

- It presents a structured approach to determine existing regulatory risk controls in the NAS for hazards related to a specific problem domain, e.g., a new technology. It is argued that the identified risk controls along with the set of hazards constitute a baseline for conducting safe operations within the context of that specific problem domain. This safety baseline establishes potential safety minimums that apply to all current and emergent operations, such as UAS.

Consequently, the safety baseline concept can be used to outline an initial set of safety provisions that apply to the UAS within the context a particular area of interest such as SAA in the NAS.

- It identifies a preliminary set of current risk controls for SAA in the NAS based on a selected group of aviation rules and regulations. The resulting analysis of the risk controls indicates to what extent the current regulations act as risk controls for hazards associated with the SAA in the NAS. This analysis can also be used to provide an understanding of potential gaps in the existing regulatory structure by identifying the hazards and underlying causal factors for which current regulations provide potentially no or limited mitigation. Since it is argued that the same set of risk controls apply to all operations in the NAS, they may also provide a roadmap for outlining safety provisions for the UAS within the context for which the risk controls were identified.

Abstract

Sense and avoid (SAA) remains one of the key enabling capabilities required for the safe airspace integration of unmanned aircraft systems (UAS) into the global airspace system. Very little has been done to satisfy the technical and operational requirements necessary for allowing the unfettered access to civil airspace, domestically and internationally, projected to be needed by the Department of Defense and the civil/commercial market. Although standard organizations like RTCA and EUROCAE are focusing on the problem, the current lack of specific UAS standards is clearly slowing the progress of the defense and commercial development of this exploding technology. In addition, as it relates to SAA,

the impact of the lack of a SAA focused “program of record” within one or all of the federal agencies and the associated funding that will be required and/or the lack of existing technical capability to move toward an autonomous solution believed by many to be necessary for complete, unfettered access to the NAS appears to be slowing progress.

The chapter entitled “Achieving Sense and Avoid for Unmanned Aircraft Systems: Assessing the Gaps for Science and Research” focuses on the efforts by the Office of the Under Secretary of Defense (OUSD) for Acquisition, Technology and Logistics (AT&L) to make progress in solving the SAA problem by the establishment of the SAA Science and Research Panel (SARP) in February 2011. The SARP consists of a panel of experts in technologies necessary to provide UAS with the ability to sense and avoid other aircraft. The panel’s primary purpose is to promote partnerships between the DoD and the broader academic and scientific community on UAS NAS Integration science and research initiatives in order to identify open questions and challenges in research and science efforts that must be addressed to provide UAS with an effectual SAA capability.

This chapter describes the methods of identifying and closing the science and research gaps that have been identified to date.

76.1 Introduction

“Airspace is the biggest hurdle that unmanned has today,” recently declared Mr. Dyke Weatherington, the Deputy Director for Unmanned Warfare Portfolio Systems Acquisition in the U.S. Office of the Under Secretary of Defense (OUSD) for Acquisition, Technology and Logistics (AT&L) (Magnuson 2012). One of the key enabling capabilities needed to overcome this hurdle of integrating unmanned aircraft systems (UAS) into the global airspace system is providing them with the ability to sense and avoid (SAA) other aircraft. Much remains to be done to satisfy the technical and operational requirements necessary for allowing UAS unfettered access to civil airspace, domestically and internationally, projected to be needed by the public aircraft (such as the U.S. Department of Defense) and the civil/commercial market. Although multiple international standards organizations are focusing on the problem, the current lack of specific UAS standard is holding back the development of UAS. In addition, as it relates to SAA, the fact that a best-of-breed SAA solution has yet to emerge for either civil or military use and/or the lack of existing technical capability to move toward an autonomous solution believed by many to be necessary for complete, unfettered access to the NAS appears to be slowing progress.

UAS flight hours have dramatically increased over the last decade. For example, U.S. Department of Defense (DoD) UAS flight hours (see Fig. 76.1) have increased almost exponentially over that time frame (United States Department of Defense). Although the primary user of UAS since that time has been the DoD, many of the other federal agencies, state agencies, and law enforcement organizations have seen

Fig. 76.1 DoD UAS flight hours per year (From [United States Department of Defense](#))

the intrinsic potential value that UAS can bring to their respective organizations. A June 2011 U.S. Congress Budget Office report stated that “Over the next 10 years, the Department of Defense (DoD) plans to purchase about 730 new medium-sized and large unmanned aircraft systems based on designs currently in operation, while also improving the unmanned aircraft already in service. By the Congressional Budget Office’s (CBO’s) estimates, completing the investments in systems for which there are detailed plans will require about \$36.9 billion through 2020” (United States Congressional Budget Office 2011). In addition, the commercial potential for UAS is beginning to gain traction, pushing the market value of these unique aircraft systems into the multibillion dollar range over the next decade. A 2012 Congressional Research Service report states that the last 10–15 years has featured UAS advances in “navigation, communications, materials, and other technologies” (Gertler 2012). However, while the development of the airframe and sensor capability has improved dramatically over the last decade, the same cannot be said for the development of SAA. This chapter will discuss a process of assessing gaps in science and research in SAA technologies in order to assist in overcoming the technical hurdles that confront achievement of SAA.

76.2 Sense and Avoid Background

Before going farther into this chapter, some discussion is needed to adequately define the challenge of assessing the science and research gaps for SAA. In today’s environment manned aviation has been the driving force for the evolution of aviation worldwide. All of the existing airworthiness, manufacturing, and operational guidance and regulations have been created with the desire to better protect pilots,

passengers onboard the aircraft, and people on the ground. These regulations have been constantly maturing since the beginning of aviation. The goal of this evolution has been to continue making the system safer.

Along come unmanned aircraft (UA) and much of the learning process over the past 100 years seem to be in need of recreation. Why? In addition to the unique airworthiness, spectrum, and security considerations with having the cockpit outside the aircraft, UAS have challenges in complying with several of the 14 Code of Federal Regulations, Part 91, General Operating Rules. Specifically, compliance with the following critical rules comes to mind from the Federal Aviation Regulations (Title 14 of the U.S. Code of Federal Regulations):

Sec. 91.111 Operating near other aircraft.

No person may operate an aircraft so close to another aircraft as to create a collision hazard. ...

Sec. 91.113 Right-of-way rules: Except water operations.

General. When weather conditions permit, regardless of whether an operation is conducted under instrument flight rules or visual flight rules, vigilance shall be maintained by each person operating an aircraft so as to see and avoid other aircraft. When a rule of this section gives another aircraft the right-of-way, the pilot shall give way to that aircraft and may not pass over, under, or ahead of it unless well clear ... (United States Code of Federal Regulations).

There are many other airspace rules with which UAS will need to show compliance for unfettered airspace access, like weather avoidance, cloud clearance, ATC clearance compliance, and terrain avoidance. Furthermore, these same issues and problems must be solved to fly outside of U.S. domestic airspace existing in all non-U.S. regulatory guidance issued by the International Civil Aviation Organization (ICAO) and the European Aviation Safety Agency.

It has been argued that the Federal Aviation Regulations (FARs) could be rewritten with UAS in mind, but this option is not straightforward in the foreseeable future due, in part, to concerns raised in the manned aircraft community (The Sunday Telegraph 2007). In fact, the Aircraft Owners and Pilots Association (AOPA) has stated, “Unmanned aircraft and their operation should be certified to the same level of safety as piloted aircraft. Their operation in the National Airspace System should not have a negative impact on general aviation operations and should not require specially designated airspace for their operation” (Aircraft Owners and Pilots Association 2008). Furthermore, the Airline Pilots Association (ALPA) has been watching UAS development very closely and has stated that “The Air Line Pilots Association’s (ALPA’s) position is that no UAS should be allowed unrestricted access to public airspace unless it meets all the high standards currently required for every other airspace user” (Air Line Pilots Association 2011). Thus any discussion of forecasting future FAR changes will not be discussed in this chapter.

How then can UAS comply with existing airspace rules such as 14 CFR Part 91.113 and others, as the regulation specifically states “see” and avoid other aircraft? This is derived from a manned aircraft capability where the pilot has access to the windscreen and can “see” directly outside the aircraft and avoid any potential collisions. The FARs also require an aircraft to have the ability to give “right-of-way” to another aircraft. In fact, ICAO Circular 328 on UAS states,

“A fundamental principle of the rules of the air is that a pilot can see other aircraft and thereby avoid collisions, maintain sufficient distance from other aircraft so as not to create a collision hazard, and follow the right-of-way rules to keep out of the way of other aircraft. Integration of (UAS) may not require a change to the Standards, however, as (UAS) technology advances, alternate means of identifying collision hazards will have to be developed . . .” (ICAO 2011).

Therefore, compliance with current airspace rules point toward a manned aircraft capability. But because UAS do not have a pilot onboard and the technical capability needed to fill the void has yet to be developed, they cannot presently comply with the regulations as written. It is specifically because of this difference that the dialogue took on the title of “*Sense & Avoid*” instead of “*See and Avoid*.” In order to comply, UAS will be required to have the sensing capability to detect traffic using ground-based or aircraft-based sensing equipment, and avoid that traffic using collision avoidance algorithms, in a manner similar to the traffic collision and alerting system (TCAS) (the ICAO term is airborne collision avoidance system or ACAS) used widely in the commercial aviation sector and mandated equipage for air carriers and air taxis that carry in excess of 19 passengers. Lessons learned for addressing research gaps in UAS SAA should be drawn from the development of TCAS/ACAS.

76.3 Lessons Learned from TCAS

TCAS development was a lengthy and expensive process. A recent MITRE review of UAS collision avoidance stated that “By some estimates, TCAS took almost 20 years and expenditures of millions of dollars per year, just for the research and development. This estimate does not include the deployment cost of TCAS” (Lacher et al. 2008). The TCAS software logic for collision avoidance is owned by the federal government and is provided to industry for use in the development of the avionics to be installed onboard aircraft to ensure a specific level of safety and compatibility across platforms. Existing guidance states that any future UAS collision avoidance system be designed so as to integrate with existing collision avoidance systems like TCAS/ACAS. RTCA DO-304 “Guidance Material and Considerations for Unmanned Aircraft Systems” states that the SAA system, “. . . must be interoperable with existing NAS, ATC, and aircraft equipped with existing collision avoidance systems such as ACAS or TCAS” (RTCA DO-304 2007). It is important to point out that TCAS was designed for a human-in-the-loop implementation (with the pilot physically located in the aircraft) and was not designed for an autonomous maneuver. The TCAS system only alarms the pilot to a potential collision and, in some versions, may provide a vertical maneuver recommendation to the pilot to resolve the forecasted collision. TCAS is only compatible with cooperating traffic, in other words, traffic that have an operating transponder onboard. For these and other reasons, direct employment of TCAS technologies on UAS is challenging as explained in ICAO Airborne Collision Avoidance System Manual: “ACAS II was not designed with the intent of being

installed on tactical military (e.g., fighter aircraft) or unmanned aircraft. As such, there are technical and operational issues that must be addressed and resolved prior to installing ACAS II on these types of aircraft” (ICAO 2006). The operational issues uncovered by comparisons to TCAS have helped to inform many of the research gaps for which closure is necessary to achieve UAS SAA.

76.4 Progress in SAA Development for Unmanned Aircraft

The journey of UAS SAA development has been epitomized by starts and stops, lack of funding, and, most importantly, the lack of defined operational/technical requirements. RTCA Special Committee 203 on Unmanned Aircraft Systems (SC-203) and its European counterpart, EUROCAE WG-73, have been working diligently to develop these requirements. However, the complexity of the challenge and the demand for near-term airspace access for UAS have in some cases led developers to pursue solution sets that on the one hand may contribute to problem resolution but on the other may not be “certifiable” by the regulatory authority. To move the process forward, the FAA supplemented the RTCA SC-203 efforts with SAA workshops. These SAA workshops have done important work in decomposing the SAA problem into defined subfunctions. One of the critical outcomes was the definition and functional decomposition of SAA. From the FAA Workshop Final Report (2009):

Definition of Sense and Avoid

Sense and Avoid (SAA) is the capability of a UAS to remain well clear from and avoid collisions with other airborne traffic. SAA provides the intended functions of self-separation and collision avoidance as a means of compliance with the regulatory requirements to “see and avoid” compatible with expected behavior of aircraft operating in the airspace system. As depicted in (Fig. 76.2), a SAA capability performs the following sub-functions:

1. Detect – Determine presence of aircraft or other potential hazards.
2. Track – Estimated position and velocity (state) of a single intruder based on one or more surveillance reports.
3. Evaluate – Assess collision risk based on intruder and UA states.
4. Prioritize – Determine which intruder tracks have met a collision risk threshold.
5. Declare – Decide that action is needed.
6. Determine Action – Decide on what action is required.
7. Command – Communicate determined action
8. Execute – Respond to the commanded action.

While these activities have been ongoing, the OUSD (AT&L) Office of Unmanned Warfare has also been applying and aligning their resources toward technologies that may offer hope in resolving this difficult problem set. Every 2 years since 2003, OUSD (AT&L) has published a roadmap for DoD unmanned systems with an emphasis on gaining airspace access. Additionally, in 2011, OUSD (AT&L) released an updated version of the Unmanned Aircraft System Airspace Integration Plan which states “Without a clear regulatory path to (UAS) integration, DoD intends to leverage new technologies, procedures, and policies to maximize regulatory compliance” (DoD UAS 2011).

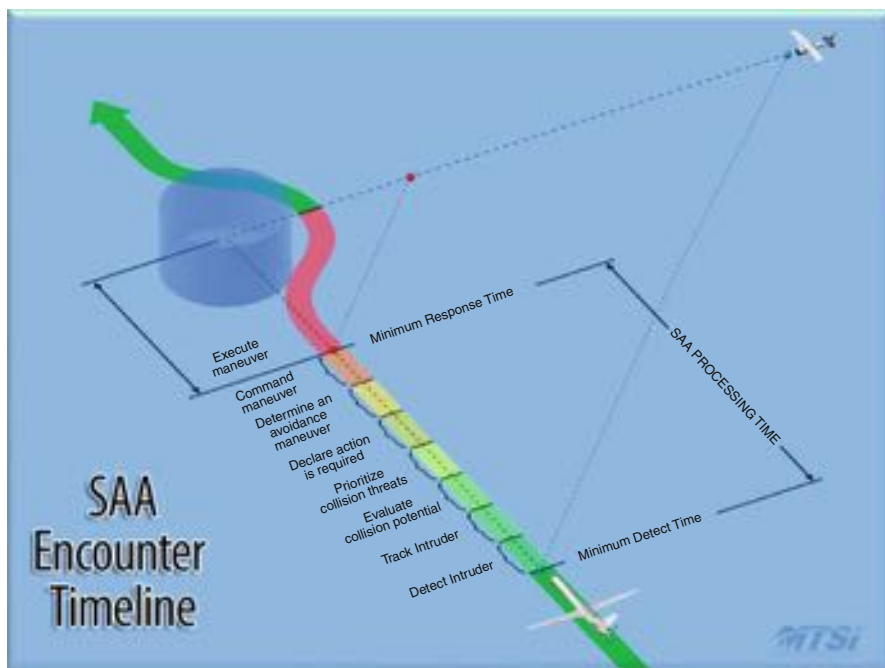

Fig. 76.2 SAA capability subfunctions (From FAA Workshop Final Report (2009))

As part of that leveraging intent, DoD has noted that science and research solutions to SAA are not being fully coordinated. The plan states that “Partnering with internal DoD and external stakeholders will be critical to success” (DoD UAS 2011). Specifically, the plan found that SAA research and development stakeholders and activities are not fully aligned. With shrinking budgets and the lack of progress being made toward tangible solutions OUSD (AT&L), in collaboration with the military services, recognized that a common forum was needed to bring the SAA science and research community together to understand common challenges and the various independent research activities ongoing that might address these open research questions.

76.5 The Sense and Avoid Science and Research Panel (SARP)

In response to this need, the OUSD (AT&L) established the SAA Science and Research Panel (SARP) in February 2011. The SARP consists of a panel of experts in technologies necessary to provide UAS with the ability to sense and avoid other aircraft. It advises the UAS Airspace Integration IPT chaired within OUSD (AT&L) and is currently cochaired by individuals outside of the DoD to provide a more independent perspective of the state of the research and science efforts.

Fig. 76.3 Means that the SARP employs to reach its goals

The panel's primary purpose is to promote partnerships between the DoD and the broader academic and scientific community on UAS NAS Integration science and research initiatives in order to identify open questions and challenges in research and science efforts that must be addressed to provide UAS with an effectual SAA capability. The DoD benefits from these partnerships through a broader range and depth of scientific expertise applied to challenges aligned with DoD priorities. The science and research community benefits from DoD advocacy of potential solutions and through evaluation, test, and implementation of viable approaches. These partnerships are critical to SAA science and research efforts to positively inform and influence OUSD (AT&L) strategic SAA decisions.

The SARP has four primary means at its disposal to promote partnerships and apply expertise to specific SAA challenges and capability gaps, shown in Fig. 76.3. The first of these tools are the panel meetings themselves. The panel consists of experts from DoD, government research facilities, federally funded research and development centers, academia, and systems engineering and technical assistance (SETA) contractors who are conducting SAA science and research. The panel meets three times per year to identify unanswered research questions and technical challenges (or "gaps") necessary to solve and implement SAA and determine how these gaps relate to OUSD (AT&L) SAA priorities. In order to classify the research gaps, the SARP uses a capability-based taxonomy developed from the eight core SAA functions displayed in Fig. 76.2. This taxonomy, originated in support of a OUSD (AT&L) SAA blueprint, describes ten core SAA capabilities – directly related to the Fig. 76.2 SAA functions – and seven crosscutting SAA capabilities which support several SAA functions, shown in Fig. 76.4.

The ten SAA core capabilities are defined in Table 76.1. An example of a research gap related to a core capability is "How does the collision avoidance algorithm address uncertainty with respect to noncooperative traffic and maneuvering targets?" This research gap is mapped to the SAA core capability of threat assessment. The seven SAA crosscutting capabilities are defined in Table 76.2. A research gap identified by the SARP that relates to a SAA crosscutting capability is "What are the advantages and disadvantages of informative, directive, and/or suggestive display

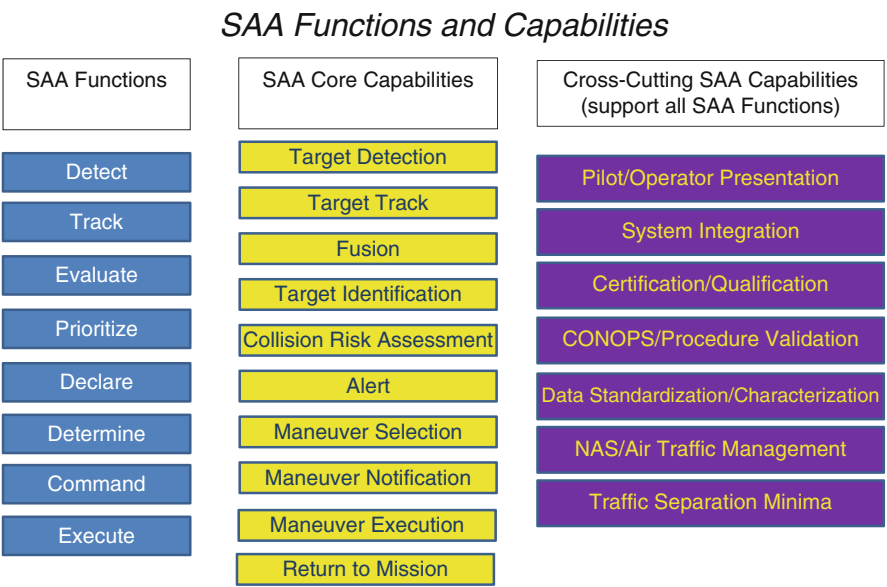

Fig. 76.4 SAA capabilities used to classify SAA research gaps

Table 76.1 Definitions of SAA core capabilities

| SAA capability | Definition |
|-----------------------|---|
| Target detection | Ability to determine presence and location of any airborne object that presents a collision threat to the UA covered by this SAA system |
| Target track | Ability to refine a detected airborne object’s position (2-D or 3-D) and velocity based on one or more target detection(s) from a single sensor |
| Fusion | Ability to refine a detected airborne object’s position (2-D or 3-D) and velocity based on one or more target detection(s) or track(s) from multiple sensors |
| Object identification | Ability to discriminate type and characteristics of a detected airborne object |
| Threat assessment | Ability to determine risk of collision based on relative position (2-D or 3-D) and velocity of the detected airborne object and the UA covered by this SAA system |
| Alert | Ability to communicate that a risk threshold has been met |
| Maneuver selection | Ability to determine the appropriate action needed to resolve identified collision risk(s) to the appropriate separation threshold |
| Maneuver notification | Ability to communicate the selected maneuver in order to execute within the timing window |
| Maneuver execution | Ability to execute the selected maneuver within the timing window |
| Return to mission | Ability of UAS to return to intended or amended course after an avoidance or separation maneuver is complete |

Table 76.2 Definitions of SAA crosscutting capabilities

| SAA capability | Definition |
|---|--|
| Pilot/operator presentation | Ability to provide the pilot/operator with the required information needed to perform/monitor the core SAA capabilities |
| System integration | Ability to integrate the core capabilities into existing and planned UAS |
| Certification/qualification | Ability to show through process and evidence that the SAA system meets an acceptable safety level |
| Concept of operations (CONOPS)/procedure validation | Ability to conform to approved CONOPS and operational procedures |
| Data standardization/characterization | Ability to enable collaboration and meaningful comparisons through databases, data standards, and data integrity |
| NAS/air traffic management | Ability to assess the impact on the NAS that UAS system performance and the performance of supporting systems, such as SAA, may have on air traffic management (ATM) |
| Traffic separation minima | Ability to determine the separation standards and the environmental or operational conditions which inform SAA design |

types for SAA and what lessons have been learned from previous applications?” This gap is mapped against the “pilot/operator presentation” as a crosscutting SAA capability.

To date, the SARP has identified 54 research gaps with at least one gap belonging to each of the 17 SAA capabilities. Figure 76.5 shows the number of gaps identified in each SAA capability. In addition to identifying research gaps, the SARP also receives presentations on ongoing SAA research activities and attempts to use its partnerships to identify ongoing science and research activities that may be ongoing that can close these gaps. These activities may include those conducted under DoD sponsorship or those being conducted outside DoD sponsorship by other government research laboratories (e.g., NASA), academic institutions, or internal corporate research initiatives.

76.6 Workshops

A second way in which the SARP accomplishes its goals is through chartering workshops on specialized topics. Workshop participants are invited from government, academia, and industry based on specific skills and expertise in an area that the workshop is investigating. Thus far the SARP has held four workshops on the following topics:

- SAA certification
- Use of bird RADARs for GBSAA Target Classification
- RADAR cross-section guidelines for SAA
- Guidelines for quantifying the effects of qualitative contributions to safety

Fig. 76.5 Number of research gaps identified in each SAA capability

Per Fig. 76.5, the highest number of research gaps belongs to SAA certification and qualification. The SAA certification workshop was held with the objective of determining the research and science efforts needed to answer key questions related to public UAS SAA certification. The workshop participants examined 12 research gaps identified by the SARP specific to SAA certification/qualification as shown in Table 76.3. For each of these areas, workshop participants identified ongoing research activities that may assist in answering these questions and provided a recommended first step.

The second workshop chartered by the SARP was to investigate how bird RADARs could be used to address some of the gaps in ground-based SAA target classification. The workshop found that the inability to differentiate between birds and other clutter in the radar data is a serious challenge for SAA systems and that while bird radars are cost-effective, they seldom have the reliability needed for safety-critical systems due to their update rates, airspace volume coverage, and frequencies. However, bird RADARs have cost advantages and some have “stop and stare” capabilities. If birds could be reliably identified by SAA systems, algorithms could be developed to use this information in a fusion tracker to provide this information to the UAS crew and ATC to improve airspace safety and lower the false alarm rate for SAA systems.

Table 76.3 Research gaps examined at SAA certification workshop

| Gap area | Description |
|---------------------------------|--|
| Airspace characterization | How should airspace characterization be included as part of SAA certification? |
| RADAR data | What types and amounts of RADAR data must be collected to assure the certifying authority that all noncooperative traffic is sensed? |
| Safety case | What safety strategy and artifacts must be included in a SAA safety case? |
| Human factors | What human factor considerations must be applied to the ground control element for certification? |
| Commercial off-the-shelf (COTS) | How can COTS equipment be used in a SAA system-of-systems that minimizes recertification and redesign? |
| Architectures | How should SAA CONOPS and concepts of employment be matched to an optimal (e.g., cost, safety) SAA system architectures? |
| Modeling and simulation (M&S) | How should the M&S tools used in the SAA certification process be evaluated and validated as accurate and representative of the SAA system? |
| Airworthiness | How do the service 3-tier airworthiness certification levels input into a target level of safety calculation for the SAA system? |
| Segregated certification | What are the criteria to determine which parts of the overall SAA system can be certified independently (e.g., ground segment, RADAR, sensors) in a systems of systems approach? |
| Multi-UAS integration | What are the certification challenges associated with multiple UAS operating in close proximity to each other (e.g., determining how to change SAA thresholds for formation flight)? |
| FAR compliance | What challenges exist for all aircraft (manned and unmanned) in complying with the FARs in their present form (e.g., right-of-way rules in 14 CFR 91.113)? |
| Software assurance | How do civil software assurance considerations in RTCA DO-178B (1992) software assurance apply to public UAS airspace integration? |

The third workshop was chartered by the SARP to determine guidelines for RADAR cross section (RCS) as part of a RADAR-based SAA solution. Participants from government, industry and academia reached a general consensus at the workshop on the most stressing targets for RADAR-based SAA systems. Additionally, participants identified RCS data needs, shared RCS data, identified areas of potential cooperation, and identified useful parameters to consider in multidimensional design trade space for RADARs used as part of a SAA system.

The fourth workshop chartered by the SARP had the objective of understanding how the qualitative safety requirement “extremely improbable” could be interpreted and measured using quantitative means (e.g., a target level of safety approach). Interim guidance provided by the FAA states, “Applicants proposing ‘see and avoid’ strategies in lieu of visual observers, need to support proposed mitigations with system safety studies which indicate the operations can be conducted safely.

Acceptable system safety studies must include a hazard analysis, risk assessment, and other appropriate documentation that support an ‘extremely improbable’ determination” (FAA 08-01 2008). In exploring this topic, the workshop participants reviewed different quantitative safety levels used in the past in civil and military aviation systems to justify an “extremely improbable” or equivalent determination and investigated means of including qualitative contributions to safety (e.g., software assurance, human factor considerations) in a quantitative safety target. The outcome of the workshop was threefold:

- A relationship between the “extremely improbable,” MIL-STD-882D (2000) safety methodology and the target level of safety methodology was proposed.
- A method to identify contribution of qualitative hazards/mitigations to a quantitative level of safety was proposed.
- A list of disciplines that should undergo qualitative hazard analysis or comparable (instead of direct quantification) was established.

76.7 Requests for Information

Another way in which the SARP accomplishes its objectives is through formal requests for information. Requests for information (RFI) appear on the Federal Business Opportunities website and solicits feedback in the form of white papers from interested parties. In August 2011, the OUSD (AT&L) submitted a SARP RFI (OUSD ATL) that listed open research questions in SAA displays and algorithms so that the SARP can obtain information on ongoing activities and obtain a sense of the state of the art in these areas. SAA algorithms and the display of SAA information are two areas that the SARP has identified as critical to the development of SAA systems. The specific questions in the RFI were developed by the SARP based on identified research gaps related to SAA algorithms and displays. The SARP received responses and feedback from over 30 parties in response to various aspects of the RFI.

76.8 Open Meetings

The fourth tool that the SARP uses to meet its goals is to sponsor open meetings. Open meetings are designed to be open to participation for interested parties beyond those that participate in the panel meetings and/or workshops. A 2-day open meeting was held in October 2011 as a forum to discuss selected white papers received in response to the RFI. Seventeen different parties from industry, government, and academia presented 20 separate presentations on ways to address research gaps related to SAA displays and algorithms. From the open meeting, the SARP was able to better understand the state of the art in these critical areas and also understand key areas where technical and/or policy guidance is needed in the community. The SARP consolidated these lessons learned from the open meeting and provided recommendations back to OUSD (AT&L).

Fig. 76.6 Number of research gaps by priority (including *closed* gaps)

76.9 Closing the Gaps

Through the four methods in Fig. 76.3, the SARP has brought to bear through partnerships the community's expertise and knowledge of ongoing research activities. As a result, over 20 % of identified research gaps are regarded as closed. As the SARP continues to address the open research gaps, a high-medium-low categorization scheme is employed to prioritize the areas where the SARP will focus its efforts and also advise OUSD (AT&L) as to the relative importance of the research gaps. Figure 76.6 shows the number of research gaps in each priority category, in addition to the number that have been closed.

76.10 Conclusions

The SARP exists to bring the science and research community together to address open research questions in SAA. The SARP has four primary means of accomplishing its objectives – panel meetings, workshops, requests for information, and open meetings. The SARP has identified 54 open research questions and has adopted a capabilities-based taxonomy to classify these research gaps using ten SAA core capabilities and seven crosscutting capabilities. Over 20 % of these research gaps have been closed as a result of SARP activities. As progress in SAA moves forward, the SARP will continue to identify and bring focus to research areas critical to the success of SAA. By promoting alignment and partnerships in the science and research community, the SARP strives to advance timely solutions to key SAA challenges for the DoD and broader UAS community.

Acknowledgments The authors are grateful to Mr. Dallas Brooks and Ms. Viva Austin for their leadership and vision in establishing the SARP. The authors recognize the dedication and technical contributions of the OUSD(AT&L) Airspace Integration IPT, the Systems Integration sub-IPT, Mr. Chris Jella, and the SARP in developing the SAA Blueprint from which the SAA Capability Definitions were derived.

Abstract

In July 2010, Cassidian installs a cooperative collision avoidance system based on Traffic Alert and Collision Avoidance System (TCAS) onboard the Barracuda Unmanned Aerial System (UAS) demonstrator.

The “Sense&Avoid” capability is a key challenge, even when only considering operation in air space classes A–C. For that reason, the demonstration is intended as a risk mitigation measure to support future UAS development efforts.

The demonstration steps involve a laboratory test with real equipment in a closed-loop demonstration and the automatic execution of a collision avoidance manoeuvre in flight. The in-flight demonstration takes place in segregated air space involving the Barracuda demonstrator platform and a real intruder.

The section outlines the setup of the cooperative collision avoidance system demonstrator, including the interface with the flight control system of

the Barracuda and the control authority granted to the cooperative collision avoidance system demonstrator.

It summarizes the Human-Machine-Interface (HMI) layout and situation awareness provided to the UAS operator and illustrates how the potential loss of data link connection is covered by the system design.

The paper details the development process applied, including requirements definition, validation, and verification steps as well as hardware-in-the-loop demonstration in support of the in-flight demonstration.

It illustrates the demonstration scenarios utilized in the flight demonstration and the results achieved.

Finally, the paper draws conclusions regarding the potential of such cooperative collision avoidance systems based on TCAS, the operational implications and the certification aspects to be solved.

77.1 Introduction

Sense&Avoid is considered as THE enabling capability required to allow routine operation of UAS in non-segregated airspace.

Several studies (Final Air4All Report for ‘UAV insertion into General Air Traffic GAT Follow On Contract’ 2009; WASLA/HALE Phase III 2008 among others) have shown that the Sense&Avoid capability is both technically challenging and lacking in mature system concepts which are able to comply with strict safety requirements.

The UAS Roadmap Study (Final Air4All Report for ‘UAV insertion into General Air Traffic (GAT) Follow On Contract’ 2009), performed by the Air4All consortium, analysed the status of the Sense&Avoid capability and concluded on a stepwise integration of UAS into the airspace. This stepwise integration is based on a preliminary step to allow operation in airspace classes A–C only, whereas a second step would cover operation in all airspace classes.

The preliminary step excludes separation and collision avoidance against non-transponding intruders, which is considered technologically challenging. No separation capability is foreseen, as separation (IFR vs. IFR and IFR vs. VFR (IFR: Instrument Flight Rules; VFR: Visual Flight Rules)) in airspace classes A–C is performed by Air Traffic Control (ATC). The measure of excluding those capabilities which are technically challenging comes at the cost of operational limitations to airspace classes A–C, with special procedures being required to transit in and out of this operational environment.

The proposed second step would extend the technical capabilities of the Sense&Avoid system to also cover separation and collision avoidance against non-transponding objects. This would allow the reduction of the operational limitations required for the preliminary step and further increase the operational benefits possible by UAS operation.

The benefit of this stepwise approach is that technically challenging capabilities are excluded for the time being, thereby allowing routine operation of UAS in non-segregated airspace in the short term. That way, more time is gained to enable further development of the technology needed to bridge the gap to the second step of the Sense&Avoid capability.

A Sense&Avoid capability covering the proposed preliminary step has to consider the operational environment in the airspace classes A–C and be compatible with mandatory equipment (Mode-S transponder and TCAS (MTOW (MTOW: Maximum Take-Off Weight) above 5.7 to or more than 19 passengers)).

77.2 Objective and Status of the Project

In July 2010, a Cassidian internal research and technology project was set up to demonstrate a technical solution enabling operation of the UAS in airspace classes A–C according to the stepped approach defined by Air4All (Final Air4All Report for ‘UAV insertion into General Air Traffic (GAT) Follow On Contract’ 2009).

With separation being the responsibility of ATC and non-transponding aircraft not being allowed to fly into those airspace classes, only a collision avoidance capability is required. Such a cooperative collision avoidance capability has to comply with the available operational framework and the equipment fit of the intruders surrounding the UAS. A TCAS II based cooperative collision avoidance system, as used in manned aviation for decades, is considered a suitable technical solution to this problem.

Consequently, Cassidian analysed a potential solution for a cooperative collision avoidance system based on TCAS II to enable routine operation of the UAS in airspace classes A–C with special procedures required to transit to and from these airspace classes.

The demonstration of this cooperative collision avoidance capability involved several steps:

- Validation and verification using Hardware-In-The-Loop simulation with closed-loop simulation involving a virtual intruder equipped with an ATC transponder
- Several flight tests being performed onboard Cassidian Barracuda UAS demonstrator with a real intruder ([Demonstration video](#)) (Fig. 77.1).

77.3 Definition of the Cooperative Collision Avoidance System

Airbus has developed and received certification for a system consisting of a common TCAS installation and a dedicated autopilot mode for the A380, allowing automated execution of TCAS Resolution advisories by the A380 AutoFlight System. The system certified by Airbus implements, among other things, a so called “opt out”

Fig. 77.1 Barracuda UAS demonstrator

logic, which automatically initiates the execution of the TCAS Resolution Advisory (RA) but gives the A380 pilots the ability to abort the automatic execution and to command a different avoidance action using the standard means they have to control the aircraft.

The cooperative collision avoidance system developed for the Barracuda UAS demonstrator further develops this concept by extending the control chain by the datalink connection.

The system has been set up to have full authority over the execution of the TCAS II defined avoidance manoeuvres, independent of data link availability. In case of data link availability, the UAS operator has the ability to override the automatic execution and to command a self defined avoidance action based on semi-automatic modes provided by the Barracuda FCS.

The automatic execution of the TCAS defined avoidance manoeuvre was performed immediately, in contrast to operation onboard a manned aircraft, where the TCAS RA needs to be indicated to and understood by the pilot, thereby causing a delay in execution before an avoidance action is initiated.

The cooperative collision avoidance system consists of the following elements:

- Commercial-Off-The-Shelf (COTS) Mode-S transponder including omnidirectional antennae.
- COTS TCAS II system including a directional antenna mounted on top the UAS demonstrator and an additional omnidirectional antenna.
- Collision avoidance software implemented as part of the Barracuda Flight Control System (FCS), involving evaluation of the TCAS II generated resolution advisories, system moding as well as commanding the avoidance manoeuvre to a dedicated autopilot mode responsible for execution of the TCAS RAs.
- Human-Machine-Interface to provide situation awareness and an interface for control commands defined by the UAS operator. HMI information was transmitted in real-time using the Barracuda datalink.

The system components are illustrated in the following picture (Fig. 77.2)

Fig. 77.2 System architecture of cooperative Sense&Avoid system

77.4 Human Machine Interface

The intention of the TCAS traffic display is to aid pilots in the visual acquisition of traffic, including the differentiation of intruder threat levels, to provide situational awareness and to ensure confidence in the presented resolution advisories. TCAS standardization documents (Minimum Operational Performance Standards for Traffic Alert and Collision Avoidance System II [2008](#)) contain detailed guidelines on the traffic display, including a standardized symbology set for the depiction of other traffic.

Since all traffic tracked by TCAS is ranked by the collision avoidance logic, intruders are sent to the display in a prioritized order, thus ensuring that those intruders most relevant to collision avoidance are displayed.

Traffic is displayed in relation to a symbol reflecting ownship position, on a display featuring range rings. The representation of other traffic is typically limited to a vertical volume of $\pm 2,700$ ft, and the symbology used depends on the alert state and the proximity of the corresponding traffic. The picture below illustrates the traffic display used for the cooperative collision avoidance system implemented onboard the Barracuda UAS demonstrator (Fig. [77.3](#)).

As is evident from the figure, the traffic symbology used is identical to that used on manned aircraft. Accordingly, traffic symbols are supplemented by a two-digit altitude data tag in the same color as the intruder symbol, indicating the altitude of the intruder aircraft relative to ownship in hundreds of feet. For traffic above the own aircraft, the tag is placed above the traffic symbol and preceded

Fig. 77.3 TCAS presentation on map display

by a “+,” whereas other aircraft below ownship feature the tag below the symbol with a “-” as prefix. Whenever an intruder is climbing or descending with a vertical rate in excess of 500 ft/min, an arrow pointing upward or downward, respectively, is presented immediately adjacent to the intruder symbol. In case bearing information is unavailable for traffic generating either a TA or RA alert, alpha-numeric information is presented on the traffic display for up to two intruders, usually centered below the ownship symbol. Information is presented in the format threat level – range (in NM) – altitude (in 100 ft, consistent with absolute/relative altitude setting) and, if applicable, an intruder vertical speed arrow. As an example, “TA 5.2 -06↑” represents an intruder causing a TA at 5.2 nm with a relative altitude of -600 ft, which is climbing with 500 ft/min or more.

Since all decisions pertaining to the flight path of the aircraft are taken using the Command & Control (C&C) HMI, there was a clear need to have an indication of the TCAS alert condition on this format. Therefore, both intruder information and the standard TCAS callouts were replicated on the C&C HMI as shown in the following picture.

For TCAS callouts, the background of the text message corresponds to the respective alert level, i.e., amber for a TCAS Traffic Advisory (TA) and red for an RA. In the latter case, the standard callout was supplemented by an alphanumeric indication of the commanded vertical speed, if applicable. For the “CLEAR OF CONFLICT” announcing the end of the traffic conflict, the background was green to announce the reversion to Normal Operations (Fig. 77.4).

Operator feedback concerning the implementation of the TCAS HMI was requested from all Barracuda operators. The operators involved stated that the

Fig. 77.4 TA/RA/“Clear of conflict” indication (extract from Command and Control HMI)

overall impression was excellent, and that the display provided them with a level of situational awareness with respect to the surrounding traffic that was otherwise unachievable. In general, the implementation of the TCAS traffic display was according to their expectations, and consistent with the solutions which the operators know from manned aircraft. The presentation of traffic information in relation to a moving map of the surrounding terrain, a feature still uncommon on most manned civil aircraft, was particularly appreciated in this context. Likewise, the textual presentation of standard TCAS callouts, a novel feature compared to current TCAS implementations, was considered as a useful feature.

77.5 Validation and Verification

The system under test was developed in compliance with a development process implementing the well-known V-model. This process is illustrated in the following picture and involves requirement definition and breakdown from system top level to equipment level. In order to ensure requirements correctness and complete-

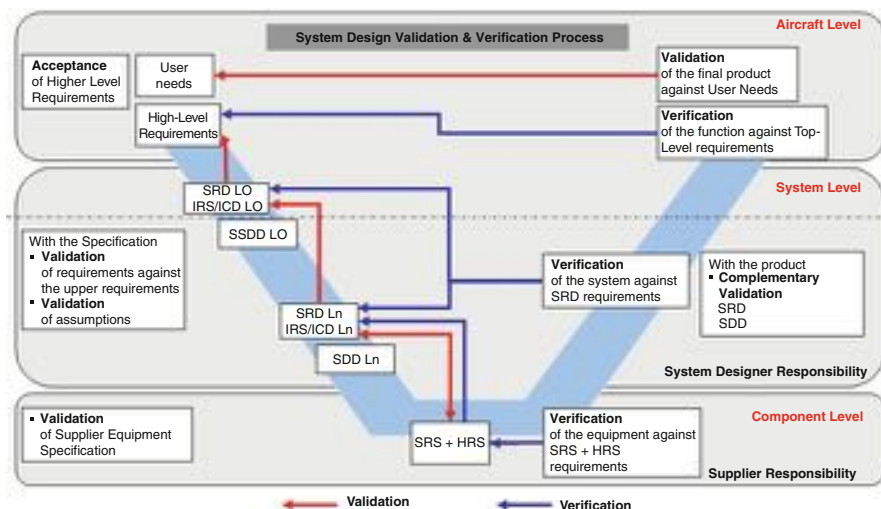

Fig. 77.5 Validation and verification process

ness, a validation matrix was set up to formalize the system validation activities (Fig. 77.5).

Requirement engineering and tracing was done using a dedicated requirements management tool, supporting validation and verification activities in the project.

A formal verification of the system was performed to ensure that the system design correctly implemented the requirements. Verification was performed using different means of verification, involving Hardware-In-The-Loop simulations including real hardware.

This Hardware-In-The-Loop Simulation (HILS) setup consisted of the system under test embedded in a closed loop simulation involving the Flight Control System (FCS) of the Barracuda UAS demonstrator, communication system involving LOS datalink simulation and Ground Control Station (GCS) for UAS operator situation awareness and monitoring system operation. This setup had been chosen to ensure end-to-end coverage for the test performed.

The system was stimulated by a dedicated TCAS test system capable of generating Mode-S equipped virtual intruders flying on a collision course to the Barracuda. This setup allowed the definition of all the relevant parameters of the collision scenario and the performance of those tests in a safe, controllable and repeatable manner.

The HILS setup is illustrated in the following picture (Fig. 77.6):

Verification of the system on closed-loop HILS was performed to ensure correct operation of the system and is considered an essential step before performing real flight tests.

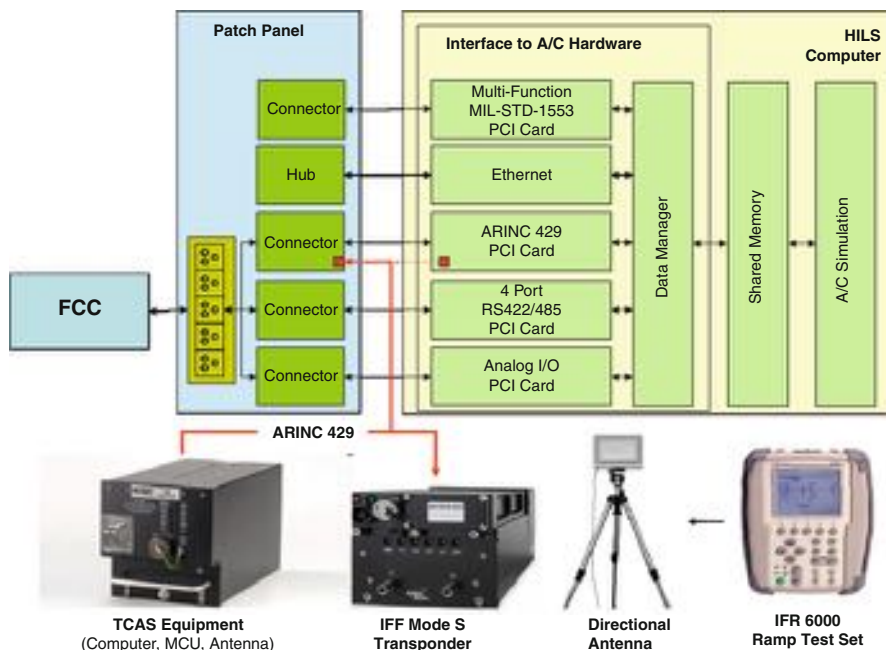

Fig. 77.6 Hardware-in-the-loop setup

The verification activity consisted of a great number of different collision scenarios with different approach angles, closing speeds and vertical separation.

77.6 Flight Test

Flight demonstration of the cooperative collision avoidance system was performed involving the Barracuda and a real intruder. The flight test demonstration took place at Goose Bay airport, Labrador, Canada in July and August 2010.

Collision scenarios were performed according to a dedicated flight test plan and involved those collision scenarios which had previously been verified using closed loop HILS.

The intruder used during flight tests was a King Air 100. It was equipped with a Mode-S transponder. However, a TCAS capability was not installed, but this did not impose any constraint on the cooperative collision avoidance system developed.

The test points were performed by visually flying the intruder in close proximity to the UAS demonstrator, which strictly followed the pre-programmed flight plan until TCAS commanded otherwise. For safety reasons, the test points required good visibility conditions.

Collision avoidance test points involved a stepwise increase in collision scenario criticality. Initial test points involved a verification of the TCAS surveillance function, correct behavior of the TCAS collision avoidance function and the UAS operator situation awareness. For these tests, the automatic execution of the TCAS RA onboard Barracuda UAS was disabled. In the related test points, the Intruder A/C approached the Barracuda UAS from behind at intruder bearing angles between approximately $\pm 135^\circ$ and relative altitudes of ± 200 ft. In all test points, detection of the intruder A/C, generation of the expected TCAS TA and RAs and indication to the UAS operator were successful.

After these test points had been performed, the automatic execution of the TCAS RAs was enabled. The test points involved a collision threat imposed by the intruder aircraft approaching the Barracuda UAS demonstrator from behind until the TCAS alert thresholds were violated, triggering the expected TCAS reactions. This time, under supervision of the UAS operator in the Ground Control Station (GCS) and the intruder pilot, the Barracuda Flight Control System executed the TCAS RA with the required climb/descend rate until the TCAS issued the "Clear of Conflict" signal. The flight test scenarios involved the intruding A/C approaching the Barracuda UAS from behind starting at a distance of approximately 900 m and at relative altitudes of +200 and -200 ft. It should be emphasized that these test scenarios did not yet involve crossing trajectories.

Detection of the intruding A/C, generation of TA and RA by the Barracuda TCAS and execution of the TCAS RA with the defined climb/descend rate were performed as expected. After the TCAS issued the "Clear of Conflict" signal, Barracuda returned to its pre-programmed flight trajectory.

Ultimately, the test points also involved two more challenging collision scenarios and higher approach speeds. In these test scenarios, the intruder A/C continued on its trajectory, crossing underneath the Barracuda UAS, thereby causing the generation of TCAS TA and climb RA, which was promptly executed by Barracuda. The following picture illustrates one of the tested collision scenarios. The intruder A/C is approaching Barracuda from the rear side (collision angle approx. 135°) at a relative altitude of -200 ft (Fig. 77.7).

The other test scenario was performed with a collision angle of approx. 90° and at a relative altitude of -200 ft. The following picture illustrates this test scenario (Fig. 77.8):

Vertical separation *before* TCAS activation for all test points was around 200 ft, with horizontal separation at point of collision being almost zero. By strict execution of the TCAS defined resolution advisory by the FCS of the Barracuda, the vertical separation was extended to approx. 350 ft in line with expectations for operation of TCAS.

When the intruder A/C was in position the performance of a scenario took about 1.5 min (until Barracuda returned to the pre-programmed flight plan after completion of the avoid manoeuvre).

Fig. 77.7 Intruder side approach scenario (collision angle 135°)

Fig. 77.8 Intruder side approach scenario (90° collision angle)

77.7 Consequences of TCAS Onboard UAS

The proposed solution of automatic execution of the TCAS generated avoidance manoeuvres provides benefits when compared to operation in manned aviation.

In the proposed solution, the automatic execution of the avoidance manoeuvre is performed by a dedicated, specialized autopilot mode. This autopilot mode is far more precise in following the TCAS defined resolution advisory than a human pilot could ever be.

Due to this fact, a more precise execution of the TCAS defined avoidance manoeuvre is possible, thereby reducing vertical and/or lateral deviation from the expected trajectory.

The achievable TCAS risk ratio is one factor (Other important factors include typical “1309-type” safety requirements applicable to the whole UAS and its operation. The relevance of the “logic risk ratio” figures can be understood as the reliability that can be attached to RAs, they are not supposed to be treated as the sole means to express safety of the system. Reference ICAO Annex 10 (2007) states: “[The ACAS risk ratio] express the effect that following an RA will have on the immediate risk of collision when, at the time it is issued, the pilot has no information other than the RA on which to base a decision whether to follow the RA or ignore it. As a rough guide, the collision risk created by ACAS arises from following the RA so the logic risk ratio overstates this “induced risk ratio”; on the other hand, it also overstates the capability of ACAS to prevent collisions because of the many other failure modes in the total system.”) to value the impact on safety achieved by such a system (ICAO Annex 10 2007):

$$\text{ACAS Risk Ratio} = \frac{\sum_{\text{all encounters}} \text{probability of a collision with ACAS installed}}{\sum_{\text{all encounters}} \text{probability of a collision without ACAS installed}}$$

Reference ICAO Annex 10 (2007) quantifies target levels of Airborne Collision Avoidance System (ACAS) risk ratio applicable to manned aviation:

[T]he collision avoidance logic shall be such that the expected number of collisions is reduced to the following proportions of the number expected in the absence of ACAS:

- a) when the intruder is not ACAS equipped: 0.18
- b) when the intruder is equipped but does not respond: 0.32
- c) when the intruder is equipped and responds: 0.04

Especially in crowded airspaces, it had been shown that the precise execution of the TCAS RA directly correlates with the risk of inducing new collision threats – the more accurate a TCAS RA is followed, the less induced new collision threats, thereby improving the TCAS risk ratio (Final Air4All Report for ‘UAV insertion into General Air Traffic GAT Follow On Contract’ 2009).

Furthermore, the TCAS risk ratio also depends on the time duration between issue of a Resolution Advisory by the TCAS system and initiation of the execution of the TCAS RA. ICAO Annex 10 (ICAO Annex 10 2007) specifies a standard pilot model, in which a typical reaction time of a human pilot is defined. According to

this standard pilot model, a typical response time between issue of TCAS RA and initiation of execution is 5 s.

It has been shown in (Final Air4All Report for ‘UAV insertion into General Air Traffic GAT Follow On Contract’ 2009), that this time duration directly impacts the TCAS risk ratio. With the proposed solution involving automatic execution of a TCAS RA, this time duration can be minimized. A direct impact on the TCAS risk ratio is illustrated in the following picture (Fig. 77.9).

The benefits possible by implementing an automatic execution of a TCAS defined avoidance manoeuvre have also been considered for manned aviation. A similar, but more complex solution has been proposed for the Airbus A380 and received certification from EASA in 2009 (EASA 2009).

The EUROCONTROL CAUSE study (Unmanned Aircraft Systems 2010) did assess the suitability of TCAS for UAS as well. Reference Unmanned Aircraft Systems (2010) puts emphasize on the UAS requirements necessary in order not to degrade TCAS operation:

- Limitations in ACAS hardware (particularly antennae and their siting) may become apparent when ACAS is deployed on a UAS airframe, and limitations in the ACAS software (particularly tracking algorithms) may become apparent if the UAS aerodynamic performance exceeds that expected from a commercial civil fixed-wing aircraft. These limitations will manifest themselves as degraded surveillance performance and lower reliability and quality of the tracking of targets.

Fig. 77.9 Dependency of TCAS risk ratio from initial RA response time, derived for Global Hawk (Final Air4All Report for ‘UAV insertion into General Air Traffic GAT Follow On Contract’ 2009)

- These RAs require a response within a specified time, at an acceleration of a specified strength, to achieve a specified vertical rate. If for any reason the UAS cannot achieve this standard response the efficacy of the RA can be compromised.

The conclusion of (Unmanned Aircraft Systems 2010) on the certification of TCAS for UAS is as follows:

Certification of any UAS equipage with ACAS II should be conducted on a case-by-case basis for each airframe/equipment configuration.

It would need to be established that ACAS II surveillance was adequate for the purposes of collision avoidance, and that the UAS was able to comply with ACAS II RAs promptly and accurately.

77.8 Conclusions and Way Ahead

The proposed solution has the potential to solve the need for a cooperative collision avoidance capability needed to achieve preliminary integration of UAS into airspace classes A–C.

Aircraft operating in those airspace classes are required to carry an operational transponder to support ATC in providing separation service as well as the intruder to perform collision avoidance. Still, even with the transponder being mandatory equipment for operation in airspace classes A–C, there is a certain risk that not all intruders actually comply with this regulation, as pilots intentionally or unintentionally fly into airspace A–C without permission and proper equipage. The risk associated to this needs to be analysed. A suitable means could be to use ATC data to compare primary RADAR detection (sensitive to aircraft with a minimum RADAR cross section) with secondary surveillance RADAR detection (sensitive to aircraft equipped with a transponder).

As the proposed solution is limited to operation in airspace classes A–C, special procedures are required for transit in and out of those airspace classes for take-off and landing. These special procedures aim to ensure that no non-transponder equipped aircraft is operated in the vicinity of the UAS. Possible procedures could be to take-off and land through segregated airspace, the usage of primary RADAR coverage or to use chase aircraft for this transit phase. Implications on the operational flexibility of UAS need to be assessed. In order to comply with the EUROCONTROL requirement to ensure adequate ACAS II surveillance for the purposes of collision avoidance, the suitability of the UAS platform itself needs to be considered (i.e., UAS climb/descend performance, ACAS antennae placement). This is no different to certification for manned aircraft, where compliance with the same requirements must be demonstrated.

The requirement for prompt and accurate compliance with ACAS II RAs is an issue which needs to be covered by the design of a cooperative collision avoidance system based on TCAS together with the capabilities of the UAS FCS.

The demonstrated solution is considered an intermediate step towards a product level system enabling operation in airspace classes A–C that will be applicable to any UAS which complies with the defined requirements for TCAS installation as defined in Unmanned Aircraft Systems (2010).

Abstract

The VUSIL program (“Validierung von UAS zur Integration in den Luftraum” in German) has developed a concept for the integration of unmanned aircraft systems (UAS) into uncontrolled nonsegregated airspace, which is also used by manned civil aviation.

For the integration of UAS it is necessary for the unmanned aircraft (UA) pilot to be aware of the surrounding traffic in order to recognize and resolve possible conflicts. In the VUSIL program, the surrounding traffic was indicated on a display in the pilot ground control station (GCS), based on radar data provided by the Air Navigation Service Provider (ANSP).

In addition, the pilot was supported by means of a “detect and avoid” tool in detecting potential conflicts. This tool shows conflicts and possible avoidance maneuvers on a separate display. To validate the integration concept, two flight campaigns with two different UAS (helicopter and fixed-wing UAS), and several intruders were conducted.

In the first flight campaign, the intruders for the real flying UAS were simulated. In the second flight campaign, the intruder was a manned helicopter. The concept has been validated by the results of both flight campaigns and by a safety analysis.

The latter has addressed demonstrating the equivalent level of safety (ELOS) of “see and avoid” in manned aviation and “detect and avoid” as developed in the VUSIL program.

78.1 Introduction

This chapter is an elaboration of the publication of the VUSIL program in (Udovic et al. [2011](#)).

78.1.1 Background

UAS are new kinds of aircraft, which have great potential for conducting various kinds of tasks. In comparison to manned aircraft, the pilot of a UAS is not onboard the aircraft. He is controlling the unmanned aircraft (UA) from the ground. UAS have been mainly developed for the military environment to conduct dull, dirty, and dangerous (3D) missions. Therefore most of the civil UAS operations considered are spin-offs from military aviation, as for instance surveillance operations. In particular pipeline surveillance, border control and maritime or environmental observations are the most described civil applications. Dangerous applications like flying into volcanic ash or radioactive contaminations for measurements are also possible missions for civil UAS. The advantage of UAS conducting 3D missions is at the same time the challenge for the integration of UAS into civil aviation. In manned aviation, the pilot sitting in the cockpit is finally responsible for the safe conduction of the flight by scanning the vicinity. All civil aviation regulations are based on this premise.

78.1.2 Structure of This Chapter

At the beginning of this chapter, the problem related to the integration of UAS outside segregated airspace is explained. Based on this problem description, the VUSIL concept to solve this problem is described, followed by the results of the VUSIL program.

The VUSIL program contains two closely linked projects. In the VUSIL I project, the VUSIL idea was validated using a real flying UAS in combination with simulated surrounding traffic (Sect. 78.4).

In the VUSIL II project, the concept was validated with a real flying UAS in combination with real intruders. Approach and results of this project are provided in Sect. 78.5 of this chapter. Ability requirements for UA pilots are briefly discussed in Sect. 78.6. In Sect. 78.7 the equivalent level of safety is analysed by comparing effectiveness of “See and Avoid” and “Detect and Avoid”. Section 78.8 concludes this chapter.

78.1.3 The Problem

Based on the pilot not being onboard the aircraft, various problems for integration into nonsegregated airspace have to be solved. The problems can be divided into three areas:

1. Technical problems: For controlling an aircraft from the ground, a data link connection between the ground control station and the aircraft must be established. This data link connection must be stable, safe, and secure. At any moment of time, the pilot must have the possibility to interact with the aircraft. To handle the aircraft safely, he needs to have all relevant information in the ground control station. In particular, the status of the aircraft, involving for example the position, flight attitude, and altitude of the aircraft, and the status of the engine must be displayed. Therefore, a two-way data link is required. To disburden the pilot, several tasks, such as stabilizing the aircraft during flight, can be integrated into the avionics of the aircraft. Alternatively, a fully autonomous UAS (in which all of the pilot’s tasks have been taken over by onboard systems) could be designed.
2. Operational problems: One of the major operational problems is that the pilot of the UAS is not onboard the aircraft. Therefore, he cannot look outside to avoid conflicts with other traffic or obstacles according to the “see and avoid” principle. It is also not possible for the pilot to see signals from other aircrafts such as anti collision lights (ACL) or signals from the ground. At the moment, no technical equipment is available to support the pilot on the ground with this information. If such equipment were available, its certification for use in aviation is another hurdle. This leads to the third problem.
3. Regulatory problems: Rules and regulations for the safe integration of UAS into civil airspace do not exist at the moment. Certification rules for UAS requirements for a safe and secure data link or rules for the necessary information exchange between ground control station and UA are not defined yet.

Neither are requirements for a “detect and avoid” system comparable to the “see and avoid” principle in manned aircraft available. The International Civil Aviation Organization (ICAO) is addressing these problems (see ICAO 2011). On a national level, only some high level requirements are available in certain states (see UK CAA 2010). In Germany, flying UAS outside the visual line of sight (VLOS) of the pilot is currently not allowed. Only in segregated areas such flights can be conducted (see Beschluss des Bundesrates 816/09 2009).

Both VUSIL projects focused on the operational problem of “see and avoid.” In addition, some regulatory problems related to legal aspects and safety analyses were addressed.

78.1.4 The VUSIL Idea

To solve the “see and avoid” problem for the UA pilot, radar equipment of DFS Deutsche Flugsicherung GmbH (DFS) has been used (see Udovic and Vielhauer 2010). The radar data are available and can be forwarded to the ground control station to display the position of the UA and the surrounding traffic. A “detect and avoid” tool can be triggered based on these data as well. As in manned aviation, the pilot is in permanent contact with ATC via radiotelephony. Figure 78.1 shows the principle of the solution.

The UAS is equipped with a common transponder (mode A/C or mode S). The Air Navigation Service Provider (ANSP) can detect the UAS and the surrounding traffic with standard radar equipment. The corresponding data can be sent via a landline to the ground control station of the UA. In the ground control station, traffic

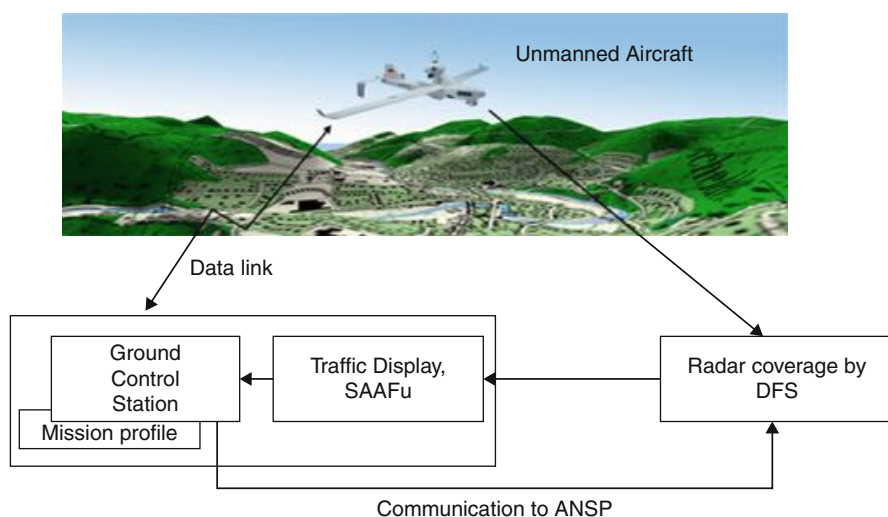

Fig. 78.1 Principle of the “detect and avoid” solution developed by VUSIL

Fig. 78.2 Traffic display “Phoenix” (see Heidger 2011)

is displayed on a radar screen comparable to those used by air traffic controllers. A “detect and avoid” tool (SAAFu) can as well be fed by radar data. Based on this information the pilot can avoid the surrounding traffic, and the UAS can be safely integrated into non-segregated airspace. The applied principle is that UAS are separated from other traffic by at least 0.5 NM laterally or 500 ft vertically. These values were based on considerations involving inter alia radar accuracy (see Eurocontrol 2007).

Figure 78.2 shows the traffic display based on the Phoenix air traffic management system of DFS. Figure 78.3 shows the “detect and avoid” display “SAAFu” developed by the German company ESG GmbH.

For successful application of the VUSIL concept, some preconditions have to be fulfilled:

- All traffic must be equipped with transponder, as for example, in a Transponder Mandatory Zone (TMZ).
- The whole concerned airspace is covered by secondary radar surveillance (in the concept developed, primary radar is not applicable due to missing altitude information and insufficient accuracy).
- Separation minima of 0.5 NM horizontally/500 ft vertically;
- If possible, collision avoidance based on existing visual flight rules (VFR).
- A traffic display is available in the control station.
- A “detect and avoid” assistance system is available.

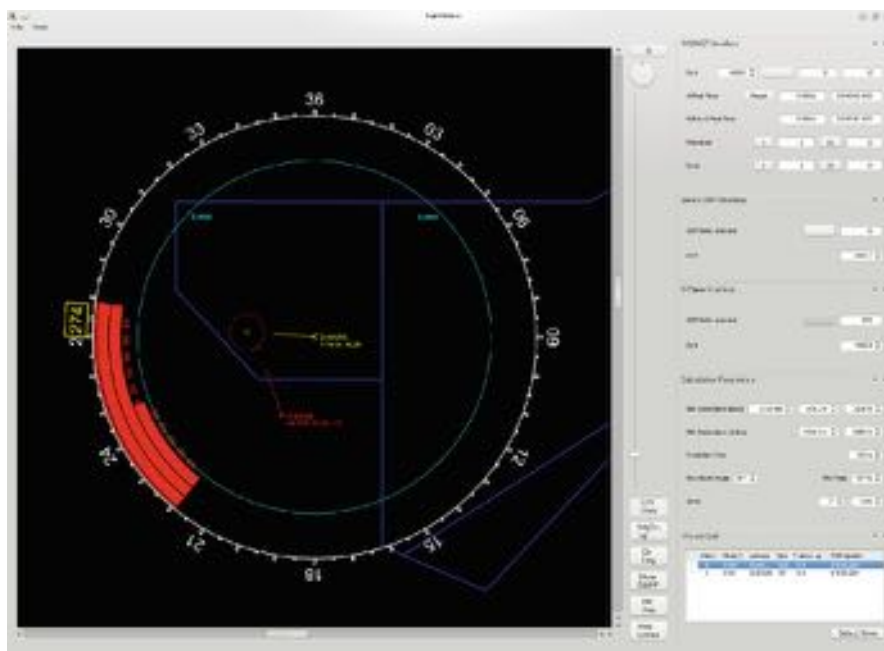

Fig. 78.3 “Detect and avoid” display (“SAAFu”)

The preconditions show that the concept is only valid for some special areas, such as TMZs. However, it can be used to gain experience with UAS to develop solutions for safe integration into a wider subset of nonsegregated airspace.

78.2 Aims of the Research

As an onboard “detect and avoid” system is not available, the idea of using a “ground-based system” was the starting point of the program. The aim of the program was to validate this idea by conducting flight trials and performing a safety analysis to investigate feasibility of safe integration of UAS into nonsegregated airspace.

In detail, the following four aims were defined for the program:

1. Development and optimization of the integration concept (conditions, equipment, and procedures)
2. Evaluation of the equivalent level of safety (ELOS) between “see and avoid” and “detect and avoid”
3. Possible certification rules of the ground-based system for UAS flights outside segregated airspace
4. Analysis of the ability requirements for UA pilots

78.3 Stepwise Approach

In a first step, a ground-based “detect and avoid” concept for the safe integration of UAS had to be developed. To that end, the DFS infrastructure had to be analyzed, and conditions for the safe integration had to be determined.

In a second step, the necessary infrastructure (radar data, simulated surrounding traffic, traffic display, “detect and avoid” tool) for the validation of the concept had to be defined. For conducting the flight trials, the infrastructure had to be built up in the test area.

To validate the concept, flight trials were conducted using certain procedures to maintain separation between the UAS and surrounding aircraft. In the first phase, the surrounding traffic was simulated (VUSIL I). This phase was sponsored by the German Ministry of Transport.

In the second phase, financed by the German Federal Police in cooperation with the Ministry of Internal Affairs, a real intruder participated in the flight trials (VUSIL II).

Based on the results of the flight trials and discussions with UA pilots, pilots of manned aircraft, air traffic controllers, and aviation experts, a safety analysis was conducted to identify and assess safety relevant differences between the UAS flight trials and normal manned flights in similar circumstances.

78.4 First Realization: UAS Test Flights in Simulated Traffic

Based on VUSIL’s integration concept, first flight trials were conducted. The UAS “LUNA” produced by the German supplier of air vehicles and aviation equipment EMT was flying during these trials. To investigate the avoid capability of the concept, simulated traffic around the LUNA was displayed on the traffic display as well as by means of a “sense and avoid” tool. Based on this information the task of the pilot of the real flying UAS was to avoid the displayed simulated traffic.

To conduct the flight trials, the necessary infrastructure was defined. As test environment, a restricted area (ED-R 138) near the military airfield Manching (in southern Germany) was selected. The radar data (of the real flying UAS) from DFS was sent via Universal Mobile Telecommunication System (UMTS) to the UAS ground control station. As foreseen in the concept, the LUNA was equipped with a transponder. The infrastructure was built up in Manching. For the data collection, questionnaires, interviews, and a structured debriefing were prepared. Furthermore, the radar data and the simulated traffic were recorded and analyzed after the flight trials were finished. For a detailed description of the infrastructure and methodology, see Udovic and Vielhauer [2010](#).

In June and July 2008, 13 flight trials were performed in ED-R 138, as planned. Radar data and data from the interviews and discussions were collected. As an example, Fig. [78.4](#) shows a flight track of the LUNA (flight number 5).

Fig. 78.5 Number of simulated aircraft during the flight trials

In most of these cases, the traffic density was very high (see Fig. 78.5). During flight number 3, there were 34 simulated aircraft, and during flight number 9, there were 30 simulated aircraft in the test area. In flight number 6, the amount of traffic was high as well (24 aircraft). During flight 13, technical problems were the reason for the separation infringement. For that reason, the flight was aborted.

Discussions with the UA pilots and the participants in the flight trials yielded the following results:

- The traffic display with the surrounding traffic was rated as very helpful for situational awareness. It was however not easy for the pilots to interpret the information on the display. To fulfill this task, more extensive training is needed.
- The “detect and avoid” tool was also rated as helpful. Especially for avoidance maneuvering this assistance was considered very supportive. Possible solutions to avoid the conflict are displayed to the UA pilot. The software could however be enhanced by integrating vertical avoidance maneuvers. More training could also enhance the effectiveness of the tool.
- The combination of both support tools was rated as very helpful. A better integration into the UAS ground equipment could further enhance their effectiveness.
- The necessary instruction and training of the UAS pilot based on the investigated integration concept was discussed. The participants agreed on a combination of a pilot licensing and elements of air traffic controller training.
- All in all, the tested integration concept was rated positively. The participants agreed that the concept could be a way to integrate UAS into nonsegregated airspace. However, training of the pilots must be taken into account, and the technical integration must be enhanced.

The results of the safety analysis workshop supported the results of the interviews and discussions. In addition, the following results were obtained:

- Compared to common manned aircraft, detection of a UAS by pilots of the surrounding traffic was rated negatively by the participants. UAS may be very small, and therefore their visibility is poor. This could generate problems if the pilots of the surrounding traffic are responsible for conflict avoidance; see the rules of the air – ICAO 2005. Special lights or a special color could increase the visibility of the UAS.
- The performance and steering of the UAS were also rated negatively. The speed of the LUNA is low, and especially during strong wind conditions, the LUNA is inert. This could create problems in avoiding collisions.
- The detection of the surrounding traffic was judged positively by the participants. The “detect and avoid” tool and the traffic display were very helpful to detect and avoid the surrounding traffic. Especially the range of the radar display was rated positively. The UA pilot can detect the traffic in advance and is able to react before the situation becomes critical.
- The instruction and training of UA pilot was not clear for the participants. Hence, a detailed analysis of the required abilities of the UA pilot was proposed. Based on these requirements, a concept for the instruction and training should be developed.

The results of the first flight trials indicate that the proposed integration concept is a viable way to integrate UAS into the air traffic outside restricted airspace. The following aspects have been indicated to further validate the integration concept:

- Test the concept in a more realistic traffic environment – with real instead of simulated intruders.
- Identify and rank the required abilities of UA pilots and develop training requirements.
- Compare the effectiveness of “detect and avoid” as developed in the integration concept with the analogue process “see and avoid” in manned aviation.

These topics are investigated in the succeeding phase.

78.5 Second Realization: UAS Test Flights with Real Intruder

The flight trials were organized by the NATO department “Centre of Excellence for Operations in Confined and Shallow Waters” and set up in segregated airspace (ED-R 10, Todendorf-Putlos), in which a UAS (“LUNA” or “NEO” by the Swiss company SWISS UAV) is flying together with a manned helicopter operated by the German Federal Police. The manned helicopter (indicated by “BPOL”) was the intruder for the UAS. Based on the VUSIL concept, the UAS should avoid conflicts with the helicopter crossing its flight path. The aim of this validation step was to prove the concept and to gather enough data for the safety analysis of the “detect and avoid” concept.

Figure 78.6 shows the technical realization of the flight trials in VUSIL II. radar data were taken from two sources: The main radar source was a local radar

antenna in Todendorf, in the neighborhood of where the flight trials were conducted; the second source was the DFS Radnet. The DFS Radnet is a broadband local area network (LAN), which provides all radar data from the different DFS radar antennas. For the VUSIL II flight trials, radar data from the Todendorf area were selected. The radar data from both sources were sent to the control station of the flight trials. A sensor bridge merged the radar data and sent them to a LAN. The Phoenix radar display and a SAAFu in the ground control station of the UAS were connected to this LAN. In the ground control station a Phoenix display to supervise and record the flight trials was connected to the LAN.

The first flight trials were conducted in October 2009. Due to windy weather, only a few flights could be accomplished. Therefore, in April 2010, the flight campaign was continued. Between 22 and 29 April 2010, 13 flights were completed (see Table 78.2). The table also indicates the participating UAS and intruder.

Table 78.3 Distribution of the approaches of UAS and intruder

| No. | Direction of the approach | No. with LUNA | No. with NEO |
|-------|---------------------------|---------------|--------------|
| 1 | Approach from ca. 90° | 17 | 2 |
| 2 | Approach from ca. 270° | 11 | 2 |
| 3 | Approach from ca. 315° | 7 | 1 |
| 4 | Approach from ca. 45° | 5 | 1 |
| 5 | Approach from ca. 225° | 9 | |
| 6 | Approach from ca. 135° | 10 | |
| 7 | Approach from ca. 180° | 5 | |
| 8 | Approach from ca. 360° | 7 | |
| Total | | 71 | 6 |

Fig. 78.7 Example of an approach between UAS and intruder

Altogether 77 approaches of a UAS and the intruder were recorded and analyzed (71 of LUNA and intruder, and 6 of NEO and intruder). The approaches of the intruder and the UAS were conducted from different directions, see Table 78.3.

Figures 78.7 and 78.8 provide plots visualizing an exemplary data analysis. For all 77 approaches, the flight paths of the intruder (red) and the UAS (dark blue) were displayed example in Fig. 78.7. If the pilot of the UA decided to fly a

Fig. 78.8 Real distance and extrapolated (calculated) distance between UAS and intruder for one approach

maneuver to avoid the intruder, the extrapolated flight path without this maneuver was calculated (light blue). Figure 78.8 shows the result of the calculation of the real distance between the UAS and the intruder (red). In a second calculation, the closest proximity between the intruder’s flight path and the UAS’s flight path without avoidance maneuver was assessed (shown in blue).

In 22 of the approaches to the LUNA, the calculated closest distance between the LUNA and the intruder would have been less than the separation minimum of 0.5NM. In all cases, the LUNA pilot started an avoidance maneuver to prevent an infringement of the separation minimum. In all but one cases, the pilot increased the distance between the intruder and the LUNA and accomplished the separation minimum. In one case, the distance was below the separation minimum. A deeper analysis showed that due to a software problem, the SAAFu display was frozen and presenting false data to the pilot. The pilot reacted according to the false information and conducted a wrong maneuver.

The six approaches involving the NEO were analyzed in the same manner. In four of the cases, the calculated distance for the extrapolation of the flight path if no maneuver had been initiated was less than the separation minimum. In three cases, the pilot conducted an avoidance maneuver successfully; in one case, the maneuver

failed. The analysis of this case showed a general problem of the integration of UAS outside segregated airspace: The speed of the UAS used in the flight trials and especially the NEO was very low. The intruder was flying at around 90 knots. Due to the speed difference between UAS and the intruder the UA pilot could not always prevent an infringement of the separation minimum even though he reacted in an appropriate manner.

The flight trials also highlighted another problem for the integration of UAS. Both UAS were small and painted in white color. Both UAS were equipped with a transponder, so the two pilots in the helicopter could see the UAS on the airborne collision avoidance system (ACAS) display in the cockpit. Although the pilots knew the position of the UAS based on the ACAS display, in most of the cases, they could not see the UAS visually. Flying under VFR rules implies that the pilot has to follow the rules of the air (see ICAO 2005). Under defined circumstances, the pilot is committed to avoid traffic by flying an avoidance maneuver. This implies that the pilot must be able to see the opponent. In case of a UAS, this may not be possible. For these cases either the “rules of the air” (ICAO) have to be adapted or the visibility of the UAS has to be significantly enhanced.

78.6 Ability Requirements for UA Pilots

Another aim of the VUSIL II project was to conduct a first investigation of the ability requirements of UA pilots. This investigation was conducted by the German Aerospace Centre (DLR) in Hamburg. For the investigation, the participating UA pilots filled in the Fleishman Job Analysis Survey (Fleishman and Reilly 1992), which was adapted by DLR. This questionnaire is also used for the evaluation of the ability requirements of air traffic controllers or pilots (Eißfeldt and Heintz 2002). Altogether, six UA pilots filled in the questionnaire. Table 78.4 shows the ranking of the 15 most important ability requirements.

Spatial orientation resulted as the most required ability. Stress resistance and staying power were ranked secondly and thirdly. In comparison to similar results for controllers and pilots, the results of the UA pilots show higher similarity to the results of pilots, although the values of the required abilities for UA pilots were in tendency lower than for pilots of manned aircraft.

Due to the low number of UA pilots participating in the study, the results are not fully comparable to the results of the pilots and controllers. Nevertheless, first hints for the required abilities for UA pilots have been found.

78.7 Safety Analysis

One of the aims of the VUSIL II project was to demonstrate an equivalent level of safety (ELOS) for the developed concept of integration. To this end, it needs to be investigated whether the collision risk for the UAS in the integration concept is equal to or smaller than for VFR flights in manned aviation.

Table 78.4 List of the 15 most important ability requirements for UA pilots

| Self-control |
| Speed of perception |
| Selective attention |
| Situational awareness |
| Speed/reaction |
| Decision making |
| Self-assurance |

This section begins with explaining the approach to answer this question, which involves comparing effectiveness of “detect and avoid” to effectiveness of “see and avoid.” Subsequently, the effectiveness of both of these processes is estimated, based on the flight trials conducted in the project, expert judgement, and results from the literature. At the end of this section, results are summarized, and conclusions are drawn.

78.7.1 Approach to Safety Analysis

In order to demonstrate an ELOS, the “detect and avoid” process, as applied in the integration concept, is decomposed into a subprocess regarding detection of traffic in the vicinity of the UAS and a subprocess regarding recognition and resolution of possible conflicts. The effectiveness of these subprocesses is quantified using conditional probabilities, multiplication of which then results in effectiveness of the “detect and avoid” process. The “see and avoid” process in manned aviation is analogously decomposed and quantified, which then allows a comparison. This approach is indicated in Fig. 78.9.

- In conducting the above comparison, the following assumptions have been made:
1. The flights of the UAS take place in a context where equipment performs as may be expected from operationally (instead of experimentally) used equipment. Consequently, equipment failures would occur as rarely as in a normal operational context. Flight trials conducted in the VUSIL project that were affected by equipment failures that would be rare in an operational context were therefore excluded. This approach is appropriate as the project aimed to evaluate the integration concept, not yet the equipment components.
 2. Manned flights are conducted by single pilots, as is not unusual for VFR flights.

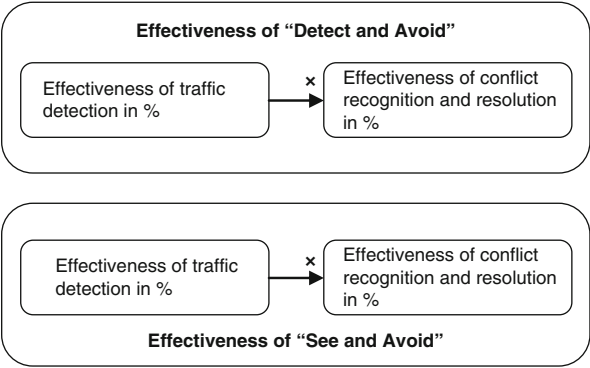

Fig. 78.9 Decomposition of “detect and avoid” and of “see and avoid” into traffic detection and conflict recognition and resolution

Fig. 78.10 Conservative assumption: manned aircraft do not react to unmanned aircraft (in manned aviation, both aircraft in a conflict may react to each other)

3. For the rest, the comparison has been made in a “conservative” manner, that is, in cases of uncertainty or lacking information, aspects of “detect and avoid” have been assessed pessimistically, whereas such aspects for “see and avoid” have been assessed optimistically. If ELOS can be still shown using a conservative approach, this gives increased confidence in the validity of this result. An example of this conservative approach is the assumption that UAS are principally not detected by manned aircraft (e.g., due to their small size), whereas in conflicts between manned aircraft, the pilots of both aircraft can detect each other and initiate a conflict resolving maneuver. In other words, it is assumed that conflicts involving UAS can only be resolved by the UA pilot. This conservative manner in comparing “detect and avoid” to “see and avoid” is indicated in Fig. 78.10.

78.7.2 Effectiveness of “See and Avoid”

The estimates regarding effectiveness of “see and avoid” are based on Andrews 1991, which reports on flight tests conducted to address the ability of pilots to visually acquire aircraft on a near collision course. More specifically, in the flight tests conducted, 24 on the average relative experienced pilots flew one of two

Fig. 78.11 Influence of conflict geometry on whether an aircraft on a conflicting course can be seen by a pilot from the other aircraft in a range of 120° around the forward direction

cross-country courses in a Beech 33 (Bonanza). During each of these flights, three encounters were planned with a Cessna 421, flying at an altitude differing 500 ft with that of the Beech Bonanza and directed to achieve as little horizontal distance as possible – usually a few tenths of a mile. The safety pilot also present in the Bonanza recorded the point of time at which the subject pilot detected the Cessna (see Andrews 1991).

The investigation restricted to encounters in which the Cessna was within 60° horizontally and 10° vertically from the forward direction of the Bonanza as the paper indicate that this is the angular region normally searched by pilots and considered most likely to contain aircraft on a threatening course.

A main result of Andrews 1991 is that only in 36 of 64 of such encounters, the subject pilot visually acquired the Cessna. On the basis of this result, the effectiveness of traffic detection by one pilot is estimated to be 56%. On the basis of the 2nd assumption that a VFR aircraft is flown by a single pilot, this is the effectiveness of traffic detection from the perspective of one of the manned aircraft involved in a conflict.

Depending on the geometry, the other aircraft may also detect the first aircraft and in this way contribute to the resolution of a conflict. The degree to which the pilots of both aircraft are able to do so depends on the geometry of the conflict. In particular, it depends on the relative flight directions and speeds of the aircraft whether the pilot in aircraft 1 can see aircraft 2 within a horizontal angle θ_1 smaller than 60° from the forward direction and vice versa. This is illustrated in Fig. 78.11.

Figure 78.12 indicates that depending on the proportion v between the speeds of aircraft 2 and aircraft 1, for an angle ϕ of less than 60° between the aircraft's horizontal directions, the pilot(s) in *at most* one of the aircraft can see the other aircraft within a range of 120° around the forward direction. For values of the angle ϕ between 60° and 120° , one or both of the aircraft are visible within this range

Fig. 78.12 How do the angles θ_1 and θ_2 indicating the horizontal angle of aircraft 2 as seen from aircraft 1 and vice versa depend on the angle ϕ between the aircraft's directions and the proportion v between the speeds of aircraft 2 and aircraft 1?

to the pilots of the other aircraft, and for angles over 120° , both aircraft are visible within this range.

In line with the conservative approach, it is optimistically assumed that the conflict geometry is always such that the pilots of both aircraft could see the other aircraft as if they were within 60° of the forward directions. Under this assumption, the probability that at least the pilot of one aircraft detects the other aircraft is $1 - (1 - 0.56)^2 \approx 0.8$.

Under the also optimistic assumption that given successful detection of traffic, conflict detection, and resolution is always successful, the overall effectiveness of “see and avoid” is estimated to be 80%.

For further information of the “see and avoid” concept, see also BEKLAS 2002 and Air Traffic Safety Board ATSB.

78.7.3 Effectiveness of “Detect and Avoid”

In contrast to the aforementioned manned flight tests, the flight tests conducted in the VUSIL project are not suitable to derive effectiveness of the traffic detection subprocess: The UA pilots knew that during the flight tests, probably several conflicts would be encountered, and they were therefore intensively paying attention to other traffic.

Nevertheless, the effectiveness of traffic detection is judged to be much better than in the VFR context in manned aviation: All traffic in the neighborhood is

indicated on the radar screen as well as the “detect and avoid” display such that aircraft cannot be overseen due to the conflict geometry or factors impeding visibility (such as clouds, small size of the aircraft, or glare). Detection of traffic by the UA pilot only fails if:

- One of the systems (radar, data link, track system, “detect and avoid” system, displays) necessary for providing the traffic picture fails (which under assumption 1 of operational grade equipment would be relatively improbable).
- Surrounding traffic is not equipped with a working transponder (which, under the assumption that surrounding traffic is equipped with a transponder is also improbable).
- The UA pilot does not pay sufficient attention to the radar screen and the “detect and avoid” display.

Regarding the last point, it was suggested to notify the UA pilot regarding new and/or conflicting traffic by means of acoustic signals. All in all, the experts involved in the project judged that under the assumptions made, the effectiveness of traffic detection would be at least 99%.

The effectiveness of the UA pilot, supported by a radar screen and the “detect and avoid” tool, to recognize and resolve conflicts can be derived from the test flights conducted in the VUSIL project. During these test flights, a manned helicopter generated potential conflicts, which had to be recognized and resolved by the UA pilot. To safeguard the helicopter and the UAS, the helicopter was always flying 500 ft above the UAS, and the conflict resolving maneuvers were restricted to the horizontal plane. In this context, conflicts were situations in which the minimum horizontal separation of 0.5 NM would be infringed if the UAS would not change its direction. This notion of conflict corresponds with the near collision courses generated in the flight tests in Andrews 1991, briefly discussed above.

In the analysis of the data generated by the flight tests, it was investigated how many conflicts had been generated and which proportion was recognized and resolved successfully by the UA pilot, such that in the end no horizontal separation infringement occurred. Separation infringements due to system failures that would be improbable for operational grade equipment have been excluded. Under these assumptions, $N = 26$ conflicts occurred of which $n = 1$ was not recognized and resolved successfully. Estimating the conditional probability p that given detected traffic, the recognition and resolution of a conflict fails, using the maximum likelihood (ML) method (see a textbook on statistics, e.g., Sivia and Skilling 2006) provides the following result:

$$p_{\text{ML}} = n/N = 1/26 \approx 4\%.$$

An alternative, conservative, estimate concerns the largest value of the conditional probability p for which the event that of 26 conflicts at most one conflict is not recognized and resolved successfully is still credible. Taking for “still credible” the value of 5%, the conservative estimate $p_{\text{conservative}}$ follows from the equation:

$$(1 - p_{\text{conservative}})^{26} + 26p_{\text{conservative}}(1 - p_{\text{conservative}})^{25} = 0.05,$$

which results in the following conservative estimate:

$$p_{\text{conservative}} \approx 0.22.$$

Combination of the estimates regarding the effectiveness of conflict recognition and resolution with the judgement that traffic is detected in at least 99% of the cases yields the following estimates for the effectiveness of “detect and avoid”:

ML estimate of “detect and avoid” effectiveness: $0.99(1 - 0.04) \approx 95\%$

Conservative estimate of “detect and avoid” effectiveness: $0.99(1 - 0.22) \approx 77\%$

78.7.4 Conclusion of Safety Analysis

Based on the flight tests conducted in the VUSIL II project and the assumptions made, the effectiveness of “detect and avoid” estimated by the maximum likelihood method is 95%, which is considerably larger than the analogously estimated effectiveness of 80% for “see and avoid,” based on flight tests reported on in the literature.

A statistically more conservative approach determining the value for which the result of at most 1 of 26 conflicts not being recognized and resolved successfully is still credible, results in an overall estimate of the “detect and avoid” effectiveness of 77%.

In other words, although the maximum likelihood estimate indicates that “detect and avoid” is considerably more effective than “see and avoid,” the results and the number of flight test performed within VUSIL are not yet large enough to state with 95% confidence that the effectiveness of “detect and avoid” is at least 80%.

The following activities should further strengthen these results:

- Detailed estimate of the effectiveness of traffic detection by the UA pilot and available equipment (radar, data link, and further developed “detect and avoid” tool).
- Extend the set of flight tests to increase confidence further.
- Verify whether the ELOS principle is sufficient for regulatory approval.

78.8 Conclusions

The VUSIL projects show that the developed concept for the integration of UAS outside segregated airspace is valid. The positive results of the flight trials with the real flying UAS in a context of simulated traffic could be validated further in the flight trials with the real intruder. It must however be considered that the concept is not valid for a complete integration of UAS into nonsegregated airspace but that it is limited to uncontrolled airspace where a transponder is mandatory.

The proposed separation minimum of 0.5 NM horizontally/500 ft vertically between the UAS and the intruder was considered sufficient during the flight trials.

High speed differences between the UAS and intruder appear to be a problem. Possibly, the concept must be supplemented by a minimum speed requirement for UAS.

Also problematic is the visibility of UAS for pilots in a manned aircraft. Due to the fact that the UAS are normally smaller than manned aircraft, their visibility is low. Perhaps additional requirements like eye-catching coloring or strobe lights are necessary to enhance the visibility of the UAS. Additionally, the rules and regulations for conflict avoidance between aircraft must be addressed. Due to the technical support of the UA pilot, it could be reasonable that UAS are always responsible for the conflict resolution. This is not in line with today's ICAO rules and regulations, so that the regulations possibly have to be adapted.

The safety analysis indicates an equivalent level of safety for "see and avoid" and "detect and avoid" as used in the VUSIL program. Even under conservative assumptions, the "detect and avoid" capabilities of a UAS pilot are comparable with the capabilities of a pilot in a manned aircraft. An important assumption underlying this statement is however that the "detect and avoid" equipment is developed to similar standards as equipment in manned aviation.

The next step for the VUSIL program is to realize UAS flights outside segregated airspace and with operational equipment. To that end, the SAAFu software must be programmed according to certification standards. Also the technical solutions for the transmission of the radar data must pass a safety analysis to fulfill the high standards of manned civil aviation.

Acknowledgments The two projects in the VUSIL program were lead and conducted by the Research and Development Centre of DFS. The first project (VUSIL I) was sponsored by the German Ministry of Transport ("Bundesministerium für Verkehr, Bau und Stadtentwicklung"); the second project was financed by the German Federal Police in cooperation with the Ministry of Internal Affairs ("Bundesministerium des Inneren"). Both projects would not have been realized without their support.

Partners in the VUSIL I project were:

- DFS Deutsche Flugsicherung GmbH (DFS)
- ESG GmbH (responsible for the SAAFu)
- Federal Office of Defence Technology and Procurement (BWB)
- EMT GmbH (manufacturer of the UAS "LUNA")

Based on the results of the VUSIL I project, the VUSIL II project was set up. The project started in October 2009 and finished at the end of 2010. The partners of VUSIL I were again participating in the project. In addition the German Aerospace Centre (DLR) with the "Institute of Flight Guidance" in Braunschweig and the "Institute of Flight Psychology" in Hamburg, as well as Swiss UAV providing a helicopter type UAS (called "NEO"), completed the team. As external partner, the NATO department "Centre of Excellence for Operations in Confined and Shallow Waters (CEO CSW)" organized the flight trials. From the contracting body, the Federal Police, a helicopter participated as intruder for the UAS. The German Federal Aviation Office (LBA) attended the projects as observer.

79.6 Conclusion 1951

References 1952

Abstract

Unmanned aircraft systems (UAS) have become increasingly prevalent and will represent an increasing percentage of all aviation. These unmanned aircraft are available in a wide range of sizes and capabilities and can be used for a multitude of civilian and military applications. However, as the number of UAS increases, so does the risk of midair collisions involving unmanned aircraft. This chapter aims to present one possible solution for addressing the midair collision problem in addition to increasing the levels of autonomy of UAS beyond waypoint navigation to include preemptive sensor-based collision avoidance. The presented work goes beyond the current state of the art by demonstrating the feasibility and providing an example of a scalable, self-contained, RADAR-based, collision avoidance system. The work can be divided into two sections: RADAR hardware and collision avoidance algorithms. The technology described herein can be made suitable for use on a miniature (maximum takeoff weight <10 kg) UAS platform. This is of paramount importance as the miniature UAS field has the lowest barriers to entry (acquisition and operating costs) and consequently represents the most rapidly increasing class of UAS.

79.1 Introduction

Modern unmanned aircraft systems (UAS) are available in a wide range of sizes from the palm-sized “Black Widow” to the 39.8 m wingspan Global Hawk (AeroVironment 2013; U.S.DOD 2012). Most modern UAS are generally limited to autonomously following preprogrammed waypoints or executing preprogrammed commands while under the supervision of a human operator. Only recently are UAS beginning to operate with some level of independence from preprogrammed commands as demonstrated by Shen et al. (2011) in which a miniature quadrotor unmanned aerial vehicle (UAV) autonomously constructs a map of an indoor environment. However, these exercises have largely been limited to computer vision and laser rangefinder-based systems operating in an indoor environment. One of the next steps for UAV technology development is to enable unmanned systems to perform the same tasks in an outdoor environment with a similar level of safety and autonomy. This level of autonomy is challenging in many ways due to the different sensor arrangements required when transitioning to the outdoor environment. This sensor paradigm shift is typically necessitated by the fact that many of the sensors used in indoor laboratory conditions are not well suited for the demands of UAV operation in an outdoor environment due to the longer ranges, higher speeds, and environmental factors normally encountered. More importantly, the threats to safe operation are dramatically different in regulated airspace wherein the risk of a collision between a manned aircraft and a UAS exists.

There are a number of existing solutions to address the midair collision problem. These solutions are typically divided into two categories which may be combined

to form a complete collision avoidance solution: transponders and noncooperative sensors.

There are a number of transponder solutions including *Traffic Collision Avoidance System* (TCAS), *Portable Collision Avoidance System* (PCAS), *FLight ALARM* (FLARM), and *Automatic Dependent Surveillance and Broadcast* (ADS-B) (FAA 2012b; ZAON 2007; Flarm.Inc 2008; ADS-B 2011). The TCAS transponders (currently required in the United States for turbine-powered aircraft with more than 10 seats) function by interrogating other TCAS transponders to determine heading, velocity, and altitude information while simultaneously responding to TCAS interrogations from opposing aircraft (FAA 2011). If a collision is detected, the TCAS automatically determines a collision avoidance maneuver and presents the information to the pilot via a cockpit display. TCAS is an effective solution for manned aircraft; however, the cost of a typical installation is often prohibitive for many general aviation craft, which comprise a substantial portion of the aircraft population (AOPA 2013b; SAI.inc 2011). To address this issue, PCAS receivers have been made available for under 2000 USD (ZAON 2011). PCAS receivers achieve this cost reduction, in part, by the elimination of the transmit functionality present within TCAS transponders. In essence, PCAS receivers listen for TCAS signals and determine the risk of collision without transmitting their own location. In this fashion, PCAS-equipped aircraft can actively avoid TCAS-equipped aircraft. However, the passive nature of PCAS makes it unsuited for avoiding collisions with other PCAS-equipped aircraft, nor does it allow TCAS-equipped aircraft to detect or avoid PCAS-equipped aircraft. There are a wide range of flight regimes present throughout aviation including many cases where aircraft routinely operate in close proximity to each other without the risk of a midair collision. Manned gliders are useful examples of this type of flight. The FLARM transponder was developed to provide a collision avoidance solution for aircraft operating under these conditions. FLARM utilizes barometric pressure and GPS data to estimate the host vehicle's location and velocity vector. It then broadcasts this data to the airspace while listening for position and velocity information from other FLARM devices. If a midair collision situation arises, the FLARM transponder alerts the pilot who can then take action if necessary. The final transponder system, ADS-B, is currently poised to supersede secondary surveillance RADAR (which is based on RADAR transponders located onboard aircraft) as the primary air traffic control method. ADS-B operates in a manner similar to FLARM but adds additional features such as weather and terrain data broadcast by ground stations (ADS-B 2011). While ADS-B use is not currently required, the FAA aims to make it mandatory for all aircraft by January 1, 2020 (FAA 2010). The common theme with all the transponder solutions is the need for cooperative infrastructure if collisions are to be successfully avoided.

In contrast to the cooperative nature of transponders, sensor-based collision avoidance otherwise known as "sense-and-avoid" (SAA) systems typically do not require cooperation between aircraft to effect a useful collision avoidance solution. There are a number of prototype systems utilizing a wide range of sensor technologies. These technologies include acoustic sensors, laser rangefinders, and camera systems (both visible and infrared wavelengths). This dissertation describes the development of an additional SAA system based on radio detection and ranging

(RADAR) (Selex [2011](#); SARA.inc [2011a, b](#); Watanabe et al. [2007](#)). More specifically, this dissertation investigates the use of RADAR technology for the detection and identification of miniature (MTOW <10 kg) UAVs. Additionally, vertical and horizontal collision avoidance maneuvers are compared and a computationally efficient method for collision avoidance is proposed and evaluated.

79.1.1 Why RADAR?

RADAR has a well-established history dating back to Heinrich Hertz's initial experiments in 1886. The publication of Heinrich Hertz's book documenting his experiments forms the foundation of modern radio concepts (Hertz [1893](#)).

The use of RADAR for active detection of objects was first demonstrated by Christian Hulsmeyer who created a device he called the Telemobiloscope. This device, patented in 1904, transmitted broadband radio frequency (RF) energy in a wide pattern while observing reflections with a narrow-beam antenna which could be directed in order to make observations of a specific area. Originally intended for use in an anti-collision role in a maritime environment, the device never saw widespread acceptance (Bauer [2005](#)).

RADAR was significantly advanced during the 1930s and 1940s in the United Kingdom, Germany, and the United States. The demands of World War II facilitated many innovations, and RADAR technology advanced rapidly during this period. Previously, only limited to ground installations, RADARs soon became small enough to install in aircraft (Goebel [2013](#)). After World War II RADAR applications in the civilian domain continued to increase, particularly with regard to civilian aviation. This trend continues to this day (Britannica [2013](#)).

RADAR-based sensors have a number of distinct advantages when compared with other sensor types such as LASER rangefinders, computer vision/focal plane arrays, and acoustic sensors. Unlike optical systems, RADARs are not affected by sunlight, smoke, fog, dust, and other factors that typically affect optical wavelengths. Furthermore RADARs typically have improved directionality and range characteristics when compared with acoustic systems; additionally, RADAR systems can be used onboard aircraft with high levels of acoustic noise and can detect aircraft with little to no acoustic noise emissions (something that is increasingly important as the number of UAS using electrical propulsion increases). At present, no other noncooperative sensor type provides all these capabilities (Tait [2006](#)).

79.1.2 Existing Challenges

There are a number of existing challenges that preclude the widespread adoption of collision avoidance RADARs on UAS. The first challenge is the physical volume and mass of many RADAR systems as most currently available RADAR systems are far too large for widespread UAS implementation.

Furthermore, most airborne RADAR systems currently installed on UAS are designed for use in air-to-ground modes either for mapping or for target detection/tracking purposes. An example of such a system is ImSAR's NanoSAR line of synthetic aperture RADARs (SAR) (ImSAR.inc 2011; Grumman 2013). This dedication to the air-to-ground operating mode often inhibits effective use when attempting to use the RADAR for air-to-air operations. This is because additionally air-to-air RADARs must often incorporate ground clutter rejection features not typically present in dedicated air-to-ground RADARs.

Power consumption is another area that must be addressed before widespread collision avoidance RADAR becomes a reality. Many airborne RADARs require hundreds of watts of electrical power to operate. This is often unavailable on small UAS. There are, however, some small RADAR systems with low electrical power consumption. The NanoSAR B utilizes 30 W of electrical power.

Finally, one of the more important issues that must be addressed is the prohibitive cost of many airborne RADAR solutions. Existing systems can easily cost upwards of 100,000 USD and greatly exceed the cost of UAS platforms with MTOWs <50 kg (ImSAR.inc 2011).

The remainder of this chapter is organized as follows: Sect. 79.2 describes a number of critical decisions that must be made when designing a RADAR; in addition, some example hardware designed at the University of Denver is presented. Section 79.4 details the ability of the RADAR prototype to localize targets and experimental results are presented. Section 79.5 describes the collision detection and pulsed evasion method, and simulations are provided to demonstrate the efficacy of the proposed approach.

79.2 RADAR Hardware

There are a number of critical design decisions that must be made regarding any RADAR architecture used in various aircraft scales. These decisions have a direct impact on operating parameters such as maximum range, minimum range, range resolution, input power requirements, and required timing resolution. This section will detail the critical design decisions and provide justifications for each.

79.2.1 Continuous Wave vs. Pulsed Operation

RADAR systems can generally be divided into two broad categories depending on the nature of the transmit energy: pulsed and continuous wave (CW). In a pulsed RADAR architecture, the transmitter generates RF pulses of a specified duration and transmits this energy towards the region under observation. These pulses then reflect off an object (if present) and a portion of the energy returns to the receive antenna. The range to the target object is determined by the following equation:

$$R = \frac{cT}{2} \quad (79.1)$$

Table 79.1 Example pulsed
RADAR performance

| Parameter | Value (m) |
|-------------------|-----------|
| Unambiguous range | 7,494.8 |
| Range resolution | 79.6 |
| Minimum range | 74.9 |

where the range, R , is defined in terms of the speed of light, c , and the elapsed time between the transmission of an individual pulse and its reception, T .

The rate at which these pulses are transmitted is referred to as the pulse repetition frequency (PRF). In pulsed RADAR systems, any subsequent pulse must be transmitted after the arrival of the previous pulse. Failing to do so will lead to range ambiguities. Therefore, the PRF has a direct impact on the maximum distinguishable range (otherwise known as the unambiguous range), R_{unamb} , which is described by

$$R_{unamb} = \frac{c}{2(PRF)} \tag{79.2}$$

Pulsed RADARs are typically limited in the minimum detectable range as the receive circuitry is deactivated during the transmit pulse, since close-range reflections (i.e., high-power reflections) would saturate and possibly destroy the highly sensitive receiver electronics. The lower bound on this minimum detectable range is defined by

$$R_{min} = \frac{c(T_{tx} + T_{config})}{2} \tag{79.3}$$

where T_{tx} is the duration of the transmit pulse and T_{config} is the time required to enable the receiver. Thus, for moderate pulse widths, the minimum detectable range can easily be in the region of tens of meters.

The range resolution of pulsed RADARs, ΔR_{min} (in the absence of more advanced techniques, e.g., intra-pulse modulation and pulse compression), is shown below:

$$\Delta R_{min} = \frac{cT_{tx}}{2} \tag{79.4}$$

Given (79.1)–(79.4) above, a theoretical RADAR system with a minimum T_{tx} of 500 ns, a T_{config} of 11 ns, and a PRF of 20 kHz will have the properties described in Table 79.1.

There are a large number of UAS with dimensions significantly smaller than the critical parameters: minimum range and range resolution. Furthermore, the design of a pulsed RADAR system with acceptably small minimum range and resolution characteristics is prohibitively expensive. This is due to the high power needed during the short pulses and the fast timing requirements of such a system.

Continuous wave (CW) RADARs operate by continuously illuminating a target object with RF energy. Unlike pulsed RADAR systems, CW RADARs tend to operate using lower overall power levels (up to three magnitudes lower power for similar range performance (Wallace et al. 2010)) and determine range to

objects using some form of frequency modulation as opposed to pulse timing. This allows for simpler circuitry due to the elimination of tight timing requirements. Additionally, CW RADARs are capable of providing arbitrary range resolutions and no limit on the theoretical minimum range.

The simplest CW RADAR configuration, Doppler RADAR, broadcasts a continuous signal towards the area of interest. If an object is present in the area of interest, a portion of the transmit energy is reflected back towards the receiver where it is then down-converted (multiplied in the frequency domain) to produce the frequency of interest, otherwise known as the “beat frequency” or “intermediate frequency” (IF) and is described by

$$F_{\text{beat}} = F_{tx} - F_{rx} \quad (79.5)$$

where F_{rx} is the frequency of the received signal and F_{tx} is the frequency of the transmitted signal. F_{rx} is determined by the radial velocity v of the target object relative to the RADAR system (assuming colocated transmit and receive antennas). F_{rx} is generally defined by

$$F_{rx} = F_{tx} \left(\frac{1 + \frac{v}{c}}{1 - \frac{v}{c}} \right) \quad (79.6)$$

Simplifying (79.6) for terrestrial applications where generally $v \ll c$ results in

$$F_{\text{beat}} \approx 2v \frac{F_{tx}}{c} \quad (79.7)$$

Unmodulated CW RADARs have no means to determine the range between the RADAR antenna and the target object. Furthermore, unmodulated CW RADARs are incapable of detecting stationary targets as F_{beat} results in a direct current (DC) signal which is lost due to the alternating current (AC) coupling between the RF front end and the amplifier stages. Furthermore, most CW RADAR front ends typically produce a DC signal regardless of the presence of a target due to leakage between the receiver and transmitter.

Nevertheless, a number of methods exist for range measurement in CW RADARs and are generally divided into two categories: frequency-modulated continuous wave (FMCW) and stepped frequency continuous wave (SFCW) (of which frequency-shift-keyed continuous wave (FSK CW) is a narrowband subset). FMCW RADARs operate by modulating the transmit frequency, typically in a triangular fashion. Due to the finite speed of light, F_{tx} will be offset from F_{rx} by an amount proportional to the range. In general terms, the range between the RADAR antenna and the target object is defined by

$$R = \frac{2cT F_{\text{beat}}}{BW} \quad (79.8)$$

where T is period of the frequency modulation and BW is the bandwidth. Unlike unmodulated CW RADARs, FMCW RADARs are capable of detecting both the

Table 79.2 CW RADAR comparison

| Parameter | Doppler | FMCW | FSKCW | X-band |
|----------------------------|------------------|------------------------|--------|--------|
| Range measurement | – | Yes | Yes | K-band |
| Velocity – range ambiguity | – | Yes | No | |
| # of receiver channels | 1 | 1 | 2 | |
| Bandwidth requirements | Single frequency | 500 MHz | 5 MHz | |
| Modulation type | – | Triangular or sawtooth | Square | |

presence and range of stationary targets. However, background clutter such as the terrain is also present in the output data.

FSKCW RADARs address this issue by replacing the linear, triangular modulation of FMCW RADARs with a square-wave modulation of the transmit frequency. F_{beat} is then sampled synchronously with the modulation. The transmit frequency modulation combined with the synchronous sampling of the received signal effectively produces two unmodulated CW RADAR channels separated by a few MHz (BW): IF_A and IF_B . (79.7) indicates that for any given moving target, F_{beat} will be marginally different for IF_A and IF_B . This marginal difference in frequency appears the same when used for velocimetry purposes but is fundamental for ranging as it manifests itself as a phase shift in the time domain. The range to the target object can then be inferred from the phase difference between IF_A and IF_B ; see (79.9) where ϕ_n is the phase of the IF_n (Skolnik 1981):

$$\text{Range} = \frac{c(\phi_A - \phi_B)}{4\pi BW} \tag{79.9}$$

FSKCW RADARs offer the same benefits of other CW RADAR types, namely, no minimum range and excellent range resolution, in addition to the benefits offered by unmodulated CW RADAR types (excellent ground clutter rejection and low overall transmit power requirements). However, the maximum practical range (in the absence of transmit power and receiver sensitivity limitations) is defined by the range corresponding to a 180° phase shift. As with pulsed RADAR systems, this range is defined as the unambiguous range and is described, in this case, by (79.10) (Skolnik 1981):

$$R_{\text{unamb}} = \frac{c}{2BW} \tag{79.10}$$

A comparison of the various CW RADAR types discussed in this section is shown in Table 79.2.

79.2.2 Transmit Frequency Selection

The transmit frequency, F_{tx} , is selected based on a compromise between the following parameters: atmospheric absorption, ratio between the wavelength and

Fig. 79.1 Atmospheric absorption of RF energy (ITU 2012)

the target object size, availability of components, desired range resolution, desired antenna size, and processing speed requirements of the intermediate frequency.

Atmospheric absorption of microwave frequencies (see Fig. 79.1) plays a role in frequency selection since absorption increases dramatically as a function of frequency. Countering this effect requires a substantial increase in power and consequently the size of most RADAR components. A cursory examination of Fig. 79.1 indicates that an X-band RADAR system (center frequency 10.5 GHz) will have a round-trip atmospheric absorption of 0.2 dB/km, while a comparable K-band RADAR system (center frequency 24 GHz) will have an absorption figure of over 2 dB/km. This effectively means that if all other system parameters are equal, then an X-band RADAR system will have a range 10 times greater than a comparable K-band RADAR. In practice, however, there are more contributing factors.

Transmit frequency selection also has a direct impact on the velocity resolution and data acquisition time. As characterized by (79.7), the Doppler shift, F_{beat} , is directly proportional to F_{tx} . If F_{tx} increases, maintaining the same velocity resolution requires that the ADC sampling rate also increase by the same proportion.

This has the effect of reducing the time required to acquire the relevant signal samples required for processing the RADAR data.

Microwave antenna sizes are also highly dependent on F_{tx} . A RADAR system designed for a mobile platform typically has limits placed on the amount of electrical power available and the overall volume and mass allocated to the RADAR payload. To reduce the required RF transmit power while maintaining the same range performance, an antenna with a narrow main lobe must be selected. However, to reduce the size of the main lobe, the physical antenna size must increase. An example of this relationship (in the case of a parabolic antenna) is described by (79.11) (Minoli 2009):

$$\Theta_{-3\text{ dB}} = \frac{k\lambda}{\text{diameter}} \approx \frac{70\lambda}{d} \quad (79.11)$$

where $\Theta_{-3\text{ dB}}$ is the -3 dB main lobe beamwidth, k is the steepness taper constant (typically 70 for parabolic antennas), λ is the operating wavelength, and d is the diameter of the antenna's reflector. Therefore, to achieve the same beamwidth, a RADAR operating at 10.5 GHz must have an antenna diameter approximately 2.3 times larger than a comparable RADAR operating at 24 GHz.

79.3 The Proposed RADAR Sensor

The University of Denver's research group has developed a number of generations of miniature RADAR sensors. A description of the earlier revisions of these systems can be found in (Moses et al. 2011). This section provides a description of the second-generation RADAR sensor hardware.

The second-generation RADAR prototype (see Fig. 79.2) makes several of significant improvements over the first generation with the most important improvement being the addition of FSKCW range detection. Other important improvements include the addition of variable gain amplifiers to expand the dynamic range of the analog section, variable cutoff frequency filters to facilitate a wide range of target velocities, and improved noise rejection due to revisions in the analog section layout. The specifications of the complete generation 2 RADAR sensor are shown in Table 79.3.

79.3.1 Generation 2 Microwave Section

The microwave section of the generation 2 RADAR sensor is comprised of a commercially available, FSKCW microwave front end and antenna module (Microwave Associates MDU4210) (Solutions 2013). This module is based on a dielectric resonant oscillator (DRO) and is electronically tunable using a varactor diode. In many commercial applications, these modules are used for motor vehicle traffic detection.

Fig. 79.2 Generation 2
RADAR sensor

Table 79.3 Generation
2 specifications

| | |
|--------------------|-------------------|
| System mass | 150 g |
| System dimensions | 10 × 10 × 10 (cm) |
| Power consumption | 4.5 W |
| Input voltage | 5–6 VDC |
| Transmit frequency | 10.587 GHz |
| Transmit bandwidth | 5 MHz |
| Transmit power | 0.4 mW |

79.3.2 Generation 2 Analog Section

The generation 2 analog electronics (see Fig. 79.3) is comprised of three separate printed circuit boards of two categories: signal switching and signal amplification. Since FSK modulation requires rapid switching between two adjacent frequencies (typically separated by less than 5 MHz), two amplifier trains are required due to the finite bandwidth of the electronics. These amplification chains (located on separate PCBs to aid in serviceability and cross-talk reduction) function as follows: The RADAR IF signal first passes through a band-pass filter to strip away the higher-order mixing harmonics and the DC offset. The relatively weak IF signal is amplified by an operational amplifier-based non-inverting amplifier with a digital potentiometer feedback element. The output of this amplifier is AC coupled with another identical variable gain amplifier. This output signal is then passed through a variable cutoff frequency low-pass filter tuned by a digital potentiometer.

Up to this point, the hardware described is capable of obtaining target information while the target is within the antenna main lobe which is fixed relative to the RADAR sensor. The fixed main lobe of the first two generations is problematic since

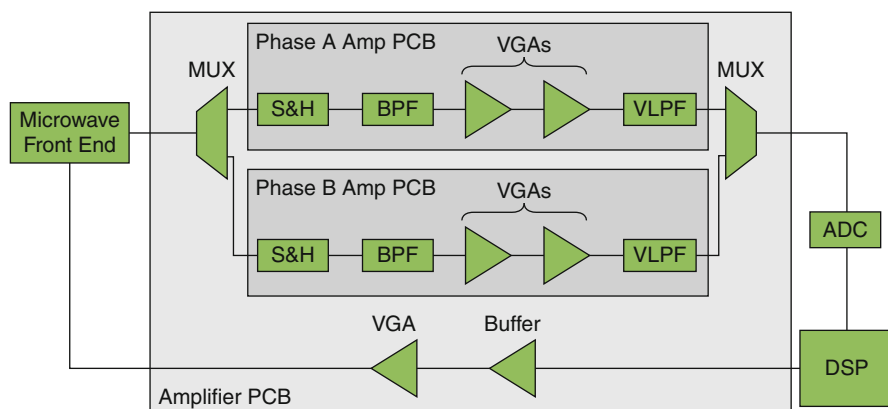

Fig. 79.3 Generation 2 electronics block diagram

they are not able to scan an area to provide a wider field of view. More importantly, they are not able to provide information regarding the relative bearing of any objects of interest.

There are a number of popular methods for obtaining target bearing information using RADAR systems including electronic beam steering, monopulse, interferometry, and mechanical scanning. Electronic beam steering utilizes an array of emitters with variable phase shifters to electronically steer the antenna main lobe. While there are a variety of methods that can be used to accomplish this, electronic beam steering is typically the most complex and most expensive solution for obtaining relative bearing information on RADAR targets (Tait 2006).

The second method, amplitude comparison monopulse (ACM) RADAR, is constructed using between 2 and 4 receive antennas arranged in a row for single axis measurement or quadrant for dual axis measurement, respectively. The target bearing information manifests as a difference in received signal strength in the antenna array. ACM RADAR types can obtain very accurate relative bearing information, but typically have limited observation angles due to high antenna gain. Therefore, ACM RADARs are most often used to track targets which have already been acquired with a search RADAR. The third method, phase comparison monopulse (PCM), is similar to the ACM architecture in that it requires an array of receive antennas. However, while ACM measures the difference in received signal strength, PCM RADARs measure the phase shift caused by the difference in the free space path length between the antenna array elements and the target of interest. Larger off-boresight angles increase the difference in the path length. A diagram of the PCM RADAR operation is shown in Fig. 79.4.

The final method, mechanical scanning, is when the entire antenna system is mechanically rotated throughout the observation angles in order to obtain target bearing information. Mechanical scanning may be used in combination with any of the above methods or may be used by itself. The primary disadvantage is the increased time required to obtain target bearing information. An additional

Fig. 79.4 Phase comparison monopulse diagram

disadvantage is the addition of a moving component (the antenna and the antenna gimbal/servo assembly). However, mechanical scanning allows the RADAR prototype described in this chapter to be utilized without completely redesigning the antenna, microwave, electronic, and software components. Mechanical scanning has an additional advantage in that narrow-beam (and consequently high-gain) antennas can be used without decreasing the sensor's field of regard as would be necessary using interferometry or monopulse architectures.

Given the above, mechanical scanning is used for the prototype to obtain target azimuth information. The result is the generation 2a hardware shown in Figs. 79.5 and 79.6. The antenna, microwave, and computing hardware of the generation 2a RADAR sensor are identical to the generation 2 hardware, the only addition being the mechanical components and electrical modifications required for mechanical scanning.

Mechanical scanning is accomplished by first separating the XMOS processor board (XMOS XC-1a) from the antenna, microwave, and analog components. This reduces the reciprocating mass by 50 g and improves antenna pointing agility. Additional benefits include the physical separation of the high-gain electronics from the high-frequency digital signals present on the XC-1a board.

The antenna, microwave, and analog components are then mounted on a plastic structure (henceforth referred to as the antenna mount) which provides mechanical stability and maintains the relative positions of the aforementioned components. This plastic structure is then directly attached (using two M3 screws) to a Hobbico CS-80 servo (1999) which serves to physically rotate the antenna mount through a 90° range in as little as 0.29 s. The addition of the servo increases the overall sensor mass by 150 g and the total power consumption by 1.3 W.

As with most radio control (RC)-type servos, the position feedback in the CS-80 is internal to the servo, and users provide position commands to the servo using

Fig. 79.5 Generation 2a
RADAR sensor front view

reference)

Fig. 79.6 Generation 2a
RADAR sensor rear view
(with 6'' (15.2 cm) size
reference)

pulse position modulation (PPM) signals with no feedback regarding the servo's actual position. Allowing the RADAR processor to monitor the position of the servo using the servo's own position encoder eliminates the need for an additional, external antenna position encoder and reduces the system complexity and overall mass. The CS-80 servo, as with most RC servos, utilizes a potentiometer directly coupled to its mechanical output shaft. The potentiometer is configured in such a way to produce an analog voltage directly proportional to the physical position of the shaft. Extracting this signal involves drilling a hole through the servo case and then routing a wire from the potentiometer's wiper to the RADAR processor's analog to digital converter (ADC). The 16-bit LTC1865 ADC used in the prototype has a voltage resolution of $76\text{ }\mu\text{V}$ which results in an antenna position resolution of 0.01° .

79.4 FSKCW Simulation and Ranging Experiments

As mentioned earlier, unmodulated CW (otherwise known as Doppler) RADARs are incapable of determining range. To address this limitation, some form of modulation must be added; the generation 2a RADAR hardware described in the previous section utilizes FSKCW modulation as described in Sect. 79.2. Range to the target is determined by comparing the phase of the two IF signals at the peak frequency. This process is illustrated in Fig. 79.7.

In practice, however, the phase measurements output by the RADAR hardware are noisy and, therefore, must be filtered prior to use. The targets of interest typically appear to be constricted by Newtonian mechanics and a simple scalar Kalman filter can be used to filter the phase measurements. Prior to hardware implementation, some amount of information regarding the sensor noise parameters must be determined. This is done through repeated executions of a non-iterative MATLAB simulation of the FSKCW ranging process. The simulation aims to simulate the processing that must be performed on the IF signals to determine the range.

The simulation begins by generating two sine waves representing the IF output corresponding to a point target. The frequency is determined by the target velocity, and the phase difference is determined by the target range. These signals are digitized and a Hamming window is applied to suppress side lobes. The resulting signals are shown in Fig. 79.8. Additive white Gaussian noise (AWGN) is then introduced to both phases such that the signal to noise ratio (SNR) is 3 dB. The result is shown in Fig. 79.9.

The methodology described in Fig. 79.7 is applied and the resulting data is analyzed over a number of non-iterative simulation runs to determine the variance of the measured phase noise. This value is used to tune the gains of an online scalar Kalman filter running in-line with the FSKCW simulation. Figure 79.10 shows comparison of the filtered (green) and unfiltered (blue) phase data for 60 simulation runs. The filter converges after 8 phase measurements; if the IF signal is sampled at

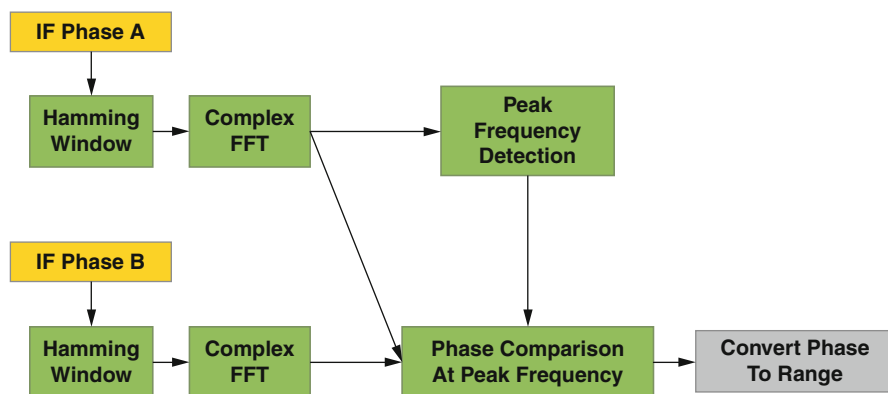

Fig. 79.7 FSKCW ranging methodology

Fig. 79.8 Simulated IF signal without noise

15 kHz, this would take approximately 0.55 s. After convergence, the typical phase error is -0.00536 radians. This is equivalent to a range error of 0.26 m.

Experimental validation of the ranging method involves the use of a moving target as relative motion of the target is a requisite of FSKCW ranging. In this case an aluminum dihedral reflector with an RCS of 2 m^2 is mounted on an O-scale model train; see Fig. 79.11. The train traverses along an oval track, while the RADAR is arranged such that the main lobe illuminates a linear section of the track. The test setup is illustrated in Fig. 79.12.

The test scenario is complicated by the presence of multipath reflections from objects within the testing room and the detection of the target by both the main and side lobes when the target is outside the area of interest. These conditions

Fig. 79.9 Simulated IF signal with noise

Fig. 79.10 Simulated phase data

necessitates the use of target discrimination to preselect the phase samples that are admitted into the Kalman filter. This target discrimination process consists of two primary metrics: target direction and velocity.

Throughout the testing, the train target traverses the track in a clockwise fashion. From the RADAR’s perspective, the target is always heading away from the antenna. This receding motion gives rise to a negative phase measurement (while the converse will give rise to a positive phase shift). This filter effectively eliminates the half of the track through which the train is heading towards the RADAR.

Fig. 79.11 O-scale train with Doppler target for FSKCW experimental validation

Fig. 79.12 FSKCW ranging experimental validation: test setup

Velocity filtering further reduces the measurement selection to periods in which the target's Doppler shift falls within a particular FFT bin. This condition is met when the target is traversing the region of interest and the antenna Poynting vector is colinear with the target motion vector.

The test begins by configuring the train's drive system to move the train and target assembly at 0.5 m/s, the velocity is then verified by a stopwatch. The RADAR system is then aligned to view the region of interest. The filtered phase data is then collected and stored for further analysis.

Figure 79.13 shows 36 range measurements gathered using this measurement setup. The region of interest bounds (represented as phase) are displayed as green and blue horizontal lines. The red trace is the measured phase data after the real-time target discrimination and range filtering process. The sinusoidal behavior of the measurement is explained by the target discrimination process. When the target enters the region of interest, the measured phase is relatively low. The target then moves away from the RADAR, thus causing the range to increase monotonically. This process ends when the target leaves the region of interest. The target goes around the track and the phase measurements are rejected due to the target

Fig. 79.13 FSKCW ranging experimental validation: results

discrimination process. When the target completes its circuit and reenters the region of interest, the measured phase value is low again and the filtered value is pulled down to reconcile the filter output with the new measurements before following the target's increasing range again.

It should be noted that as the region of interest is small, the prediction stage of the Kalman filter is omitted in these tests. This essentially assumes a stationary target. When transitioning to targets of a more dynamic nature, the Doppler shift in addition to the measurement timestamp can be used to provide a more accurate estimate of the target's current range. The phase estimate would then be of a form described by

$$\hat{\phi} = \frac{4\pi \left(R_{(k-1)} + c \left(\frac{F_{IF}}{2F_T} \right) (T_k - T_{(k-1)}) \right)}{c} \quad (79.12)$$

where $\hat{\phi}$ is the predicted phase shift and $R_{(k-1)}$ represents the previous range value taken at time $T_{(k-1)}$ ($R_{(k-1)}$ is obtained from the output of previous time steps).

79.4.1 Azimuth-Enabled RADAR Evaluation

Previous sections within this chapter have detailed the hardware and software methods utilized for performing FSKCW ranging against moving targets. However, relative bearing information is unavailable without one of the methods discussed in Sect. 79.3.2. This section first describes the hardware developed to test the generation 2a RADAR sensor. The software methods for determining target azimuth are then discussed. Finally, the accuracy of the RADAR is quantified.

79.4.2 RADAR Targets

The evaluation performed in Sect. 79.4 demonstrates the FSKCW concept; however, more accurate evaluation benefits from the use of RADAR targets with a more concentrated distribution of reflecting surfaces (by comparison, the reflecting surface of the train target is distributed over the length of the target which is approximately 0.53 m long). To address these issues and to evaluate the RADAR using multiple targets, two quad-dihedral reflectors are used; see Fig. 79.14.

The use of well-documented geometries (see Figs. 79.15 and 79.16) in the construction of these reflectors allows for the application of standardized formulas to determine the reflector RCS; see (79.13) and (79.14) (Gallman 2005):

$$\sigma_{\text{panel}} = \frac{4\pi a^2 b^2}{\lambda^2} \quad (79.13)$$

$$\sigma_{\text{dihedral}} = \frac{8\pi a^2 b^2}{\lambda^2} \quad (79.14)$$

where a is the width of the panels, b is the height, λ is the wavelength of incoming radiation, and σ is the RCS.

Applying Eqs. 79.14 and 79.13 to the reflectors shown in Fig. 79.14 produces the RCS values shown in Table 79.4.

Since FSKCW RADARs can only detect objects with some motion relative to the RADAR antenna, the reflectors in Fig. 79.14 are mounted on a Pololu “3pi” line following robot; see Fig. 79.17. This arrangement allows for reflector motion paths to be created using any high-contrast line, which the vehicle follows using optical sensors at speeds up to 0.9 m/s (Pololu.Inc 2013).

Within this research, two oval tracks are created using 19 mm wide electrical tape on a white poster board substrate. The dimensions of the tracks are shown in Fig. 79.18.

79.4.2.1 Azimuth Measurement Methodology and RADAR Interface

The generation 2a RADAR hardware uses mechanical scanning to direct the main lobe of the antenna. Throughout the research, the angular width of the path swept by the antenna is 90° with the period of the sweep being set to 2 s. RADAR range measurements are not synchronized with the motion of the antenna, and samples are continually gathered at the RADAR’s maximum rate. The maximum range measurement rate is limited by the FSKCW processing method which requires the use of floating point FFTs. Unfortunately, the XMOS hardware does not possess a floating point unit, and floating point operations are emulated using the XMOS’ fixed-point hardware. This causes a performance reduction, thus limiting the RADAR sample update rate to approximately 7 Hz (a measurement period of 0.14 s). As a result, during each measurement period, the antenna rotates 6.3° and each 90° antenna sweep has, on average, 14.3 range measurements. Before and

Fig. 79.14 Quad-dihedral RADAR reflectors (with 6'' (15 cm) size reference)

Fig. 79.15 Panel RCS geometry (Gallman 2005)

after each range measurement period, the antenna position is sampled and the range measurement is associated with the linear interpolation of these angles.

Each range measurement also has an associated “activity metric” which is simply the sum of the FFT bin magnitudes (excluding bin 0 which represents the DC component of the IF signal). When the activity metric values are arranged spatially and plotted, the local maxima of the plot represents individual targets if the local

Fig. 79.16 Dihedral RCS geometry (Gallman 2005)

Table 79.4 RADAR reflector RCS

| | Large reflector | Small reflector |
|-------------------------------------|-----------------|-----------------|
| Panel peak RCS (m ²) | 3.73 | 2.23 |
| Dihedral peak RCS (m ²) | 1.87 | 1.02 |

maxima amplitude exceeds the noise threshold for the activity metric values. The noise threshold is determined experimentally by directing the RADAR towards an area with no Doppler activity and increasing the threshold value to eliminate false detections. For the purposes of this research, each local maxima is associated with a particular target, and the azimuth values are filtered using a scalar Kalman filter in the same manner that the FSKCW phase values are filtered.

Figure 79.19 is a screen capture of the laptop-based RADAR interface developed for this research and shows a plot (in the lower left) of the activity metrics for a scenario with two targets. Written in the *Processing* programming language, the RADAR interface software serves to provide a real-time visual representation of the RADAR data and record the RADAR data to a file for off-line analysis.

79.4.2.2 Combined Range and Azimuth Measurement

Combined range and azimuth measurements are made using a series of small- scale scenarios in which the target vehicles described in Sect. 79.4.2 are arranged and then set in motion about oval tracks also described in Sect. 79.4.2. Throughout all scenarios, the target vehicle velocity is approximately 0.5 m/s and is measured by using a quartz chronograph (Seiko SDNA57) to determine the time the target vehicles require to make a circuit of their respective tracks.

RADAR target (with 6''
(15 cm) size reference)

Fig. 79.18 RADAR
reflector path dimensions

Figure 79.20 shows the physical layout of the RADAR and the target vehicles during the first evaluation scenario. Scenario 1 is performed with all test elements located in a reinforced concrete room with no effort to reduce multipath reflections. For this scenario three tests are performed. First, target 1 is placed within the environment and data is gathered for 5 min, while target 1 is traversing the track in a clockwise direction. The second test is performed by introducing target 2 into the environment along with target 1. Throughout the second test, target 1 is stationary and target 2 is moving around its track in a counterclockwise direction. As with the first test, data is gathered for 5 min. The third and final test is performed with both target 1 and target 2 moving. As with the previous tests, data is gathered for 5 min.

Figure 79.21 displays the results from scenario 1, test 1, with the view centered around target 1. The path made by the target vehicle is indicated by the dashed

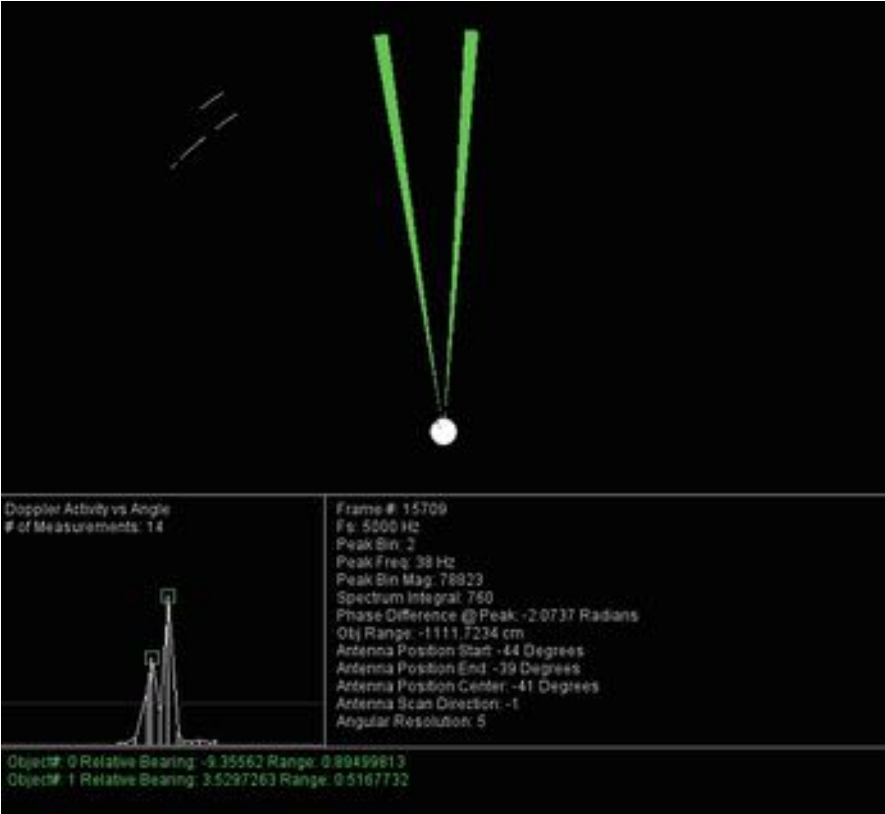

Fig. 79.19 RADAR interface screenshot

oval. However, the reflector is not a point target and physically sweeps the area bounded by the two solid ovals. The RADAR measurements are shown (after filter convergence) as a scatter plot with each measurement being the result of a single 90° antenna sweep. The mean and standard deviation of the measurements are also plotted with the X and Y axis mean values shown in green and the standard deviation shown in magenta and presented numerically in Table 79.5. Figure 79.22 presents the aforementioned information for scenario 1, test 2.

Figure 79.22 displays the results from scenario 1, test 2, with the view centered around target 2. A numerical analysis of the test is shown in Table 79.10. Figure 79.23 shows the results for scenario 1, test 3, which involves both target vehicles moving simultaneously. A numerical analysis is shown in Table 79.7.

Scenario 1 demonstrates the sensitivity of the FSKCW ranging technique to multipath signal propagation. Multipath signal propagation is defined within this research as any signal path not of the same length and direction as the LOS vector

Fig. 79.20 Generation 2a test scenario 1

Fig. 79.21 Scenario 1, target 1 only (the RADAR is positioned at the origin, (0,0))

between the RADAR antenna and any given target. Within scenario 1, the primary cause of multipath errors is the addition of another RADAR reflector within the area swept by the antenna. As Tables 79.5 through 79.7 show, the average angular measurement error is 0.49° and the majority of the position measurement error is due to range measurement inaccuracies. For scenario 1, test 1, the average range measurement error is 0.1 m. Throughout the test, the transmit frequency modulation bandwidth is 4.45 MHz; thus a 0.1 m error is equal to a phase error of 0.5329° , which is, in turn, 0.3 % of the 180° unambiguous range limit. Table 79.8 shows the range error analysis for the tests performed in scenario 1. While range measurement errors are ideally 0 %, the range measurement errors throughout scenario 1 are comparable with other sensor technologies. For example, the Hokuyo URG-04LX-UG01 scanning laser rangefinder has a rated accuracy of ± 3 % the measurement range (Hokuyo.Inc 2009).

Table 79.5 Scenario 1, test 1: numerical analysis

| Parameter | Physical layout | RADAR measurement | Error |
|------------------------------|-----------------|-------------------|--------|
| X axis mean (m) | 2.50 | 2.38 | 0.12 |
| X axis std. dev. | – | 0.21 | – |
| Y axis mean (m) | 1.10 | 1.11 | 0.01 |
| Y axis std. dev. | – | 0.15 | – |
| Mean relative bearing | 23.70° | 25.03° | –1.33° |
| Mean line of sight range (m) | 2.73 | 2.63 | 0.1 |

Fig. 79.22 Scenario 1, target 2 moving, target 1 stationary

Figure 79.24 shows the physical layout of the RADAR and the target vehicles during the second evaluation scenario. All measurements in scenario 2 are made within a steel hanger and no multipath mitigation steps are taken. For this scenario, two tests are performed. For the first test, target 2 is placed within the environment and RADAR measurements are made for 5 min (0.5 Hz update rate). During the second test, target 1 is introduced and RADAR measurements are made in an attempt to gather position information regarding both targets. A graphical representation of scenario 2, test 1, RADAR measurements is shown in Fig. 79.25, while a numerical analysis of the test results is shown in Table 79.9. Figure 79.22 and Table 79.10 provide the same information for scenario 2, test 2. As with scenario 1, the RADAR is located at the origin throughout scenario 2 (coordinate 0,0).

Scenario 2 demonstrates another vulnerability of FSKCW RADARs: target masking. During test 2, target 1 is masked by target 2 in that target 2 interrupts the line of sight path between the RADAR and target 1. Due to the longer measurement range, target 1 returns less power to the RADAR than target 2 despite target 1

Fig. 79.23 Scenario 1, both targets in motion

Table 79.6 Scenario 1, test 2: numerical analysis

| Parameter | Physical layout | RADAR measurement | Error |
|------------------------------|-----------------|-------------------|-------|
| X axis mean (m) | 2.50 | 3.23 | 0.73 |
| X axis std. dev. | – | 0.20 | – |
| Y axis mean (m) | –0.9 | –1.17 | 0.27 |
| Y axis std. dev. | – | 0.21 | – |
| Mean relative bearing | –19.80° | –19.91° | 0.11° |
| Mean line of sight range (m) | 2.25 | 3.44 | –1.21 |

having a larger RCS. Nevertheless, the range filter converges for target 1 rather than target 2. This is due to the more rapid phase reversals observed for target 2 that are not as prevalent in target 1; explained differently, the sign of the phase difference between the two IF channels used for FSKCW ranging depends on whether or not the target is heading towards or away from the RADAR. When utilizing the oval tracks described in Fig. 79.18, this phase reversal occurs twice for every lap of the target vehicle. Since both target vehicles are traveling at the same speed, and target 2 utilizes a shorter track, the RADAR measurements of target 2 contain more phase reversals which serve to corrupt the range measurement and prevent convergence of the range filter (Fig. 79.26). An analysis of the range errors for scenario 2 is shown in Table 79.11.

Table 79.7 Scenario 1, test 3: numerical analysis

| Parameter | Physical layout | RADAR measurement | Error |
|------------------------------|-----------------|-------------------|--------|
| Target 1: | | | |
| X axis mean (m) | 2.50 | 3.63 | −1.13 |
| X axis std. dev. | – | 0.32 | – |

79.4.3 Remarks

Within this section, the FSKCW ranging process presented in this chapter is first simulated in Sect. 79.4 wherein simulations indicate that with a 3 dB SNR, the range errors should be, on average, 0.26 m. Throughout the hardware evaluation process, the average measured range error is 0.62 m or 138 % of the range error encountered during the simulation. While there are a number of factors that cause this discrepancy, there are three dominant causes: multipath error, frequency setting error, and the direction reversals of the RADAR targets. As multipath errors are

adequately explained above, this section will provide more in-depth information regarding frequency setting and direction reversals.

Frequency setting error is, in itself, comprised of two parts: the unmodulated carrier error and the frequency modulation error. The first item, unmodulated carrier error, is defined as an error in the assumed transmit frequency of the RADAR without the square-wave modulation used for determining the range to the target. For the RADAR front end used in the generation 2 and 2a prototypes, the unmodulated carrier frequency is 10.587 GHz. However, due to the construction technology, this frequency is temperature dependent and can vary by up to 6.5 MHz throughout the operating temperature range. Assuming a linear relationship between frequency and temperature, this equates to approximately 230 kHz/°C and is a relatively minor error source accounting for no more than 0.06 % of the unmodulated carrier error (Solutions 2013).

The frequency modulation error is markedly more important and is defined as the error between the expected and actual frequency shifts caused by the modulation process. The maximum frequency modulation range of the RADAR front end is theoretically as 5 MHz (at room temperature) and is obtained by applying a square wave between 0 and 5 V to the tuning pin of the RADAR front end (Solutions 2013). However, during the initial evaluation, the actual frequency range was determined to be 4.45 MHz. This value was obtained by assembling a test scenario with a moving RADAR reflector which passes through a marker located at a specific distance from the RADAR. An oscilloscope then used to measure the relative phase between the two IF signals as the RADAR target passes the marker. Since the speed of light, measured phase, and range to the target are known quantities, the modulation

bandwidth is determined by rearranging (79.9) to the form shown in (79.15) and solving for the bandwidth, BW :

$$BW = \frac{c(\phi_A - \phi_B)}{4\pi \text{Range}} \quad (79.15)$$

The dependence of the accuracy of the range measurements on the accurate knowledge of the modulation bandwidth is demonstrated by noting that for an object with a measured phase difference of 20° , the calculated range is 1.87 m for a modulation bandwidth of 4.45 MHz. If however, the modulation bandwidth is 5 MHz, the calculated range is 1.67 m. This is an error of 0.2 m or 10 % of the original measurement and is therefore a more significant source of range measurement errors than the unmodulated carrier error mentioned above.

In addition to errors caused by the uncertainty in the microwave section, there exist errors caused by the nature of the motion of RADAR targets used throughout this research. In order to simplify the experimental validation of the RADAR prototypes, it is necessary to have RADAR targets whose average location is a known constant. By definition, this conflicts with the need for the mobile targets required by the FSKCW ranging method. Therefore, throughout the evaluation process, the RADAR reflectors travel about oval tracks. Circular tracks would allow more convenient error measurement metrics to be used; however, their use would exacerbate the phase reversal problem briefly mentioned during the analysis of scenario 2.

Since the sign of the phase difference between the two IF signals used for FSKCW ranging is dependent on the direction of the target motion, a reversal of the apparent target motion direction results in a phase reversal. Figure 79.27 shows an oscilloscope capture of both RADAR IF signals while a target within the RADAR's field of view undergoes three direction reversals. The phase reversal is indicated by the regions with low signal amplitudes.

Figure 79.28 shows an enlarged view of a phase reversal. On the left side of the image, the green trace is leading the yellow trace, while on the right side, the yellow trace is leading the green trace. The figure shows 1 second of IF data; however, the RADAR system is sampling at 512 samples at a time at 5 kHz giving rise to a data packet length of 0.1024 s. Thus, over Fig. 79.28 the RADAR would make roughly 10 phase measurements (ignoring the 7 Hz processing speed limit). The phase reversal of the signals takes approximately 300 ms to complete and therefore for the data set shown in Fig. 79.28, 30 % of the phase measurements are erroneous. The use of oval tracks (as opposed to circular) reduces the percentage of erroneous measurements by increasing the percentage of time the RADAR reflector spends traveling either towards or away from the RADAR. Nevertheless, the routine phase reversals are the driving factor behind the gathering of data for 5 min for each test within the scenarios. This allows adequate time for the range filters to converge and filter the noise caused by phase reversals. Furthermore, the data is only analyzed after the convergence of the filters, which on average, require 10 samples to converge on a useful range value.

Fig. 79.27 Oscilloscope capture of both IF signals for three target direction reversals

Besides range, the other measurement required to localize targets is the target relative bearing. Throughout scenarios 1 and 2, the average relative bearing error is 1.01° . However, it should be noted that for all but two of the tests, the angular errors are below 0.36° . This is achieved by not synchronizing RADAR sampling with the motion of the antenna. The lack of synchronization serves to dither the angle measurements and reduce the measured angular error over time.

Also important is the horizontal antenna beamwidth (see Fig. 79.29) which shows the generation 2/2a antenna radiation patterns. The vertical pattern is shown on the left, while the horizontal pattern is shown on the right. The -3 dB beamwidths are 36° and 18° , respectively. Throughout each measurement, the antenna rotates 6.3° . Since this is less than the horizontal -3 dB beamwidth, the entire 90° sector swept by the antenna is covered by the main lobe with no gaps. If the antenna main lobe beamwidth were to be narrower than the angle traversed during the measurement period, there would be gaps in the main lobe coverage throughout any given antenna sweep and targets that would otherwise be detectable would remain undetected.

This chapter evaluates the hardware developed in Sect. 79.2 and provides a number of metrics regarding the RADAR's accuracy. While the hardware developed is not suited for flight testing due to the low transmit power, limited range, and slow scan speed, it does provide a valuable proof of concept. In the next

Fig. 79.28 Enlarged view of IF signals during a target direction reversal

Fig. 79.29 Generation 2/2a antenna radiation pattern (Solutions 2013)

chapter, a collision avoidance algorithm that is capable of utilizing the RADAR's identification functionality is presented and evaluated.

79.5 Collision Detection and Evasion

There exist a number of different methods for avoiding collisions between aircraft. This chapter first describes the method this research uses for detecting collisions. Collision avoidance maneuvers are then divided into two categories, and a method for determining the lower energy maneuver is presented. Finally, this chapter describes the method this research uses to calculate collision avoidance maneuvers, and an empirical evaluation of the method is performed.

Stated differently, the collision mitigation process consists of a number of operations: target detection, target identification, collision detection, and host motion planning. The first two operations are described in Sect. 79.4. This chapter is concerned with the remaining two: collision detection and host motion planning.

79.5.1 Collision Detection

Collisions between two objects can be described in terms of relative bearing and range. A perfect collision between two point objects involves maintaining a constant relative bearing while the range between the two objects decreases. Aircraft have a nonzero volume and cannot be considered to be point objects. Furthermore, there exists a region around most aircraft that should remain free from other aircraft due to both safety and aerodynamic concerns. Throughout this dissertation, the shape of this exclusion region is assumed to be circular as viewed along the gravity vector. The dimensions of these regions are defined in terms of their radii, r_n . Figure 79.30 illustrates an arrangement involving two aircraft.

A minimum distance miss is achieved when the exclusion regions intersect at a single point and is defined as $r_1 + r_2$. The boundary dividing a collision condition and safe trajectories is defined in (79.16), where Φ is the line of sight (LOS) angle and R is the LOS range. Figure 79.31 displays the collision boundary for $r_1 = 5$ m and $r_2 = 10$ m.

$$\frac{d\Phi}{dR} = \frac{r_1 + r_2}{R^2 \sqrt{1 - \frac{(r_1 + r_2)^2}{R^2}}} \quad (79.16)$$

This plot is divided into several regions. The first region is the area of the plot in which the LOS range is less than or equal to $r_1 + r_2$. For values within this region, a collision has already occurred and (79.16) is invalid. Likewise, for $R = r_1 + r_2$ the required change in angular rate approaches infinity. The second region is represented by the region above the collision boundary for all $R > r_1 + r_2$. Within this region,

Fig. 79.30 Collision geometry

Fig. 79.31 $\frac{d\Phi}{dR}$ plot for $r_1 = 5$ m and $r_2 = 10$ m

$\frac{d\Phi}{dR}$ is high enough to avoid a collision. The final region is the region below the collision boundary for all $R > r_1 + r_2$. Within this region, $\frac{d\Phi}{dR}$ is low enough to cause a breach of the clearance regions.

For every time step, R , r_1 , and r_2 are entered into Eq. 79.16 to determine a value of $d\Phi$ against which the RADAR data is compared. If the measured $d\Phi$ value is below the calculated threshold $d\Phi$, then a collision is detected.

79.5.2 Collision Avoidance Maneuver Classes

Once a collision has been detected using the methodology described in Sect. 79.5.1, some action by the host vehicle is required to avoid the collision. The proposed method divides collision avoidance actions into two categories: purely vertical maneuvers (altitude changes) and horizontal maneuvers with no vertical component (heading changes). Complex paths, incorporating both vertical and horizontal maneuvers, are not investigated in an effort to simplify the analysis. Furthermore, as the currently implemented transponder technology discussed in Sect. 79.1 prescribes vertical collision avoidance maneuvers, this section aims to examine the efficacy of collision avoidance maneuvers within the horizontal plane when the energy consumed in such a maneuver is less than or equal to the energy consumed in a vertical maneuver.

There are two key assumptions made for this analysis. First, it is assumed that the host vehicle maintains a constant forward velocity throughout the scenario, i.e., throughout the analysis, the rate at which the vehicles follow their trajectories is a constant. This is because smaller vehicles are able to rapidly vary their velocity, while, larger, faster moving, vehicles are unable to adjust their velocities on similar timescales. Furthermore, rapidly varying forward velocities while maintaining a constant altitude makes poor use of a vehicle's available energy by not trading kinetic energy (velocity) for potential energy (altitude).

The second assumption is that collision avoidance maneuvers in the horizontal plane require more physical separation than maneuvers in the vertical plane. This is representative not only of the physical dimensions of most aircraft which are typically wider and longer than they are tall but also of Federal Aviation Administration (FAA) regulations (Order JO 7110.65U) which requires more vertical separation than horizontal separation. In some cases under Instrument Flight Rules and RADAR guidance rules, 1,000 ft vertical separation or 3 miles lateral separation is required (FAA 2012a).

A collision avoidance scenario for a single host and a single opposing aircraft, for both horizontal and vertical avoidance maneuvers, is shown in Figs. 79.32 and 79.33, respectively. The host aircraft is shown on the bottom of the figures with the goal of traversing towards some goal at the top of the figures. Between the current host aircraft location and the goal is a region where, at some point in the future, a collision will occur between the host aircraft and some airborne threat. This "collision region" is modeled as an oblate spheroid with a minor semidiameter equal to r'/a and a major semidiameter equal to r' . a therefore determines the aspect ratio of the collision region and may be made to conform to arbitrary dimensions on a case-by-case basis.

Fig. 79.32 Horizontal evasion geometry (top down view)

The energy required for the vehicle to perform a horizontal maneuver is described by (79.17), while the energy required for a vertical maneuver is described by (79.18):

$$E_H = b \left(0.5d + \frac{0.5d}{\cos \left(\arctan \left(\frac{2r'}{d} \right) \right)} \right) \quad (79.17)$$

$$E_V = b \left(0.5d + \frac{0.5d}{\cos \left(\arctan \left(\frac{2r'}{da} \right) \right)} \right) + mg \left(\frac{r'}{a} \right) \quad (79.18)$$

where E_H and E_V are the energies required for horizontal and vertical evasion, respectively. b is the baseline energy consumed by the aircraft for every unit of distance traveled and is determined by dividing the engine output power while cruising by the aircraft cruising velocity. d is the nominal path distance as shown in the figures, a is the aspect ratio of the collision region, m is the mass of the vehicle, g is acceleration due to gravity, and r' is the lateral or vertical displacement required to avoid the collision region.

For any given aircraft, (79.17), and (79.18), can be used to determine when a vertical maneuver is superior from an energy standpoint to a horizontal maneuver. Furthermore, this comparison allows practical limits to be placed on horizontal

Fig. 79.33 Vertical evasion geometry (side view)

maneuvers so that the energy consumed in an in-plane horizontal maneuver will not exceed the energy of a vertical maneuver. Figure 79.34 shows the energy required for a horizontal maneuver with a heading change up to 30° compared with an equivalent vertical maneuver.

The parameters used to obtain Fig. 79.34 for a theoretical aircraft are shown in Table 79.12. For comparison, the baseline energy of a 1.5 kg radio-controlled aircraft (Eflite Ultra Stick 25e) is approximately 18 J/m (Hobby 2013).

In the case described by Fig. 79.34, horizontal collision avoidance maneuvers are more energy efficient than their vertical counterparts, provided that the heading is not modified by more than 19.7° .

Figure 79.35 shows the same analysis performed for a Cessna 172 fixed-wing airplane, given the parameters in Table 79.13. The parameters are selected under the assumption that the aircraft is equipped with a standard Lycoming IO-360-L2A engine operating at 75 % of its maximum power rating. This results in the aircraft cruising at 122 knots (62.76 m/s) at an altitude of 8,000 ft (Company 1977). As shown in Fig. 79.35, horizontal maneuvers are more energy efficient than vertical maneuvers for heading changes up to 28° .

Compared with fixed-wing aircraft, helicopters have higher baseline energy consumption rates. Due to the longer path length, horizontal collision avoidance

Fig. 79.34 Horizontal vs. vertical collision avoidance energies for a theoretical aircraft

Table 79.12 Parameters for a theoretical aircraft. See Fig. 79.34

| Parameter | Value |
|--------------------------------|----------------------|
| Vehicle mass (m) | 5 kg |
| Baseline energy (b) | 100 J/m |
| Aspect ratio (a) | 2 |
| Nominal path distance (d) | 100 m |
| Gravitational acceleration (g) | 9.8 m/s ² |

maneuvers require lower energies only over a narrower angle than fixed-wing aircraft. Figure 79.36 displays the results of an evasion maneuver energy analysis for a Bell 206 helicopter. The analysis specifications are shown in Table 79.14 (Inc 2000). In this case, horizontal collision avoidance maneuvers require lower energies for heading modification angles up to 12°.

79.5.3 Collision Avoidance Maneuver Planning

As mentioned earlier, the algorithm proposed in this section focuses on investigating the efficacy of collision avoidance maneuvers in the horizontal plane. Section 79.5.2

Fig. 79.35 Horizontal vs. vertical collision avoidance energies for a Cessna 172

Table 79.13 Parameters for a Cessna 172

| Parameter | Value |
|---------------------------|-----------|
| Vehicle mass (m) | 1,111 kg |
| Baseline energy (b) | 1,438 J/m |
| Aspect ratio (a) | 15.8 |
| Nominal path distance (d) | 2,000 m |

demonstrates that such maneuvers are only more energy efficient over an specific angle whose size is dependent on the host vehicle properties and the aspect ratio of the collision region, while this section describes the collision avoidance method. The description begins with a single opposing aircraft, and then the method is generalized for an arbitrary number of threats.

Section 79.5.1 describes a geometric method for detecting collisions, where a collision is detected when the line of sight (LOS) vector’s rate of change as a function of range is not greater than the boundary described by Eq. 79.16. This condition occurs when the angular separation between the LOS vector and the relative velocity vector between the host and any given threat is not sufficiently large. Such a condition is illustrated by Fig. 79.37, where Ψ is the angular distance between the LOS and relative velocity vectors.

Fig. 79.36 Horizontal vs. vertical collision avoidance energies for a Bell 206

Table 79.14 Parameters for a Bell 206 helicopter

| Parameter | Value |
|---------------------------|-----------|
| Vehicle mass (m) | 1,400 kg |
| Baseline energy (b) | 4,175 J/m |
| Aspect ratio (a) | 15.8 |
| Nominal path distance (d) | 2,000 m |

The collision avoidance algorithm begins by creating a series of alternate LOS vectors for each threat. This is accomplished by rotating the LOS vector about the threat in uniform increments throughout an angular range centered about the current LOS vector known as the “search range.” The alternate LOS vectors are shown in Fig. 79.38. Where the alternate LOS vectors are displayed in red, the original LOS vector is shown in green, and the relative velocity vector is shown in blue.

The absolute magnitude of the angular distances between each alternate LOS vector and the relative velocity vector is then calculated and stored in an array, henceforth referred to as the “vector_distance” array. This has the effect of creating an array where each element represents one possible host vehicle heading change. As Fig. 79.38 shows, the alternate vectors are generated from the opposing aircraft’s reference frame. This is transformed to the host aircraft reference frame by shifting

Fig. 79.37 Collision geometry

Fig. 79.38 Collision geometry with alternate LOS vectors

Fig. 79.39 Plot of “vector_distance” array after the shifting and weighting operations

the vector_distance array element values to the left for threats on the left side of the host vehicle (relative to the host longitudinal axis) and to the right for threats on the right side of the host vehicle. The magnitude of this shifting operation is such that the angular displacement of the threat LOS vector from the host vehicle boresight vector is equal to the shift distance multiplied by the angular resolution of each element. The vector_distance array element magnitudes are then weighted so that the magnitudes are inversely proportional to the range between the host and the opposing aircraft.

A plot of the vector_distance array for a single opposing aircraft is shown in Fig. 79.39. Figure 79.40 shows the vector_distance array evolution over time for a threat on a collision course. For both figures, the opposing aircraft's relative LOS angle is 296.7° , and the relative velocity vector angle is 297.3° .

Once a vector_distance array is created for a particular opposing aircraft, it is added to a global array (known as the global_heading_distance array) which incorporates the vector_distance array values for all detected opposing aircraft (regardless of whether or not the aircraft in question is on a collision course). The heading modification angle is determined by finding the index of global maximum of the global_heading_distance array multiplied by the angular resolution of the generated alternate LOS vectors.

Throughout this section, 180 alternate LOS vectors are utilized for each opposing aircraft. The alternate LOS vectors are uniformly distributed throughout a 180° range resulting in an angular resolution of 1° .

The collision avoidance algorithm proposed in this section is described by the following pseudocode.

It is important to note that this algorithm does not take into account any heuristics regarding which aircraft has the “right of way” (as defined in FAA 14 CFR

Fig. 79.40 Plot of “vector_distance” displayed over time

91.113 or 91.115). This is because the algorithm described herein is a last resort collision avoidance methodology, rather than a high level path planner. Ideally “right of way” considerations would be handled by the higher level guidance software in addition to human operators such that this algorithm will never be needed. However, when the need for a collision avoidance maneuver arises, the priority is placed on avoidance rather than “right of way.”

The performance of the algorithm is evaluated by translating the method into C and then executing the algorithm on the XC-1A development board used for RADAR control, as described in Sect. 79.2. Execution time is indicated by setting an I/O pin to *logic 0* before execution of the algorithm and then setting the same I/O pin to *logic 1* upon completion of the algorithm. Execution time is measured by observing the state of the I/O pin using an oscilloscope (Agilent DSO5012A). The execution time measurement is performed for up to 20 opposing aircraft with 180 alternate LOS vectors per aircraft. The results are shown in Fig. 79.41.

79.5.4 Airspace Simulation Software

Due to the expense and difficulty of evaluating midair collision scenarios in hardware, algorithm evaluation takes place in simulation environment. To this end, a custom simulation software package was written in *Processing*, a branch of the Java programming language. This simulation software is comprised of a number

Fig. 79.41 Algorithm execution rate on the RADAR processor hardware

of modules each responsible for a certain portion of the simulation. The modules each act on a global state matrix that stores information on all aircraft within the simulation such as current coordinates, destination coordinates, velocity, exclusion region size, and aircraft maneuverability. The modules acting upon this data are as follows:

Initialization

The *initialization* module is executed upon the start of any given simulation sequence. While the module is routinely executed, the effect of the module is selectable to provide randomization of the positions, destinations, sizes, and velocities of all aircraft within the simulation.

Motion

The *motion* module's primary function is to update the current positions of all aircraft within the simulation based on the destination waypoint and the current velocity. As the global state matrix describes the vehicle position using latitude and longitude with precision of 0.111 m, relatively fine positioning control over the various simulated aircraft is possible.

Pilot Input

At any point in the simulation, a pilot may take control of the host aircraft using keyboard inputs. This has the effect of updating the "destination waypoint" for the host aircraft. Updates to this parameter are effected during the next simulation time step.

RADAR Track Generator

This module serves to simulate the data as gathered by the RADAR sensor by sampling the global state matrix and generating RADAR track data. This module is capable of simulating the real-world parameters including limited range, azimuth, and range errors.

Performance Monitoring

The primary metric used for evaluating the effectiveness of the collision avoidance algorithms is the minimum distance between the host aircraft and any other aircraft in the simulation. This module records this parameter for further investigation.

Graphical Representation

As the name implies, the *graphical representation* module is responsible for parsing the global state matrix and displaying a graphical representation of the airspace. Also represented are pertinent values regarding the host vehicle parameters and the performance of the collision detection and avoidance software; see Fig. 79.42. Due to the additional computational overhead involved in the rendering process, this module is only active during debugging when visual feedback is beneficial.

Fig. 79.42 Airspace simulation software screenshot

79.5.5 Collision Avoidance Algorithm Evaluation

The collision avoidance algorithm described in Sect. 79.5.3 is evaluated using the collision avoidance simulation software described in the previous section. The goal of this evaluation is to examine the efficacy of collision avoidance maneuvers in the horizontal plane. There are, however, a number of key constraints placed upon the simulation environment. They are as follows:

Opposing Vehicle Initial and Final Range

Throughout the algorithm, the *initialization* module is configured to generate opposing aircraft with random initial locations and destinations. The random generation is constrained such that, upon initialization, the latitude or longitude of the start and end points is no closer than 200 m and no further than 300 m from the host aircraft.

Thus, the initial LOS range between any aircraft and the host is between 282.8 and 424.3 m. This prevents the spawning of opposing vehicles colocated with the host; additionally it provides time for the host vehicle to effect a collision avoidance maneuver.

Opposing Vehicle Dispersion Time

Due to the constraints placed upon the locations of opposing aircraft, initial simulations indicated that opposing aircraft's starting locations may sometimes be generated closely together. Therefore, upon initializing any given scenario, collision avoidance maneuvers are inhibited for 2 s, thus allowing the opposing aircraft to disperse. Failure to do so artificially improves the performance metrics of the algorithm since there are large swaths of empty airspace.

Vehicle Collision Radii

Throughout the simulation, all aircraft have a collision avoidance radii of 10 m. This results in a collision being registered when the range between the host and any opposing aircraft within the simulation is less than 20 m; see Fig. 79.30. Ten meters is justified as a collision avoidance radius since it provides adequate clearance between many small UAVs and the maximum dimension of the Cessna 172 which has an 11 m wingspan (Company 1977). The Cessna 172, while not the most challenging threat to evade, is the most likely opposing aircraft in many municipalities since more Cessna 172s have been built than any other manned aircraft (more than 43,000 examples have been produced) (Niles 2007).

Single Collision Avoidance Maneuver

Throughout the evaluation process, a single collision maneuver is permitted. This is to avoid a meandering, in-plane path which would consume more energy than a vertical maneuver.

Throughout the evaluation process, the simulated area represents a horizontal slice of extremely high-density airspace. In this simulation, the slice is a square with an area of 0.36 km^2 , although airspace density values are normalized to represent aircraft/ km^2 . For every major parameter variation, a batch of simulations are run to determine the effect for various airspace densities up to $55.6 \text{ aircraft/km}^2$. For each incremental increase in airspace density, the simulation is executed 10,000 times (10,000 random scenarios). A scenario is defined as lasting from the end of the randomization process used during the beginning of the simulation to the time when all aircraft have reached their destination waypoints. Although the duration of any given scenario will vary due to the random nature of the waypoints and the velocities of the aircraft involved, the average duration of a scenario is 36.76 s. The results presented below represent 2.09 million scenarios (approximately 21,341 h of simulated flight time). For all efficacy plots, the vertical axis represents the probability of a collision, while the horizontal axis represents the airspace density.

Figure 79.43 displays the probability of a collision with and without the collision avoidance algorithm. Throughout the simulation, the velocities of all opposing

Fig. 79.43 Twenty degree heading modification angle

aircraft are 20 m/s. Furthermore, the maximum heading modification angle is limited to 20° to approximate the theoretical vehicle described in Table 79.12.

Figure 79.44 displays the effect of varying the maximum heading modification angle from the 20° used in Fig. 79.43. All vehicle velocities are 20 m/s.

Figure 79.45 shows the efficacy of the algorithm utilizing a range of homogeneous opposing aircraft velocities and a fixed host aircraft velocity. The maximum heading modification angle is 20°.

Figure 79.46 shows the efficacy of the algorithm with a maximum heading modification angle of 20° and randomized opposing aircraft velocities between 10 and 40 m/s.

Figures 79.47–79.50 show the data from Fig. 79.46 with and without collision avoidance enabled.

79.5.6 Remarks

Within this chapter, a geometric collision detection and evasion method is proposed and evaluated for a nontrivial number of random scenarios. Throughout the evaluation process, a number of key parameters are varied for each sweep of airspace densities: the maximum heading modification angle, velocities of both the host

Fig. 79.44 Various heading modification angles

Fig. 79.45 Various homogeneous opposing aircraft velocities with constant host velocity

Fig. 79.46 Random opposing aircraft velocities with host velocity sweep

Fig. 79.47 Random opposing aircraft velocities with 10 m/s host

Fig. 79.48 Random opposing aircraft velocities with 20 m/s host

Fig. 79.49 Random opposing aircraft velocities with 30 m/s host

Fig. 79.50 Random opposing aircraft velocities with 40 m/s host

and the threat, and whether or not the scenario utilizes homogeneous or random opposing aircraft velocities.

Figure 79.44 shows the efficacy of the algorithm as a function of various maximum heading modification angles. The best performance within this data set occurs when the maximum heading modification angle is 20°. For values below 20°, the host aircraft is unable to avoid flying into the collision region described in Fig. 79.32. For values greater than 20°, the host aircraft is able to clear the original collision region, but often initiates a collision with another aircraft in the process.

The efficacy of the algorithm is also affected by the velocities of the vehicles involved and the opposing aircraft velocity distribution. With homogeneous opposing aircraft velocities, the simulations show that out of the examined configurations, the best efficacy is achieved when the host vehicle velocity is half the opposing vehicle velocity. With this velocity configuration, there is adequate time for the “cloud” of opposing aircraft to pass by the host vehicle. Increasing the host vehicle speed is detrimental to the performance in that it increases the closing speeds between the host and any opposing aircraft. This increased closing speed reduces the amount of time available for the host to clear the various collision regions.

The situation is reversed (for airspace densities up to 44 aircraft/km²) once random opposing aircraft velocities are introduced. Under these conditions, the best efficacy achieved during this simulation occurs when the host vehicle velocity

Fig. 79.51 Airspace simulation screenshot with 55.56 aircraft/km²

is equal to the upper bound of the opposing aircraft velocity distribution. This is explained by the “threat cloud” not dispersing due to the low-speed vehicles. Simultaneously, the host vehicle lacks the velocity to escape high-velocity opposing aircraft which penetrate the cloud of low-speed vehicles.

The efficacy of the algorithm is evaluated for airspace densities up to 55.56 aircraft/km² (see Fig. 79.51) at which point the probability of a collision exceeds 30 % for many of the scenarios in Sect. 79.5.5. It should be noted, however, that such airspace densities are highly improbable. For the sake of example, it can be assumed that the highest airspace density occurs within the airspace surrounding airports (the FAA classifies these regions density as “class B” airspace) (FAA 2001). The busiest airport in the world (according to the number of takeoffs and landings) is the Hartsfield-Jackson Atlanta International Airport (ATL) in Atlanta, Georgia, with 950,119 such events in 2010 (ACI 2011). While ATL’s class B

Fig. 79.52 Atlanta International Airport region airspace map (AOPA 2013a)

airspace (see Fig. 79.52) extends up to 56 km from the airport itself, the physical area within which the runways are contained can be modeled as a rectangle 4.64 km wide by 3.7 km long; see Fig. 79.53 (AOPA 2013a; FAA 2013). This results in an area of 17.17 km² through which it is assumed all aircraft serviced by ATL must pass. The average duration of a scenario in Sect. 79.5.5 is 36.76 s and there are 858,458.3 such time periods within a year. Assuming a uniform distribution

Fig. 79.54 Data in Fig. 79.43 for lower airspace densities

of aircraft arrival and departures, throughout any given day, there must be 1.1 flying aircraft over ATL every simulation period. This gives rise to an average airspace density of 0.0641 aircraft/km² which is 866.8 times less dense than the maximum airspace density simulated. Stated another way, if ATL operated under the maximum airspace density used in this research, an aircraft would be either taking off or landing every 39 ms (25.9 aircraft/s).

Figure 79.54 shows the data in Fig. 79.43 enlarged to provide more detail throughout lower airspace densities. For cases where the host and the opposing aircraft have homogeneous velocities and the heading modification angle is limited to 20°, the probability of avoiding a collision is 99.995 % when the airspace density is 1.66 aircraft/km². As the airspace density continues to decrease, the probability of avoiding a collision approaches 100 % when the airspace density is 1.5 aircraft/km², nearly 23 times the airspace density of ATL.

79.6 Conclusion

This chapter presents two components which aim to improve the safety of unmanned aircraft systems and ease their future integration into the national airspace. These components are as follows: a lightweight RADAR sensor and a computationally efficient method for determining collision avoidance maneuvers.

Due to the limitations of the available hardware, the prototype RADAR sensor is evaluated on a small scale using mobile RADAR reflectors to simulate opposing aircraft. This process revealed a number of limitations of the developed hardware, primarily its vulnerability to multipath reflections in addition to the limited range and measurement update rates. Nevertheless, the construction and experimental evaluation of a miniature RADAR sensor capable of localizing moving targets

demonstrates the feasibility of RADAR-based collision avoidance. While the hardware is evaluated on a small scale, the collision avoidance algorithm is evaluated extensively in order to characterize its efficacy well beyond the current maximum airspace density.

Flying implementations will, however, require more than is presented here. First, higher RADAR transmit power levels are required to achieve the detection ranges required for collision avoidance. Next, the collision avoidance algorithm should be expanded to incorporate three-dimensional collision avoidance maneuvers. Finally, collaborative collision avoidance must be incorporated to address the issues that arise when numerous vehicles are equipped with this technology. Nevertheless, this chapter provides a foundation to support the idea of RADAR-based collision avoidance for unmanned aerial vehicles.

Abstract

Unmanned Aircraft Systems (UASs) emerge as new possibility for civil and military aircraft applications, without having the need for a pilot onboard the aircraft. Although there is great potential, there is also the need to show that the introduction in nonsegregated airspace can be done without endangering other (manned) traffic. In this chapter the most promising candidate solutions for Detect and Avoid (DAA) for use of UAS in nonsegregated airspace are assessed against a set of DAA requirements. A DAA solution is the combination

of the sensor suite, the avoidance algorithms, and the method of operation. The functions of a DAA solution are collision avoidance and, in uncontrolled airspace, separation provision. The focus of this chapter is the detection of conflicting traffic by the sensor suite. The sensor suite needs to be able to detect different classes of conflicting traffic in varying environments. Requirements for DAA solutions have to be set, and DAA systems must then be developed to meet these requirements.

ATM requirements for use of UAS in nonsegregated airspace have been drafted by EUROCONTROL (2007). This set includes a subset of requirements that are directly or indirectly of influence on the sensor suite used to Detect and Avoid other traffic. This subset is used as baseline for the establishment of DAA requirements and expanded by development of five additional generic requirements based on the main tasks of a DAA solution: (1) detection of other traffic, (2) tracking of other traffic and assessing if there is a conflict, (3) if there is a conflict, determining which evasive maneuver is to be executed, and (4) executing the selected maneuver. Five candidate solutions are assessed against the requirements: a noncooperative solution, a cooperative solution, and three solutions mixing cooperative and noncooperative sensors.

Overall it is concluded that it is a great challenge to develop a collision avoidance solution for UAS with a satisfactory level of safety. It is even more difficult to develop a DAA system that is capable of both collision avoidance and separation provision. Therefore, collision avoidance is considered a first step in developing DAA solutions for UAS, restricting the operations to flights in controlled airspace with ATC providing separation at all times. It is recommended to continue to develop suitable methods to perform the safety analysis for introduction of UAS equipped with DAA solutions in nonsegregated airspace.

80.1 Introduction

80.1.1 Background and Scope

Historically, pilots have to use their eyes as the sensors to detect other aircraft. It is commonly agreed that like manned aircraft, UAS should adhere to the general rules of the air. According to ICAO Annex 2 (ICAO 2005), all pilots need to exercise vigilance for the purpose of detecting potential collisions and are responsible for taking collision avoidance action when in flight, irrespective whether the flights is under instrument flight rules (IFR) or visual flight rules (VFR) and irrespective of Air Traffic Control (ATC) services. UAS also needs to adhere to the right-of-way rules, as can be found in ICAO Annex 2. For a UAS to adhere to the rules of the air and the right-of-way rules, a DAA solution is needed. The DAA solution should include a collision avoidance function at all times. A separation provision function is needed where this is not provided by ATC. The DAA solution must detect at a sufficient range to allow a timely maneuver to avoid a collision.

In the future both manned and unmanned traffic are expected to be integrated in nonsegregated airspace according to established procedures. This study investigates the current technological capabilities to support UAS with the detection and avoidance of potential traffic conflicts in nonsegregated airspace, thereby building on public references to studies on DAA solutions in Europe. A DAA solution is the combination of the sensor suite, the avoidance algorithms, and the method of operation of the UAS. The functions of a DAA solution are collision avoidance and, in uncontrolled airspace, separation provision. The sensor suite needs to be able to detect different classes of conflicting traffic in varying environments. The avoidance algorithms must assure that the conflicting traffic is avoided by taking appropriate avoidance action. The method of operation determines the autonomy of the DAA solution and is therefore of influence on the required performance of the systems. Requirements for DAA solutions have to be set, and technical systems must be provided to meet these requirements.

The mode of operation of the UAS considered for this study involves a designated UAS operator (DUO). It is assumed the detection of traffic and assessment of collision course is executed automatically, informing the DUO about the conflicting traffic. The focus is the detection of conflicting traffic by the sensor suite which is part of the DAA solution. This choice is made because most European research on detect and avoid focus on the needed sensors. It is assumed that avoidance will be executed automatically with human approval or veto. The type of UAS considered are those categorized as medium range or larger (i.e., a maximum take-off weight (MTOW) of 1,250 kg and up (van Blyenburgh 2011)). Due to this scope of UAS categories, it is believed the accommodation of sensors is not a major issue and is not further discussed in this chapter. The type of aircraft considered as traffic to be detected and avoided is UAS or manned aircraft with a take-off weight of 1,250 kg and up. The airspace classes considered are A–G. Airspace classes A–E are referred to as controlled airspace by ICAO, and subsequently airspace F and G are referred to as uncontrolled airspace. Only technologies to detect and avoid other airborne aircraft are considered. Technologies to avoid terrain, objects on the ground, and adverse weather are not considered. Legal aspects of UAS, DAA, and non-nominal events other than traffic on collision course are considered out of scope.

80.1.2 Objective

The objective of this study is to determine what the most promising candidate technological solutions are for detect and avoid solutions for UAS in nonsegregated airspace considering the requirements imposed.

80.1.3 Approach

The approach of this study is to match the most feasible DAA requirements with the most feasible DAA solutions. Therefore, the trend of requirement definition and

the viability and feasibility of these requirements is determined. The key technical issues while developing these requirements and the research efforts to resolve these issues are identified. This leads to a final set of requirements that is deemed most likely. This set of requirements is then matched to five potential DAA solutions, so as to determine which candidate solution is most feasible and viable in terms of satisfying the requirements. The five solutions are determined considering the technologies available and European studies performed to assess these technologies. As Detect and Avoid is considered a “dual” technology that can be used for military and civil UAS, both civil and military initiatives will be considered in this study.

80.2 Detect and Avoid Requirements

This section discusses the requirements for the detect and avoid solution of UAS. It first discusses the generic requirement for the DAA solution to fulfill its primary functions. A set of generic requirements are drafted to be used in the assessment of DAA solutions as given in the final part of this chapter. Next, the requirements in development at by various European standardization and regulatory organizations are described and discussed. A relevant set of requirements is obtained to use for assessment of DAA solutions.

80.2.1 Generic Requirements of the DAA Solution

The two primary functions of a DAA solution are the provision of collision avoidance and, in uncontrolled airspace, separation provision. Table 80.1 lists the responsibilities regarding collision avoidance and separation provision per airspace class and flight rules for manned aviation. It is assumed these responsibilities are unaltered for UAS, where the pilot’s role will be fulfilled by either a DUO with the help of a DAA solution or by the DAA solution itself. Therefore, collision avoidance will always be a function of the DAA solution. In case ATC is not responsible for

Table 80.1 Responsibilities related to airspace and flight rules

| Flight rules <i>responsibility</i> | Airspace classes | | | | | | |
|--|------------------|-------|------------|------------|------------|------------|-------|
| | A | B | C | D | E | F | G |
| IFR/IFR <i>Separation provision</i> | ATC | ATC | ATC | ATC | ATC | Pilot w/TA | Pilot |

| All <i>Collision avoidance</i> | Pilot | Pilot | Pilot | Pilot | Pilot | Pilot | Pilot |

TA ATC traffic advisory

separation provision, the DAA solution needs to fulfill both the separation provision and collision avoidance function. In the latter case ATC, if available, can aid the operator of the UAS (or the UAS itself) by giving traffic advisories, although it has not been established how to provide a UAS traffic advisories.

For both separation provision and collision avoidance, there are four generic tasks of a DAA solution. The requirements that arise from these tasks can be different for separation provision and collision avoidance. The four tasks are

- 1. Detect of other traffic.
- 2. Track other traffic and assess if there is a conflict.
- 3. If there is a conflict, determine which evasive maneuver is to be executed.
- 4. Execute the selected maneuver.

As indicated in the introduction, the focus of this study is the detection of conflicting traffic; task 1 and task 2 combined. Task 3 must be done by algorithms and communication between traffic. Task 4 is either executed by a DUO or UAS itself again using algorithms. For the purpose of drafting the requirements, task 1 and task 2 are modeled in an event tree, given in Fig. 80.1.

Traffic in proximity of the UAS needs to be detected. Each DAA solution can detect traffic in the volume of airspace that it scans, the surveillance volume. To be able to detect other traffic in time, the DAA solution needs to scan a sufficient large part of the airspace; in other words the surveillance volume needs to be sufficiently large. The surveillance volume is made up by two components: the field

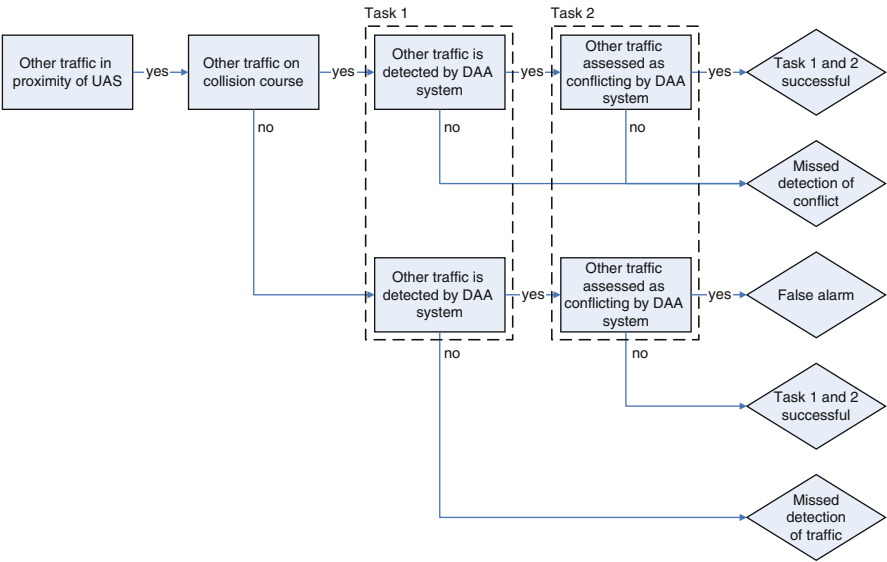

Fig. 80.1 An event tree including task 1 and task 2 of a DAA solution

Fig. 80.2 Field of regard and range

of regard (the combination of azimuth and elevation) and the detection range; see Fig. 80.2.

This results in the following two, of five, generic requirements (GR):

- GR01: *The DAA system must provide a sufficient surveillance volume by having a sufficient field of regard.*
- GR02: *The DAA system must provide a sufficient surveillance volume by having a sufficient detection range.*

If these two requirements are met, the performance of the sensor suite is determined by its success rate (the ratio of detected traffic to total traffic in the surveillance volume). This ratio needs to be sufficiently high. An implicit resultant of this requirement is the need to detect both cooperative and noncooperative traffic. A failure of task 1 results in a missed detection of traffic, which can result in the missed detection of a conflict. The latter is of course unwanted since it can result in an actual collision. The failure to detect traffic that is not conflicting is also unwanted since one cannot depend on providence in designing a DAA solution. Summarizing, the third requirement is

- GR03: *The success rate of traffic detection must be sufficient.*

If task 1 is fulfilled, the sensor suite will detect (nearly) all traffic in its surveillance volume. However, not all traffic will be conflicting. The system needs to assess if traffic is conflicting and needs to include a classification of traffic in case the traffic mix includes balloons, gliders, and powered aircraft. The classification is needed to be able to comply with right-of-way rules. Erroneous assessments can be caused by inaccurate sensor information of the other traffic's range, bearing, altitude, and lateral, and vertical speed. Also incorrect assessment of traffic that is not conflicting is unwanted, since it leads to false alarms and can possibly lead to a maneuver that induces a conflict. Summarizing, the fourth requirement is

- GR04: *When traffic has been detected, the rate of correct assessments if a situation is a conflict or not must be sufficient.*

Since the function of a DAA solution is to provide collision avoidance and in some instances separation provision, the solution must be able to detect traffic conflicts. Any missed conflict can lead to a loss of separation or, worse, a collision. To emphasize this need the third and fourth requirement are combined into a fifth requirement:

GR05: *The DAA system missed conflict detection rate must be kept at an acceptable level.*

80.2.2 Requirements Under Development by European Organizations

A DAA solution has to fulfill the generic requirements as defined in the previous section. Complimentary to those requirements are those requirements that have to be met if a UAS is operated in nonsegregated airspace. For the analysis of those requirements, four European organizations drafting requirements are considered. The organizations considered are the European Aviation Safety Agency (EASA), EUROCONTROL, the European Organization for Civil Aviation Equipment (EUROCAE), and the Flight in Non-Segregated Airspace (FINAS) group of the North Atlantic Treaty Organization (NATO).

EASA develops the regulatory framework for civil UAS with a maximum take-off weight larger than 150 kg. In 2008, EASA stated the following on DAA:

Airworthiness certification is considered to address the intrinsic safety of the UAS. “Sense and Avoid” falls outside this area as its sole purpose is for anti-collision. The operating criteria on which it relies to adequately perform its function are dependent on the airspace being used and the aircraft flying into it. Such criteria should be defined by the authorities responsible for the safety regulation of air navigation services. (EASA 2008)

In Europe, the organization that usually dealt with harmonized safety regulation of air navigation services was EUROCONTROL. However, EASA will gradually take over this responsibility in the coming years.

EUROCONTROL distinguishes two types of air traffic: Operational Air Traffic (OAT) and General Air Traffic (GAT). GAT flights are all movements of civil aircraft, as well as all movements of State aircraft, when these movements are carried out in accordance with the procedures of ICAO. OAT flights are all flights which do not comply with the provisions stated for GAT and for which rules and procedures have been specified by appropriate national authorities. The EUROCONTROL UAV OAT Task Force has drafted Air Traffic Management (ATM) specifications for the use of military UAS as OAT outside segregated airspace (EUROCONTROL 2007). This set includes a subset of requirements that are directly or indirectly of influence on the sensor suite used to Detect and Avoid other traffic. These requirements are independent of the chosen solutions and are based on three main principles:

- UAS operations should not increase the risk to other airspace users.
- ATM procedures should mirror those applicable to manned aircraft.
- The provision of air traffic services to UAS should be transparent to ATC controllers.

It is considered likely that for the use of UAS as GAT in nonsegregated airspace, similar specifications will be developed. The EUROCONTROL Collision Avoidance Requirements for UAS (CAUSE) study confirm this (EUROCONTROL 2010).

According to EUROCONTROL a DAA solution should achieve an equivalent level of safety to a manned aircraft (EUROCONTROL 2007). Since the first discussions on certification of UAS, many attempts have been undertaken to quantify this level of safety for manned aviation. Clearly, when it is not possible to quantify all the elements related to detect and avoid, it is not possible to define an equivalent level of safety. The alternative is to establish a target level of safety (TLS) for UAS. A safety assessment is then needed to prove the TLS can be met by a particular UAS operation. UAS proponents have to work closely with the authorities (e.g., FAA and EASA) to determine what the TLS should be or how it should be defined. Although not easy, the task focus can initially be on a comparison of UAS with manned aircraft.

The NATO FINAS group has also drafted DAA requirements, which are restricted to the situation where separation provision responsibility rests with the designated UAS operator (NATO 2007). The FINAS requirements have been evaluated by the NATO NIAG Steering Group 134. The steering group's conclusion was that the FINAS requirements are incomplete, not coherent in level of detail and often without proper rationale (NATO 2010). Their recommendation toward NATO is to use the EUROCONTROL subset of DAA requirements.

EUROCAE is a European body in which industries work on commonly accepted standards for specific implementations. Generally, showing compliance with these standards can serve industry as certification evidence to convince authorities that their system is safe to use and also increases interoperability between products of different manufacturers. EUROCAE Working Group 73 is tasked to develop a requirement framework that will support civilian UAS airworthiness certification and operational approvals (Hawkes et al. 2008; Kallevig 2011). EUROCAE WG73 has expressed that it is unlikely that a single company producing UAS will make the step as a certification applicant for a UAS to fly in nonsegregated airspace. Focusing on DAA only, WG73 expects that huge efforts, beyond the budget of most industry, are needed to show compliance for requirements such as equivalent level of safety with manned aviation and compliance of DAA solutions with existing ACAS equipment. Instead, a standard would collect the common requirements of potential users, share data for establishing safety, performance and interoperability criteria, and validate the result. This should simplify the process for each applicant who can conform and for the approving authority. WG73 proposes a stepwise UAS integration process:

1. To develop initial standards offering significant additional flight capabilities in nonsegregated airspace compared to flight in segregated airspace, in a reasonable timeframe and with an affordable effort (i.e., UAS nominally flying under IFR with ATC providing separation from other airspace users at all times and UAS flight within Visual Line Of Sight (VLOS) of the DUO)

2. To benefit from the experience of initial standards to develop more complex steps to follow

As a consequence, the result will be a number of EUROCAE standards (e.g., Minimum Aviation System Performance Standards (MASPS) and Minimum Operational Performance Standards (MOPS)) that express system requirements for a specific system or solution. By complying with this standard, the industry is then better able to develop a DAA solution that becomes certifiable and accepted by aviation authorities. Hopefully, this approach will be better than trying to develop several independent and proprietary DAA solution. EUROCAE is currently drafting a framework for such UAS standards. At this stage, no concrete DAA requirements have been published by EUROCAE WG-73 in the public domain.

A continuing discussion is the separation minima; a DAA solution should accomplish if no ATC separation is provided. There are no prescribed ICAO separation minima for manned aircraft where responsibility for separation rested with the onboard pilot. Instead, according to EUROCONTROL it is only necessary that aircraft should not be operated in such proximity to other aircraft as to create a collision hazard (EUROCONTROL 2007). However, industry required something less vague. As a consequence, a practical minimum separation to be achieved by a UAS pilot-in-command is proposed. According to EUROCONTROL several organizations quote or imply that 500 ft is an appropriate and acceptable miss distance for UASs (EUROCONTROL 2007). In the USA, the FAA view of “well clear” (i.e., so as to not represent a collision hazard) is a minimum separation of 500 ft between aircraft. To a considerable degree, this figure is accepted by the Joint JAA/EUROCONTROL UAV Task Force as the basis for recommending work to identify minimum performance standards (MPS) for future DAA systems. Industry itself regards 500 ft as a minimum “worst-case separation” distance for DAA (EUROCONTROL 2007). Finally, in the context of maneuvering between aircraft to achieve safe separation, NATO defines 500 ft as “well clear” (NATO 2007). The use of 500 ft vertical separation is routine between manned aircraft and should therefore not cause undue concern to other airspace users; the application of 500 ft horizontal separation could generate a heightened sense of collision risk. An increase in horizontal separation to 0.5 nm would reduce this perception and also the collision risk and is therefore preferable.

According to EUROCONTROL, ATM regulations and procedures for UASs should mirror as closely as possible those applicable to manned aircraft. UAS-specific ATM procedures should therefore only be implemented where the absence of an onboard pilot – particularly in combination with loss of control data-link – generates a need for special arrangements. Otherwise, the provision of an air traffic service to a UAS should be transparent to the ATC controller and other airspace users. Due to the maturity of the requirements, they can be used in the assessment of DAA solutions and more specifically the sensor suite. A number of requirements are independent of the sensor suite of the DAA solution either because they are relevant for ATM only or for other operational aspects of the UAS. Some requirements are not deemed relevant for this study since they are part of the DAA solution but not dependent on the mix of sensors used; one

such requirement is the requirement to notify the DUO in case of separation violation. For this study only those requirements that are directly or indirectly of influence on the sensor suite are considered. These requirements are given below (EUROCONTROL 2007) (note that the numbering from EUROCONTROL is adopted here as well).

Specification UAV4 UAVs should comply with the right-of-way rules as they apply to other airspace users.

Specification UAV6 For VFR flight by UAVs, the UAV pilot-in-command should utilize available surveillance information to assist with separation provision and collision avoidance. In addition, technical assistance should be available to the pilot-in-command to enable him to maintain VMC and to detect and avoid conflicting traffic. An automatic system should provide collision avoidance in the event of failure of separation provision.

Specification UAV7 A UAV DAA system should enable a UAV pilot-in-command to perform those separation provision and collision avoidance functions normally undertaken by a pilot in a manned aircraft, and it should perform a collision avoidance function autonomously if separation provision has failed for whatever reason. The DAA system should achieve an equivalent level of safety to a manned aircraft.

Specification UAV9 Implementation of separation provision and collision avoidance functions in a DAA system should as far as is reasonably practicable be independent of each other. In execution, they should avoid compromising each other.

Specification UAV10 Within controlled airspace where separation is provided by ATC, the separation minima between UAVs operating IFR and other traffic in receipt of a separation service should be the same as for manned aircraft in the same class of airspace.

Specification UAV11 Where a UAV pilot-in-command is responsible for separation, he should, except for aerodrome operations, maintain a minimum distance of 0.5 NM horizontally or 500 ft vertically between his UAV and other airspace users, regardless of how the conflicting traffic was detected and irrespective of whether or not he was prompted by a DAA system.

Specification UAV12 Where a UAV system initiates collision avoidance autonomously, it should achieve miss distances similar to those designed into ACAS. The system should be compatible with ACAS.

80.3 Detect and Avoid Solutions

Detect and Avoid is the capability of a UAS to remain well clear from and avoid collision with other airborne traffic; therefore, it is a combination of self-separation and collision avoidance. In this research a DAA solution is defined as the combination of the sensor suite and the avoidance algorithms and the method of operation of the UAS in order to detect and avoid conflicting traffic. The method of operation is not further discussed; it is assumed a dedicated UAS operator will be in the loop. Many studies do, either briefly or more elaborately, consider operational

issues of UAS as part of their work. The issues are related to UAS integration in an operational environment and not on detect and avoid specifically. In the short term, it is not expected that the UAS will fly completely autonomous. Only “last ditch” collision avoidance could be made autonomous. Avoidance algorithms are not widely discussed since the initial focus seems to be on the detect task and not on the avoid task. This is understandable because in order to be able to avoid air traffic, it has to be detected first. There is no detailed information available in the public domain regarding the avoidance algorithms used. One European research project does state that they aim at standardized avoidance logic, and as consequence the algorithms will be in the public domain (MIDCAS 2010a). The focus is on the sensor suite, being a combination of sensors used. A reason for the need for more than one sensor would be the ability to detect both cooperative and noncooperative traffic.

80.3.1 Sensor Suite

The European research projects and the sensors studied are shown in Table 80.2. The background of the projects discussed in this section is publicly available (USICO 2004a,b; EDA 2007; Hutchings et al. 2007; Korn and Edinger 2008; Selier et al. 2008; MIDCAS 2010a,b).

All studies except OUTCAST combine EO/IR sensors with radar technology. Cooperative traffic can be detected better using a cooperative technology such as TCAS (note that the concept is named ACAS). TCAS is equipment compliant with the ACAS concept. In this chapter the term TCAS is used (When referring to the specific equipment TCAS II is meant). Other types of sensors that have not been studied by the above research projects are active and passive acoustic systems, active millimeter wave systems, and collision avoidance systems such

^bThe surveillance part of TCAS equipment (transponder interrogator) is considered as a candidate MIDCAS sensor (MIDCAS 2010a)

as FLARM (a commercially available active and cooperative traffic and collision warning system capable of giving traffic advisories) and TCAD (Traffic Collision Avoidance Device: a passive collision avoidance device capable of giving traffic advisories that is commercially available).

The most important ongoing projects with a focus on DAA technology are MIDCAS and ASTRAEA. The importance of these projects is due to the stakeholders involved and the budget available. MIDCAS is a project of the European Defense Agency (EDA) and 14 partners with a budget of 50 million euros. It started in 2009 and will finish in 2013. ASTRAEA is a research program of a UK consortium with a budget of 32 million pounds.

MIDCAS has as objective to demonstrate a DAA system for UAS able to fulfill the requirements for traffic separation and midair collision avoidance in nonsegregated airspace for both cooperative and noncooperative intruders. ASTRAEA aims to ensure that UAS operation is transparent to manned aviation. The behavior of the UAS in flight must be consistent with that expected by manned aviation. Within the ASTRAEA framework, there is a dedicated project focusing on collision avoidance systems. The project seeks to verify the merits of enabling technologies and system capabilities that could be used by UAS for collision avoidance.

80.3.2 Candidate Detect and Avoid Solutions

Five candidate solutions for DAA, representing a number of combinations of sensor technologies, are derived. The DAA solution should include a collision avoidance function at all times. A separation provision function is needed where this is not provided by ATC. For the five candidate solutions the following sensors are considered: TCAS, ADS-B, Radar, IR, and EO. Next, the five conceptual solutions are described, starting with a full noncooperative concept and a full cooperative concept:

1. *Full Noncooperative Concept* This concept combines Radar sensors with EO/IR. This concept is inspired by projects such as WASLA-HALE and USICO. Radar is capable of quickly scanning a large area, also in IMC, although it requires more energy to detect objects through clouds and rainy conditions (when more energy is absorbed) than in VMC. In general powerful Radar introduce more weight and require more power. Besides traffic detection Radar can also be used to detect terrain and weather phenomena. Although this is beyond the scope of DAA for air traffic, it may enhance UAS intrinsic safety. Once directed properly on the conflicting aircraft, EO/IR provides a highly accurate bearing toward the other aircraft and can be used to classify the object by visual inspection.
 - a. Advantages: requires no cooperation from the object to be sensed and avoided.
 - b. Disadvantages: Detection of objects highly depends on a single type of sensor (Radar) with limited bearing accuracy.
2. *Full Cooperative Concept* This concept combines two cooperative sensors: TCAS II and ADS-B. TCAS II is de facto system for collision avoidance and is mandated in Europe for larger aircraft with a maximum take-off weight greater

than 5,700 kg or authorized to carry more than 19 passengers. Beside detection TCAS II can also advise the pilot with an avoidance maneuver. A version of TCAS that is capable of automatically performing the resolution advisory maneuver has been certified (Airbus 2009). TCAS can therefore be considered the most mature collision avoidance system available. Detection and avoidance is based on information contained in the reply of an interrogated mode-S transponder in the other aircraft. If the conflicting aircraft is also equipped with TCAS II, the avoidance maneuvers of both aircraft are “negotiated” by the systems to maintain maximum safety. An ADS-B equipped aircraft automatically transmits the aircraft identity, position, altitude, and intent information (among others) to other airspace users. With this information other airspace users, but also Air Traffic Control, are able to construct a traffic picture. This way ADS-B can provide a basis for separation provision, which is especially useful when separation is not provided by ATC. The completeness of such a traffic picture depends on the population of nearby aircraft equipped with “ADS-B out,” which at this moment is not yet the case in Europe.

- Advantages: Once detected good tracks may be obtained of nearby traffic, and ADS-B may provide information useful for classification.
- Disadvantages: With this system it is not possible to detect noncooperative traffic.

The next three concepts mix both cooperative and noncooperative sensors. These concepts are described below:

3. *Mixed Concept 1* This concept combines one cooperative sensor TCAS II with the noncooperative sensor EO/IR. It is based on the work performed in the project OUTCAST that had the objective to investigate a DAA solution with equipment readily available on the market. The use of operation is thought to be as follows: detect other traffic with TCAS and estimate if there is a reasonable chance of collision course. If that is the case, use EO/IR to classify the intruder (for separation provision) and obtain a better bearing toward the intruder. With this information an evasive maneuver can be calculated.
 - Advantages: simple concept.
 - Disadvantages: limitations of TCAS sensing accuracies (bearing), detection of noncooperative traffic only by EO/IR, difficult to keep track of multiple intruders by EO/IR.
4. *Mixed Concept 2* This concept extends Mixed Concept 1 (TCAS and EO/IR) with Radar. It is based on the work performed in the DAA study by EDA. The use of operation is thought to be as follows: detect other traffic with TCAS and Radar and, estimate if there is a reasonable chance of collision course. If that is the case, use EO/IR to classify the intruder (for separation provision). With this information calculate an evasive maneuver and obtain a better bearing toward the intruder.
 - Advantages: In addition to Mixed Concept 1, detection of noncooperative traffic can primarily be done by Radar.
 - Disadvantages: Use of Radar adds more weight to the UAS and requires more power.

Table 80.3 Summary of five candidate detect and avoid solutions

| | 1. Full non-cooperative concept | 2. Full cooperative concept | 3. Mixed concept 1 | 4. Mixed concept 2 | 5. Mixed concept 3 |
|-------|---------------------------------|-----------------------------|--------------------|--------------------|--------------------|
| EO/IR | • | | • | • | • |
| Radar | • | | | • | • |
| TCAS | | • | • | • | |
| ADS-B | | • | | | • |

5. *Mixed Concept 3* This concept combines one cooperative sensor (ADS-B) and two noncooperative sensors (Radar and EO/IR) and only differs from Mixed Concept 2 in the sense that TCAS is replaced by ADS-B as the cooperative sensor. It is based on the work performed in the ASTRAEA project. The rationale for the replacement of TCAS is that through ADS-B more accurate information about air traffic can be obtained, compared to TCAS. In that case, for the collision avoidance function another solution must be in place (not necessarily performed by ADS-B only, but likely a combination of all sensors). ADS-B may provide information useful for classification.

- Advantages: Mix of sensors gives a high probability of detecting all nearby traffic.
- Disadvantages: ADS-B not mandated.

The five concepts are summarized in Table 80.3.

80.4 Assessment of Detect and Avoid Solutions

Tables 80.4 and 80.5 provide an assessment of the 5 DAA conceptual solutions (in columns) against the identified UAS requirements (in rows). The table is filled using the information available and NLR expert judgment. In Table 80.4 the situation is considered where ATC is responsible for separation provision and the DUO/UAS for collision avoidance. In Table 80.5 the situation is considered where the DUO/UAS is responsible for separation provision and collision avoidance. For each conceptual solution, the feasibility of compliance with the requirement is discussed; to what extent is the DAA conceptual solution compliant with the UAS requirement? Specific issues that are still in the way of compliance are indicated.

Using the full noncooperative concept with Radar and EO/IR sensors, it is harder to detect cooperative traffic than when using cooperative concepts. Using only a cooperative system is not feasible however, because there is always a need to detect noncooperative traffic. Even if transponders are mandated, transponder system failures are possible, resulting in de facto noncooperative traffic. The most feasible solution in the near future is combining TCAS, EO/IR, and Radar. Such a system is only possible in fairly large UAS where accommodation is not an issue. To reliably detect noncooperative traffic, high performance is required from sensors. Replacement of the cooperative surveillance functionality of TCAS by ADS-B (as in mixed concept III) is not foreseen in the near future. No practical DAA solutions are fully compliant with the requirement for independence between collision avoidance and separation assurance.

Table 80.4 Assessment of five DAA sensor suites. Case: ATC is responsible for separation

| 1. Full non-cooperative concept | | | | |
|--|---|---|--|---|
| 2. Full cooperative concept | | | | |
| 3. Mixed concept 1 | | | | |
| 4. Mixed concept 2 | | | | |
| 5. Mixed concept 3 | | | | |
| | Radar, EO/IR | TCAS, ADS-B | TCAS, EO/IR | ADS-B, EO/IR, Radar |
| Generic Requirements | | | | |
| GR01: field of regard (azimuth, elevation) | | | | |
| Note: assessed for noncooperative (NC) and cooperative (C) traffic separately. Cooperative traffic is assessed considering the means available to exchange state information | | | | |
| + = Large - = Small 0 = None | NC: +/- | NC: 0 | NC: - | NC: +/- |
| | C: 0 | C: + | C: + | C: + |
| | Both EO/IR and Radar suffer more from masking by aircraft structure when increased field of regard is required | TCAS and ADS-B have a full sphere field of view; reception does not suffer from masking by aircraft structure | EO/IR suffer from masking by aircraft structure; TCAS for cooperative traffic only | EO/IR and Radar suffers from masking by aircraft structure; compensated by TCAS for cooperative traffic |
| GR02: detection range | | | | |
| Note: assessed for noncooperative (NC) and cooperative (C) traffic separately. Cooperative traffic is assessed considering the means available to exchange state information | | | | |
| + = Long range - = Short range 0 = None | NC: +/- | NC: 0 | NC: - | NC: +/- |
| | C: +/- | C: + | C: +/- | C: + |
| | EO/IR detection range is limited and unable to detect airspace users through clouds; Radar has longer detection range | ADS-B detection range is high, and TCAS detection range is medium; both are hardly influenced by weather | TCAS detection range is medium and hardly influenced by weather | ADS-B detection range is high and hardly influenced by weather. For noncooperative traffic equal to concept 1 |

|---|---|---|--|---|--|
| | Radar, EO/IR | TCAS, ADS-B | TCAS, EO/IR | TCAS, EO/IR, Radar | ADS-B, EO/IR, Radar |
| Generic Requirements | | | | | |
| GR03: success rate of traffic detection | +/- | - | +/- | + | + |
| + = High success rate | DAA potentially capable to detect all nearby traffic | Detection of all traffic is poor, as DAA is only capable to detect cooperative traffic | Both DAA sensors needed for detection of traffic (TCAS for distance EO/IR for accurate bearing) | DAA in potential capable to detect all nearby traffic | DAA in potential capable to detect all nearby traffic |
| - = Low success rate | capability to detect cooperative traffic is less than mixed concepts | | | | |
| GR04: rate of correctly assessed conflicts | | | | | |
| Note: the correctness of an assessment of a whether a situation is a conflict or not depends on accuracies of bearing/range estimations and tracking errors. For the rating it is assumed traffic has been detected | | | | | |
| + = High success rate | - | + | - | +/- | + |
| - = Low success rate | Radar has good range accuracy but poor bearing accuracy, partly compensated by EO/IR, depending on weather conditions | ADS-B provides accurate position of conflicting aircraft; hence tracking accuracy is high, improved by TCAS | TCAS has good range accuracy but poor bearing accuracy, partly compensated by EO/IR, depending on weather conditions | TCAS and Radar have good range accuracy but poor bearing accuracy, partly compensated by EO/IR, depending on weather conditions | ADS-B provides accurate position of conflicting aircraft; hence tracking accuracy is high, improved by Radar and EO/IR |

| | | | | | |
|---|--|--|---|--|---|
| GR05: missed conflict detection rate + Low missed conflict detection rate - High missed conflict detection rate | Note: this is a combination of GR03 (success rate of traffic detection) and GR04 (rate of correctly assessed conflicts) | | | | |
| | - | - | - | +/- | + |
| | Medium detection success rate, but low tracking performance | Poor detection success rate of all traffic | Medium detection success rate, but low tracking performance | High detection success rate and capable of accurate tracking | High detection success rate and well capable of accurate tracking |
| Eurocontrol Requirements | | | | | |
| UAV04: comply with the right-of-way rules | Derived requirement: bearing of intruders must be determined | | | | |
| | Feasible | Feasible | Feasible | Feasible | Feasible |
| UAV06: VFR flight: system to assist DUO in separation provision. An automatic system should provide collision avoidance in the event of failure of separation provision | Note: in the assessment it is assumed that SSR transponders are mandated, but may fail during flight, therefore collision avoidance with noncooperative traffic must be included | | | | |
| | Challenging The challenge is to detect all nearby traffic with noncooperative sensors only. The performance of the sensors must be very high to estimate distance, bearing, and altitude difference with the intruder aircraft | Not possible Detection of noncooperative traffic is not possible with cooperative sensors only | Challenging The challenge is to detect all nearby noncooperative traffic only by visual detection | Likely solution Cooperative traffic is handled by TCAS. Detection of remaining noncooperative traffic would be possible by combining Radar and EO/IR | Likely solution Cooperative traffic is handled by ADS-B as a TCAS replacement. Detection of remaining noncooperative traffic would be possible by combining Radar and EO/IR |

(continued)

Table 80.4 (continued)

80.5 Conclusions and Recommendations

Overall it is concluded that it is a great challenge to develop a *collision avoidance* solution for UAS with a satisfactory level of safety. It is even more difficult to develop a Detect and Avoid (DAA) system that is capable of *both collision avoidance and separation provision*. Many consider therefore collision avoidance as the first step in developing DAA solutions for UAS, restricting the operations to flights in controlled airspace with ATC providing separation at all times.

There is no consensus that the requirement for equivalent level of safety (ELOS) compared to manned aircraft is feasible to work with. The level of safety for manned aviation is difficult to adequately quantify. As an alternative quantified Target Levels of Safety (TLS) for UAS operations could be set.

There is general consensus that DAA solutions require multiple sensors to detect and avoid both cooperative and non cooperative air traffic. Therefore, in this study, five conceptual solutions combining different types of sensors are assessed against UAS. The conclusions are:

- The full noncooperative concept with Radar and electro-optical/infrared (EO/IR) sensors is flawed because cooperative traffic is harder to detect than when using cooperative concepts.
- The full cooperative concept seems not feasible because there is always a need to detect noncooperative traffic.
- DAA solutions combining a Traffic Collision Avoidance System (TCAS), EO/IR and Radar, seem to be the most feasible ones in the near future if accommodation is not an issue. However, high performance is required from sensors to reliably detect noncooperative traffic. Replacement of the cooperative surveillance functionality of TCAS by Automatic Dependent Surveillance-Broadcast (ADS-B) (as in mixed concept III) is not foreseen in the near future.
- No practical DAA solutions are fully compliant with the requirement for independence between collision avoidance and separation assurance.

The following recommendations are made:

- Existing passive and active sensors capable of detecting noncooperative traffic need to be further developed such that the performance is sufficient to reliably detect noncooperative traffic.
- DAA solutions for small UAS where accommodation is an issue need further study.
- It should be assessed if it is possible to develop a practical DAA solution that is fully compliant with the requirement for independence between collision avoidance and separation assurance.

Acknowledgments The NLR research underlying this chapter was sponsored by the FAA UAS Research Program, managed by the FAA Research and Technology Development Office, as part of a Cooperation Agreement between FAA and Civil Aviation Authorities (CAA) the Netherlands. This specific chapter was funded by the NLR Project “Knowledge for Development of a Safety

Policy for General Aviation (including UAS)” for the Dutch CAA. The support and guidance of Dr. Xiaogong Lee and Tong Vu (both FAA), Ron van de Leijgraaf (Dutch CAA), and Dr. ir. Lennaert Speijker (the project manager for the NLR research studies) was very much appreciated.

Networked UAVs and UAV Swarms

***Randal Beard and
Camille Alain Rabbath***

Kimon P. Valavanis and George J. Vachtsevanos

The unmanned aircraft military and civilian communities are already experimenting with UAV swarms flying in formation while cooperating in the execution of specific missions. Research in networked UAVs is also proceeding via simulation studies and limited experimentation. Networked UAVs and UAV Swarms addresses sensing, supervisory control, coordination and cooperation, computing, and communication issues that constitute the basic ingredients of safe and effective flight for multiple UAVs, emphasizing the “intelligence” requirements for safe flight and cooperative/supervisory control.

► **UAV Swarms: Models and Effective Interfaces** by Chapman and Mesbahi examines the modeling and design of effective control interfaces for human operators of UAV swarms. The swarm is modeled as a two-component hierarchical system consisting of the interaction dynamics among the UAVs in the swarm, referred to as the *network dynamics*, and the *UAV dynamics* itself. Human operators are assumed to be able to interface with the swarm via the network dynamics, which in turn has adopted a *leader–follower consensus model*. The system-theoretic and topological features of the network dynamics are then examined in order to design effective mechanisms for interfacing with the swarm. A performance metric is selected for reasoning about effective human swarm interaction. The role of topological features of the network is highlighted in the context of the chosen metric and is related through the effective resistance of the corresponding electrical

network. This is then followed by exploiting such topological features for designing a network rewiring protocol to maximize the metric. These topology design tools are applied to wind gust rejection in disturbed swarming scenarios, demonstrating the viability of topology-assisted design for improved swarm performance. A network-based model reduction is also proposed to form a lower-order model of the network which is easier for the human operators to conceptualize and manage. The reduction process involves a novel partitioning scheme, dubbed *leader partition*, in order to fuse “similar” states in the UAV network and to form a graph-theoretic method for model reduction. This model reduction technique is then applied to derive improved swarming performance in the presence of wind gusts.

► **Decentralized Multi-UAV Coalition Formation with Limited Communication Ranges** by Sujit, Manathara, Ghose, and Sousa discusses a communication protocol derived to search for potential coalition members over a dynamic UAV network and a strategy for a UAV coalition to track and destroy moving targets. The effects of communication ranges and delays as well as the scalability of the proposed schemes with change in number of targets and UAVs are studied. The results show that it is beneficial to search for potential coalition members over a wide diameter in the UAV network when the communication delay is less, while it is more advantageous to determine a coalition from among the immediate neighbors in the presence of significant communication delay.

► **Coordinated Convoy Protection Among Teams of Unmanned Aerial Vehicles** by Egerstedt, Rahmani, and Young investigates how to control and coordinate teams of UAVs to provide protection to convoys of ground vehicles. This is a rich yet canonical problem when coordinating multiple UAVs in that coordinated movements, task assignments, and resource balancing must all be performed for a successful completion of the mission. Time optimal paths for providing convoy protection to stationary ground vehicles are presented, and these algorithms are extended to moving ground vehicles. The assignment problems, associated with dispatching UAVs from the convoy to inspect and clear potential threats, are also discussed.

► **UAV Routing and Coordination in Stochastic, Dynamic Environments** by Enright, Frazzoli, Pavone, and Savla focuses on a technical approach that relies upon methods from queuing theory, combinatorial optimization, and stochastic geometry. The main advantage of this approach is its ability to provide analytical estimates of the UAV system performance on a given problem, thus, providing insight into how performance is affected by design and environmental parameters, such as the number of UAVs and the target distribution. This approach also provides provable guarantees on the system’s performance with respect to an ideal optimum. To illustrate this approach, a variety of scenarios are considered, ranging from the simplest case where one UAV moves along continuous paths and has unlimited sensing capabilities, to the case where the motion of the UAV is subject to curvature constraints, and finally to the case where the UAV has a finite sensor footprint. Finally, the problem of cooperative routing algorithms for multiple

UAVs is considered, within the same queuing-theoretical framework, and with a focus on control decentralization.

Collectively, this section introduces the reader to requirements of swarms of UAVs operating in unison to complete complex missions and also paves the way for future developments in unmanned–manned swarms.

1987

network dynamics are then examined in order to design effective mechanisms for interfacing with the swarm. Specifically, the open loop \mathcal{H}_2 norm of the network is selected as a performance metric for reasoning about effective human-swarm interaction. The role of topological features of the network is highlighted in the context of this metric and is related through the effective resistance of the corresponding electrical network. This is then followed by exploiting such topological features for designing a network rewiring protocol to maximize the \mathcal{H}_2 norm. These topology design tools are applied to wind-gust rejection in disturbed swarming scenarios, demonstrating the viability of topology-assisted design for improved swarm performance. A network-based model reduction is also proposed to form a lower-order model of the network which is easier for the human operators to conceptualize and manage. The reduction process involves a novel partitioning scheme, dubbed *leader partition*, in order to fuse “similar” states in the UAV network and to form a graph-theoretic method for model reduction. This model reduction technique is then applied to derive improved swarming performance in the presence of wind gusts.

82.1 Introduction

Manageability of unmanned aerial vehicle (UAV) swarms presents new challenges at the intersection of interdisciplinary fields. The first challenge pertains to advances in designing small UAVs and micro aerial vehicles (MAVs) involved in complex mission scenarios (Mueller 2001; Pines and Bohorquez 2006; Shyy et al. 2007; Ulrich et al. 2010). The reduced physical scale of such vehicles limits their sensing and actuation capabilities, often requiring their cooperative operation for successful missions. The second challenge relates to the improved autonomy of individual and multiple UAVs, removing the need of a single operator for each UAV (Griffiths et al. 2007; Ren and Beard 2007; How et al. 2008; Michael et al. 2010; Mellinger and Kumar 2011).

In this chapter, components of the UAV swarm are abstracted away to reason about creating effective interfaces with a swarm of interacting UAVs. These interactions, forming a *UAV interaction network*, consist of inter-UAV wireless communications or relative sensor measurements. The UAV swarm involves a large number of dynamic vehicles, making it infeasible for human operators to interface directly with every UAV. An approach for creating effective interfaces is to have only a subset of the UAVs directly controlled by ground or airborne human operators. The remaining UAVs are then allowed to be indirectly controlled via the UAV interaction network, depicted in Fig. 82.1. This setup, although more advantageous than the scenario where each operator manage one UAV, results in a highly coupled high-order nonlinear control model, that proves to be difficult for human operators to manage.

The approach advocated in this chapter for creating effective human-swarm interaction is via a two-component hierarchical model, consisting of the vehicle dynamics building on the UAV interaction network dynamics. This in turn leads to a methodology for improving operators’ ability to manage the swarm, based

Fig. 82.1 A UAV swarming concept where only a subset of the UAVs are directly controlled by human operators. These operators influence the remaining UAVs through an interaction network between vehicles

on the topological features of the swarm interaction network. The main tool for investigating the effectiveness of the operator's interface with the swarm is the open loop \mathcal{H}_2 norm of the resulting networked system – used in this chapter as a measure of system manageability. In fact, when the network dynamics is diffusive, the open loop \mathcal{H}_2 norm provides a means of relating topological features of the network that promote manageability of the swarm. In situations where the UAV network is particularly poor for effective operator interfaces, an option is to redesign the network online – made possible by the wireless nature of the interactions. In particular, the open loop \mathcal{H}_2 norm for the network can be employed to dynamically rewire the interaction topology, improving the effectiveness of the operators' interface with the swarm.

This chapter focuses on UAV interaction networks that have adopted a diffusive protocol, specifically leader-follower dynamics based on the *consensus protocol*. An attraction of the consensus protocol is that a group of UAVs can manage, in a distributed way, to converge to agreement, for example, a common altitude or a formation. More generally, consensus provides a framework for simple but effective distributed information sharing and control for networked, multi-agent systems in settings such as multi-vehicle control, formation control, swarming, and distributed estimation; see, for example, Bullo et al. (2009) and Mesbahi and Egerstedt (2010). One of the popular adaptations of traditional consensus is *leader-follower consensus dynamics* (Tanner et al. 2004; Mesbahi and Egerstedt 2010), in which controllers (leaders), that do not conform to traditional consensus, can act as traditional agents to impact the network behavior by exploiting the other agents' (followers') consensus dynamics. The relationship between the network topology

and the effectiveness of the controllers' input in a leader-follower consensus system is explored in this chapter. Topological features of the network are then investigated that vary the controllers' impact, measured in terms of the open loop \mathcal{H}_2 norm of the network dynamics. Favorable network topologies are then designed, via a decentralized rewiring protocol, to exploit the aforementioned topological features.

An attraction of networked systems is that system performance is strongly coupled with the underlying network topology. For traditional consensus, system performance and its ties to network topology is a well-researched problem where the second smallest eigenvalue of the graph Laplacian is a judicious metric to quantify the convergence rate (Olfati-Saber 2006). Interest has also been shown for other network measures, for example, the largest eigenvalue of the graph Laplacian (Li and Cao 2009). However, these metrics prove less attractive in leader-follower consensus where convergence rates can vary dramatically depending on where the leaders are located within the network. For the leader-follower consensus, the selected performance metric in this chapter is the open loop \mathcal{H}_2 norm. The system-theoretic interpretation of this metric provides a tangible link to system performance in the presence of leaders. Further, the equivalent circuit representation of the network, described in Bollobás (1998) and Barooah and Hespanha (2006), provides the representation of the open loop \mathcal{H}_2 norm as the total *effective resistance* of the network.

The open loop \mathcal{H}_2 norm is studied when the manageability of the system is a concern. Increasing the open loop \mathcal{H}_2 norm tends to increase the receptiveness of the system to control. Work in this area has focused on allocating the weights on the interaction links between UAVs (Ghosh et al. 2008). This chapter examines the structure of the interaction topology that exhibits a favorable open loop \mathcal{H}_2 norm. Unfortunately, maximizing this metric via topological means is NP-hard (a generally considered intractable problem), and thus, a suboptimal protocol to improve this metric is required. The proposed approach is to perform edge trades among neighboring agents within the network that tend to increase the total effective resistance of the graph and consequently the open loop \mathcal{H}_2 norm.

Designing and adapting topologies to optimize for certain metrics has been addressed by several authors: Ghosh and Boyd (2006) aimed to maximize the second smallest eigenvalue of the graph Laplacian, Zelazo and Mesbahi (2011) examined the minimization of the network's \mathcal{H}_2 performance when noise is applied to the interaction links in the network, and Wan et al. (2007) considered maximizing the largest eigenvalue of the graph Laplacian. All aforementioned authors used centralized optimization techniques over *weighted* graphs. Kim and Mesbahi (2006) used fading functions to approximately represent the on/off linkage relationship when searching for the maximum second smallest eigenvalue of the graph Laplacian to increase the convergence properties of the network dynamics. Wu and Wang (2009) have approached the same problem using genetic algorithms. Intuitive methods for network reconfiguration have been designed to improve network resilience, for example, using thresholding methods to decide when to alter the topology (Tyson et al. 2010).

One of the challenges in reducing the size of a UAV is its increased susceptibility to external disturbances, such as wind gusts. An example is provided that examines

the wind-gust swarming scenario which involves a swarm of UAVs with the objective of maintaining a constant altitude aided by relative sensing between neighboring UAVs. An \mathcal{H}_2 controller is implemented by operators to reject the effect of wind-gust disturbance on the overall network. As the swarm is cooperative, favorable controller disturbance corrections can be inadvertently dampened via coordination between UAVs. This chapter presents techniques to manipulate the UAV coordination network topology to improve the swarm's resilience to wind gusts. A network topology-based model reduction method is further proposed for the network dynamics that takes advantage of symmetries or near-symmetries in the network, with the goal of reducing the order of the system, requiring lower-order controllers and reducing monitoring overhead.

The effect of wind gusts on aircraft is a well-researched area (Mutuel and Douglas 1997; Stevens and Lewis 2003). The single and collective response of micro aerial vehicle (MAV) swarms to wind gusts (Hall 2007), on the other hand, is an emerging research field. Shyy et al. (2008) have investigated a bio-inspired MAV design to combat environmental disturbances. A myriad of controllers have been proposed for such a task; for example, \mathcal{H}_2 and \mathcal{H}_∞ controllers have been proposed in Cheviron (2006) and Yang et al. (2006). One of the few papers that have studied a gust-exposed network-based UAV swarm is Meskin et al. (2010) who proposed a hybrid fault-detection and isolation approach involving thresholding between small tolerable and large disturbances in the system, *without* explicit attention to the coordination topology of the UAV swarm. The approach in this chapter aims instead to maintain the underlying consensus dynamics and favorably alter the coordination topology.

Another facet presented in this chapter is motivated by the observation that large-scale UAV swarms are difficult for humans to conceptualize and manage. A traditional system-theoretic solution for reducing the complexity of large-scale systems is the formulation of lower-order approximate models using model reduction techniques. For the UAV swarm, this leads to obscuring the UAV network topology in the reduced order model. A network-centric model reduction technique that produces an approximate lower-order model is proposed, preserving certain characteristics of the network topology.

Traditional methods of model reduction such as balanced realization, balanced residualization, and Hankel norm approximations (Dullerud and Paganini 2000) are purely system-based with minimal, if any, network interpretation. The significance of network symmetry and its role in controllability has recently been investigated (Martini et al. 2008; Rahmani et al. 2009) and provides a natural extension of system-based to network topology-based model reduction. Preliminary work in this direction was undertaken by Martini et al. (2008) using single-leader leader-follower consensus systems. Extending this to multi-leader scenarios is presented in the chapter.

This chapter is organized as follows. Section 8.2 contains the problem formulation and relevant background. The proposed modeling approach consists of a two-component hierarchical model, separating the role of the network dynamics from the vehicle dynamics. Consensus-based, leader-follower dynamics is described for the network dynamics. An analysis of the open loop \mathcal{H}_2 norm is then presented in

Sect. 82.4, and its relationship to system performance and the effective resistance of the network is established. Also in Sect. 82.4, a network rewiring method is proposed to design network topologies optimized for the open loop \mathcal{H}_2 norm and conducive to wind-gust disturbance rejection. Section 82.5 presents a network partitioning technique that can be used for fusing nodes to form a reduced order model but without losing the graph-theoretic interpretation of the dynamics. The chapter is concluded with a few remarks in Sect. 82.6.

82.2 Model

This section provides the models that will be used in this chapter, including abbreviated descriptions of graphs and the consensus protocol in both its traditional and leader-follower versions. The following notation is used in this chapter: $\|\cdot\|_1$, $\|\cdot\|_2$ and $\|\cdot\|_\infty$ denote the one, Euclidean and infinity norms, respectively; $\text{tr}(\cdot)$ denotes the trace of a matrix; $|\cdot|$ denotes the cardinality of a set; $\mathbf{1}$ denotes the column vector of ones; and \otimes denotes the Kronecker product. The spectrum of a symmetric matrix $M \in \mathbb{R}^{n \times n}$ is denoted and ordered as $\lambda_1(M) \leq \lambda_2(M) \leq \dots \leq \lambda_n(M)$. For matrices $M, N \in \mathbb{R}^{n \times n}$, $N \preceq M$ denotes that $M - N$ is positive semi-definite.

82.2.1 Two-Component Hierarchical Approach

A common approach to modeling large-scale multi-agent systems is to decompose the system into a hierarchy of manageable components. This process decouples a multi-agent system into a network component which interfaces with the individual system agents. Many applications adopt such an approach, for example, to design inner- and outer-loop systems and to decouple longitudinal and lateral modes in aircraft dynamics (Schmidt 1998; Stevens and Lewis 2003).

In a two-component hierarchical structure, the network dynamics drives the vehicle dynamics and in turn is influenced by the human operators. A benefit of this approach is that if there exists a weak coupling between components, then complicated systems can be reduced to simpler decoupled systems, with only small performance degradation. Also, existing theory regarding one component can be applied to other models with only minimal changes to that component.

For the specific case of a UAV swarm, the swarm is decomposed into an inter-agent network dynamics component (*network dynamics*) and a closed loop vehicle dynamics component (*vehicle dynamics*). The vehicle dynamics encapsulates the individual characteristics of the platform such as a six degrees-of-freedom UAV dynamic model. The study of vehicle dynamics is a well-researched area, while the study of network dynamics is relatively new. Examples of network infrastructure through which the network dynamics act include communication links between agents, range sensors to measure interagent distance and relative-agent velocities, and cameras for interagent relative bearing measurements. A set of human operators may be considered as part of the network in this decomposition. The operators may

Fig. 82.2 (a) Original UAV swarm. The UAV swarms' communication links are marked with *solid lines*. The *squares* denote airborne and land-bound human operators, and the *dotted lines* represent their intercommunication links. The *dashed lines* denote the human operators, communication links to the swarm. (b) The two-component hierarchical design approach

communicate from ground stations and nearby aerial vehicle or directly control all or a subset of UAVs.

This hierarchical approach is graphically represented in Fig. 82.2. The operators' signal drives the network dynamics. The network dynamics is a representation of the interagent interaction that runs a simplified version of the UAV dynamics, such as a particle or unicycle model. The states of the network dynamics are then used for output tracking by the vehicle dynamics. Additional decoupling can be inserted into this hierarchy, such as a reduced order network component, explored in Sect. 82.5.

Care must be taken to place necessary constraints on the dynamics to account for coupling that has been removed. For example, if the network is based on Euclidean distances, the topology of the network must be maintained throughout the trajectory of the vehicle, or alternatively the network must be time varying, based on the states of the vehicle dynamics. Another case, addressed in Sect. 82.4, is that perturbations of the vehicle dynamics should have equivalent perturbations accounted for in the design of controllers for the network component.

This decoupling of the network dynamics serves to isolate the role of the interaction dynamics from the vehicle dynamics. The benefit is that system-theoretic features of the network can be formed and applied to many different vehicle models. The network can then be considered as a design tool in forming a more manageable UAV swarm. The role of the network will be the main focus of this chapter including system's attributes like the controllability Gramian, as well as design attributes like network topology, discussed in Sect. 82.4.

82.2.2 Network Topology

To represent the network topology, the communication points in the network are denoted as nodes, and edges are communication links between points.

$$\mathcal{A}(\mathcal{G}) = \begin{bmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \Delta(\mathcal{G}) = \begin{bmatrix} 2 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \mathcal{L}(\mathcal{G}) = \begin{bmatrix} 2 & -1 & -1 & 0 \\ -1 & 2 & -1 & 0 \\ -1 & -1 & 3 & -1 \\ 0 & 0 & -1 & 1 \end{bmatrix}$$

Fig. 82.3 A sample network graph $\mathcal{G} = (V, E)$ where $V = \{v_1, v_2, v_3, v_4\}$ and $E = \{\{v_1, v_2\}, \{v_1, v_3\}, \{v_2, v_3\}, \{v_3, v_4\}\}$. The adjacency matrix $\mathcal{A}(\mathcal{G})$, degree matrix $\Delta(\mathcal{G})$, and Laplacian matrix $\mathcal{L}(\mathcal{G})$ of the graph are provided

For UAV swarms, the nodes represent UAVs, and the edges correspond to inter-UAVs links, such as wireless communications or relative sensors. It is assumed that all communication links are bidirectional. These nodes and edges can therefore be considered as forming an undirected graph.

Abstractly, an undirected graph $\mathcal{G} = (V, E)$ is defined by a node set V with cardinality n , the number of nodes in the graph, and an edge set E comprised of pairs of nodes, where nodes v_i and v_j are adjacent if $\{v_i, v_j\} \in E \subseteq [V]^2$, the set of two-element subsets of V . One special family of undirected graphs are *tree graphs*, denoted by the set \mathcal{T} , where all two-node pairs are connected by exactly one simple path, that is, a connected graph without cycles. A *spanning tree* of a graph is a tree subgraph that connects all vertices in the graph.

The *neighborhood set* $\mathcal{N}(v_i)$ is composed of the set of nodes adjacent to v_i . The scalar $d(v_i, v_j)$ is the minimum path length, induced by the graph \mathcal{G} , between nodes v_i and v_j . The degree ∂_i of node v_i is the number of its adjacent nodes. The *degree matrix* $\Delta(\mathcal{G}) \in \mathbb{R}^{n \times n}$ is a diagonal matrix with ∂_i at entry (i, i) .

There are many matrix representations of a graph; the two most popular are the adjacency matrix and graph Laplacian matrix that each fully characterize the graph (Bollobás 1998; Diestel 2000). The *adjacency matrix* is a $n \times n$ symmetric matrix with $[\mathcal{A}(\mathcal{G})]_{ij} = 1$ when $\{v_i, v_j\} \in E$ and $[\mathcal{A}(\mathcal{G})]_{ij} = 0$ otherwise. The *graph Laplacian matrix* is defined as $L(\mathcal{G}) = \Delta(\mathcal{G}) - \mathcal{A}(\mathcal{G}) \in \mathbb{R}^{n \times n}$. Figure 82.3 shows an example graph with its corresponding graph matrices.

The graph Laplacian matrix plays an important role in the dynamics of the network. An important feature of this matrix is that it is a (symmetric) positive semi-definite matrix. The spectrum is ordered as $0 = \lambda_1(\mathcal{G}) \leq \lambda_2(\mathcal{G}) \leq \dots \leq \lambda_n(\mathcal{G})$, where, for brevity, $\lambda_i(\mathcal{G})$ is used instead of $\lambda_i(L(\mathcal{G}))$. The spectrum of the graph Laplacian matrix displays many features of the network. For example, the number of zero eigenvalues is equal to the number of connected components. Other features that couple the network topology and dynamics are explored in the following subsection.

82.2.3 Network Dynamics

A common objective for UAV swarms is to reach agreement on one or more of their states. For example, agreement on UAV position achieves rendezvous, or, if agreeing on a virtual position, formation flight can be acquired with known position offsets from the virtual position. Velocity agreement is another attractive property for formation flight. For distributed surveillance, bearing agreement is often desired.

If agreement is required over a network of UAVs without all-to-all communications, a distributed approach is necessary. A protocol which is particularly adept at distributed agreement is the consensus protocol, which is detailed below, and runs within the network dynamics of the UAV swarm.

82.2.3.1 Consensus Dynamics

Consider $x_i(t) \in \mathbb{R}$ to be the i -th node's state at time t on which agreement is required for all nodes. The continuous-time consensus dynamics is defined over the graph $\mathcal{G} = (V, E)$ as

$$\dot{x}_i(t) = \sum_{\{v_i, v_j\} \in E} (x_j(t) - x_i(t)). \quad (82.1)$$

Thus, to update the i -th node's state, only the relative state of node i 's neighbor's state is required. In a compact form with $x(t) \in \mathbb{R}^n$, the collective dynamics is represented as

$$\dot{x}(t) = -L(\mathcal{G})x(t),$$

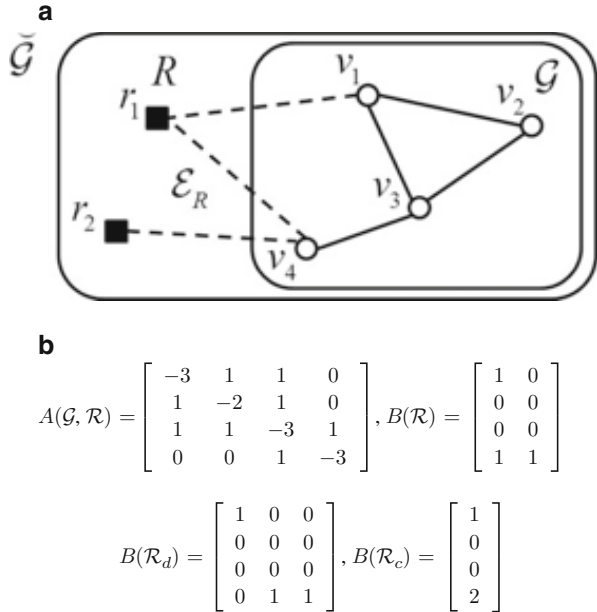

with $L(\mathcal{G})$ being the graph Laplacian matrix of the underlying interaction topology, described in the previous subsection. For a connected graph \mathcal{G} , the network dynamics will converge to an agreement on the state, that is, $x_1(t) = x_2(t) = \dots = x_n(t) = \alpha$, for some constant α , for all initial conditions (Olfati-Saber et al. 2007). Further, the slowest convergence of the dynamics is determined by $\lambda_2(\mathcal{G})$ which is a measure of graph connectivity.

82.2.3.2 Leader-Follower Consensus Dynamics

One of the advantages of the consensus dynamics is that the human operators can seamlessly integrate into the dynamics by directly applying an appropriately designed signal to the interface link. As human operators do not follow (82.1), the operator-influenced consensus is dubbed *leader-follower consensus*. The operators are considered as leaders, and the UAVs as followers.

To form the leader-follower consensus dynamics, the network graph $\mathcal{G} = (V, E)$ is extended to incorporate operator nodes into the graph. This is accomplished by considering the operator pair $\mathcal{R} = (R, \mathcal{E}_R)$, where R is the r element operator node set and $\mathcal{E}_R \subseteq R \times V$ is the set of edges used by the operators to inject signals into the network. It is assumed that for an operator $r_j \in R$, the same signal $u_j(t) \in \mathbb{R}$ is delivered along every edge adjacent to it. A new graph $\check{\mathcal{G}} = (\check{V}, \check{E})$ is thus formed with $\check{V} = V \cup R$ and $\check{E} = E \cup \mathcal{E}_R$. Any communication links between human

Fig. 82.4 (a) The network nodes V with coordination edges E form a graph \mathcal{G} . The human operator in the set R is connected to the rest of the network via the communication links corresponding to the edge set \mathcal{E}_R . The complete operator-network node graph containing all agents $\tilde{V} = V \cup R$ and edges $\tilde{E} = E \cup \mathcal{E}_R$ is denoted as $\tilde{\mathcal{G}}$. (b) The operators r_1 and r_2 communicate to UAVs v_1 and v_4 , leading to an altered graph Laplacian matrix $A(\mathcal{G}, \mathcal{R})$ and the input matrix $B(\mathcal{R})$ of model (82.3). The control matrices relating to the special cases of distinct and common control

operators are removed. This assumption is justified as the operators are assumed to be working cooperatively and do not require coupled dynamics to the other operators' states. Figure 82.4 provides a graphical representation of this notation and setup.

The resulting leader-follower consensus system now assumes the form

$$\dot{x}_i(t) = \sum_{\{v_i, v_j\} \in E} (x_j(t) - x_i(t)) + \sum_{\{v_i, r_j\} \in \mathcal{E}_R} (u_j(t) - x_i(t)) \quad (82.2)$$

with the full dynamics

$$\dot{x}(t) = A(\mathcal{G}, \mathcal{R})x(t) + B(\mathcal{R})u(t), \quad (82.3)$$

where $B(\mathcal{R}) \in \mathbb{R}^{n \times r}$ with $[B(\mathcal{R})]_{ij} = 1$ when $\{r_j, v_i\} \in \mathcal{E}_R$ and $[B(\mathcal{R})]_{ij} = 0$ otherwise, and

$$A(\mathcal{G}, \mathcal{R}) = -(L(\mathcal{G}) + D(\mathcal{R})) \in \mathbb{R}^{n \times n}, \quad (82.4)$$

where $D(\mathcal{R}) \in \mathbb{R}^{n \times n}$ with $[D(\mathcal{R})]_{ii} = \delta_i^r$, where δ_i^r is the number of operators adjacent to v_i , and $[D(\mathcal{R})]_{ij} = 0$ otherwise. The scalar δ_j^v is defined as the number of network nodes adjacent to r_j . There are two special operator interfaces examined in this chapter: one in which there is exactly one operator for each edge \mathcal{E}_R , and so an independent (or *distinct*) control signal is delivered through each edge, denoted with the operator pair \mathcal{R}_d , and one where there exists only one operator, so a *common*

signal is delivered through each edge of \mathcal{E}_R , denoted with pair \mathcal{R}_c . A sample model and its system matrices as well as the special cases of \mathcal{R}_d and \mathcal{R}_c are depicted in Fig. 82.4. The set $\pi(\mathcal{E}_R)$ is composed of all nodes $v_i \in V$ such that $\{r_j, v_i\} \in \mathcal{E}_R$. In other words, $\pi(\mathcal{E}_R)$ is simply the set of agents that directly connect to an operator

The matrix $A(\mathcal{G}, \mathcal{R})$ in (82.4) is the *Dirichlet matrix*, or grounded Laplacian (Barooah and Hespanha 2006; Salsa 2008). The spectrum of $A(\mathcal{G}, \mathcal{R})$ relates closely to the spectrum of $L(\mathcal{G})$. In this way, the topology of the underlying graph is related to the dynamics of model (82.3). An auxiliary observation about the Dirichlet matrix, to be used subsequently, is the following.

Proposition 1 (Chapman and Mesbahi 2010) *The matrix $A(\mathcal{G}, \mathcal{R})$ of model (82.3) is negative definite and so invertible, if the original graph is connected.*

In the following discussion, only connected graphs are considered as each component of a disconnected graph can be analyzed separately.

82.3 Effective Interfaces Using the Open Loop \mathcal{H}_2 Norm

The two-component hierarchical model approach separates factors that contribute to the formation of manageable UAV swarms. The first is the familiar vehicle dynamics controllability, where the hardware and software design of individual UAVs affects the vehicles' receptiveness to operator commands. The second is network dynamics controllability which is unique to multi-vehicle platforms. Network dynamics controllability is a function of the network protocol and the underlying interagent connections, which can be represented by a graph as described in the previous section. The following will be focusing on network-theoretic aspects to controllability. The results can be used to select effective interfaces (attachment points) for the operators to interact with the UAV swarm.

The main tool of analysis is the open loop \mathcal{H}_2 norm of the system. For a linear system, with inputs, outputs and internal states, $u(t)$, $y(t)$ and $x(t)$, respectively, of the form

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t),\end{aligned}$$

the open loop \mathcal{H}_2 norm is defined in terms of the controllability Gramian,

$$P_T(A, B) := \int_0^T e^{A\tau} B B^T e^{A^T \tau} d\tau,$$

for the system. Specifically, the open loop \mathcal{H}_2 norm is

$$\|G(s)\|_2 = \sqrt{\text{tr}(C P_\infty(A, B) C^T)}, \quad (82.5)$$

where the state-space realization is $G(s) = C(sI - A)^{-1}B$. The open loop \mathcal{H}_2 norm serves as an attractive metric of the manageability of a dynamic system. This is evident from its relationship to the controllability Gramian, as well as the relationship to the state-space realization describing the mapping of inputs to outputs, that is, $y(s) = G(s)u(s)$. Another relationship is to the energy amplification of the system. The energy of the states at the system output, from a unit impulse input $u(t)$ when $x(0) = 0$, is

$$\int_0^\infty y(t)^T y(t) dt = \|G(s)\|_2^2.$$

From these observations, in general, inputs perturb the outputs more effectively as $\|G(s)\|_2$ increases. In other words, systems with a larger open loop \mathcal{H}_2 norm tend to be more manageable.

For the leader-follower consensus model introduced in Sect. 8.2.3.2, the operators are assumed to be able to monitor all of the UAVs in the swarm. This implies that $C = I$, and the open loop \mathcal{H}_2 norm reduces to

$$\|G(s)\|_2 = \sqrt{\text{tr}(P_\infty(A(\mathcal{G}, \mathcal{R}), B(\mathcal{R})))}.$$

If $A(\mathcal{G}, \mathcal{R})$ is negative definite, then $\|G(s)\|_2$ is bounded. From Proposition 1, this requirement is met when \mathcal{G} is connected. For a specific model, the open loop \mathcal{H}_2 norm is henceforth denoted as $\|G_{\mathcal{G}, \mathcal{R}}(s)\|_2$, as it is solely dependent on \mathcal{G} and \mathcal{R} . Similarly, $P_\infty(A(\mathcal{G}, \mathcal{R}), B(\mathcal{R}))$ is denoted as $P(\mathcal{G}, \mathcal{R})$. For UAV swarming applications, the open loop \mathcal{H}_2 norm quantifies the network's amplification of the operators' inputs.

Directly, for connected graph \mathcal{G} , from the definition of the controllability Gramian,

$$\begin{aligned} \|G_{\mathcal{G}, \mathcal{R}}(s)\|_2^2 &= \text{tr} \left(\int_0^\infty e^{A(\mathcal{G}, \mathcal{R})\tau} B(\mathcal{R}) B(\mathcal{R})^T e^{A(\mathcal{G}, \mathcal{R})^T \tau} d\tau \right) \\ &= \text{tr} \left(\int_0^\infty B(\mathcal{R}) B(\mathcal{R})^T e^{A(\mathcal{G}, \mathcal{R})^T \tau} e^{A(\mathcal{G}, \mathcal{R})\tau} d\tau \right) \\ &= \text{tr} \left(B(\mathcal{R}) B(\mathcal{R})^T \int_0^\infty e^{2A(\mathcal{G}, \mathcal{R})\tau} d\tau \right) \\ &= -\frac{1}{2} \text{tr} (M(\mathcal{R}) A(\mathcal{G}, \mathcal{R})^{-1}), \end{aligned} \tag{82.6}$$

where $M(\mathcal{R}) = B(\mathcal{R}) B(\mathcal{R})^T$.

82.3.1 Common Signal Operator

Equation (82.6) provides network-theoretic properties of the open loop \mathcal{H}_2 norm for the special case introduced in Sect. 82.2.3.2, where the same signal is delivered along every edge in \mathcal{E}_R with operator pair \mathcal{R}_c . Here, either only one operator applies a signal or all operators apply the same signal. The following proposition states that the open loop \mathcal{H}_2 norm only depends on the number of communication links between the operators and the UAV nodes, $|\mathcal{E}_R|$.

Proposition 2 *For a connected graph \mathcal{G} where all operators apply the same signal,*

$$\|G_{\mathcal{G}, \mathcal{R}_c}(s)\|_2^2 = \frac{1}{2} |\mathcal{E}_R|.$$

Proof. The eigenvalue $\lambda_1(\mathcal{G}) = 0$ is associated with the left eigenvector $\mathbf{1}$ and $B(\mathcal{R}_c) \in \mathbb{R}^{n \times 1}$ where $B(\mathcal{R}_c)_i = [D(\mathcal{R}_c)]_{ii}$, for $i = 1, \dots, n$. Then,

$$\begin{aligned} -\mathbf{1}^T A(\mathcal{G}, \mathcal{R}_c) &= \mathbf{1}^T (L(\mathcal{G}) + D(\mathcal{R}_c)) \\ &= \mathbf{1}^T D(\mathcal{R}_c) \\ &= B(\mathcal{R}_c)^T. \end{aligned}$$

From Proposition (82.6),

$$\begin{aligned} \|G_{\mathcal{G}, \mathcal{R}_c}(s)\|_2^2 &= -\frac{1}{2} \text{tr}(B(\mathcal{R}_c)B(\mathcal{R}_c)^T A(\mathcal{G}, \mathcal{R}_c)^{-1}) \\ &= \frac{1}{2} \text{tr}(B(\mathcal{R}_c)\mathbf{1}^T) \\ &= \frac{1}{2} |\mathcal{E}_R|. \end{aligned}$$

■

In some UAV swarming scenarios, an operator may have a group of UAVs to control directly. Proposition 2 provides the best selection of UAVs from the swarm based on the network topology.

Corollary 3 *For a graph $\check{\mathcal{G}}$ and model (82.3) with one operator,*

$$\|G_{\check{\mathcal{G}}, \mathcal{R}}(s)\|_2^2 = \frac{1}{2} \delta(r_1),$$

where $\delta(r_1)$ is the degree of the operator in the graph $\check{\mathcal{G}}$.

Fig. 82.5 Equivalent electrical network of the graph in Fig. 82.4. The potential difference $V_{v_3} - V_{\mathcal{R}}$ is the effective resistance between v_3 and common resistor node $\{r_1, r_2\}$

Proof. The statement of the corollary follows directly from Proposition 2. ■

The implication of Corollary 3 is that the operator should select the UAV with the largest number of neighboring UAVs to maximize the open loop \mathcal{H}_2 norm of the system, independent of other network features.

82.3.2 Independent Signal Operator

The matrix $-A(\mathcal{G}, \mathcal{R})^{-1}$ in (82.6) is not unfamiliar to graph theorists and describes features of an equivalent electrical network interpretation of the graph (Bollobás 1998; Baroah and Hespanha 2006). In this interpretation, the edges \hat{E} of $\hat{\mathcal{G}}$ are replaced with one-ohm resistors and the nodes \hat{V} by connection points between resistors. In addition, all connection points corresponding to the node set R are electrically shorted. The effective resistance between two connection points in an electrical network is defined as the potential drop between the two points when a one-Amp current source is connected across the two points. This interpretation is that the i -th diagonal element of $-A(\mathcal{G}, \mathcal{R})^{-1}$ is the effective resistance $E_{\text{eff}}(v_i)$ between the common shorted external agents R and node v_i (Bollobás 1998). An example of the equivalent electrical network of the graph in Fig. 82.4 is displayed in Fig. 82.5.

With the graph-based machinery of the effective resistance, the open loop \mathcal{H}_2 norm can be reformulated for another special operator pair. Specifically, the following proposition presents an equivalent relation for the open loop \mathcal{H}_2 norm for the case where there is an independent (or distinct) control signal delivered along each edge of \mathcal{E}_R , described in Sect. 82.2.3.2 and denoted with the operator pair \mathcal{R}_d .

Proposition 4 *For a connected graph \mathcal{G} , if each operator has exactly one edge, and each edge in \mathcal{R}_d supplies an independent signal, then*

$$\|G_{\mathcal{G}, \mathcal{R}_d}(s)\|_2^2 = \frac{1}{2} \sum_{v_i \in \pi(\mathcal{E}_R)} E_{\text{eff}}(v_i). \quad (82.7)$$

Proof. The matrix $M(\mathcal{R}_d)$ is a diagonal matrix with $[M(\mathcal{R}_d)]_{ii} = 1$ if $v_i \in \pi(\mathcal{E}_R)$ and $[M(\mathcal{R}_d)]_{ii} = 0$ otherwise. Therefore,

$$[M(\mathcal{R}_d) A(\mathcal{G}, \mathcal{R}_d)^{-1}]_{ii} = \begin{cases} [A(\mathcal{G}, \mathcal{R}_d)^{-1}]_{ii} & \text{if } v_i \in \pi(\mathcal{E}_R) \\ 0 & \text{otherwise.} \end{cases}$$

From (82.6) and the effective resistance interpretation of $[A(\mathcal{G}, \mathcal{R}_d)^{-1}]_{ii}$, the statement of the lemma now follows. ■

From Proposition 4, the selection of directly controlled UAVs to maximize the open loop \mathcal{H}_2 norm will, in general, involve selecting UAVs with a large number of neighbors and a large separation between UAVs. The intuition is that the placement of resistors in series as opposed to parallel increases resistance; thus, maximizing the path length between UAVs effectively introduces more resistors in series and less in parallel, thus generating a larger effective resistance sum.

82.3.3 Generic Signal Operator

The open loop \mathcal{H}_2 norm of the special cases with constant and distinct operator pairs, \mathcal{R}_c and \mathcal{R}_d , respectively, can be used to bound the open loop \mathcal{H}_2 norm of a generic \mathcal{R} . The approach to relate the special operator cases involves fusing all the leaders in \mathcal{R} and causing a common control signal to be sent along all edges in \mathcal{E}_R , thus forming a constant operator pair $\widetilde{\mathcal{R}}_c$. Similarly, designating a distinct leader for each \mathcal{E}_R in \mathcal{R} forms a distinct operator pair $\widetilde{\mathcal{R}}_d$.

Additionally, scaling is required for the comparable operator pairs $\widetilde{\mathcal{R}}_c$ and $\widetilde{\mathcal{R}}_d$ such that a control signal applied to the edges in \mathcal{E}_R of $\widetilde{\mathcal{R}}_c$ maps to the same signal along the edges of \mathcal{R} and similarly for \mathcal{R} to $\widetilde{\mathcal{R}}_d$. The special operator pair $\widetilde{\mathcal{R}}_c$ is defined such that a control u_c of system $\widetilde{\mathcal{R}}_c$ maps to a control u of system \mathcal{R} so that there exists a transformation matrix H_1 such that $B(\widetilde{\mathcal{R}}_c)u_c = B(\mathcal{R})u$ and $\|u_c\|_2 = 1$ implies $\|u\|_2 = 1$ when $H_1 u_c = u$. Similarly, there exists a transformation matrix H_2 such that $B(\mathcal{R})u = B(\widetilde{\mathcal{R}}_d)u_d$ and so that $\|u\|_2 = 1$ implies $\|u_d\|_2 = 1$ when $H_2 u = u_d$. This ensures that $B(\mathcal{R}) = B(\widetilde{\mathcal{R}}_d)H_2$, $B(\widetilde{\mathcal{R}}_c) = B(\mathcal{R})H_1$, where $H_1 = \frac{1}{\sqrt{|\mathcal{R}|}} \mathbf{1} \in \mathbb{R}^{|\mathcal{R}| \times 1}$ and $H_2 \in \mathbb{R}^{|\mathcal{R}_d| \times |\mathcal{R}|}$. Arbitrarily ordering the edges in \mathcal{E}_R , then each edge $k = 1, \dots, |\mathcal{E}_R|$ corresponds to some $(r_j, v_i) \in \mathcal{E}_R$. The transformation matrix H_2 is defined as $[H_2]_{kj} = 1/\sqrt{\delta_j^v}$ for each edge k and zero otherwise. Therefore, $[B(\widetilde{\mathcal{R}}_c)]_i = \frac{\delta_i^r}{\sqrt{|\mathcal{R}|}}$ if $(r_j, v_i) \in \mathcal{E}_R$, and zero otherwise and $[B(\widetilde{\mathcal{R}}_d)]_{jk} = \sqrt{\delta_j^v}$ for each edge k , and zero otherwise.

When \mathcal{R} is a constant operator pair, $H_1 = I$ and $\mathcal{R} = \widetilde{\mathcal{R}}_c$. Similarly, when \mathcal{R} is a distinct operator pair, $H_2 = I$ and $\mathcal{R} = \widetilde{\mathcal{R}}_d$.

Proposition 5 For a graph \mathcal{G} with operator pair \mathcal{R} and operator pairs $\widetilde{\mathcal{R}}_c$ and $\widetilde{\mathcal{R}}_d$ defined above,

$$P(\mathcal{G}, \widetilde{\mathcal{R}}_c) \leq P(\mathcal{G}, \mathcal{R}) \leq P(\mathcal{G}, \widetilde{\mathcal{R}}_d).$$

Proof. Let $b_1, \dots, b_{|R|}$ be the columns of the matrix $B(\mathcal{R})$, then $B(\mathcal{R}_c) = \sum_{i=1}^{|R|} b_i$, and $B(\widetilde{\mathcal{R}}_c) = \frac{1}{\sqrt{|R|}} \sum_{i=1}^{|R|} b_i$. Hence, using the fact that $\|x\|_1 \leq \sqrt{p} \|x\|_2$ for all vectors $x \in \mathbb{R}^p$, for $y \in \mathbb{R}^n$

$$\begin{aligned} \|B(\widetilde{\mathcal{R}}_c)^T y\|_2^2 &= \frac{1}{|R|} \left(\sum_{i=1}^{|R|} b_i y \right)^2 \\ &\leq \frac{1}{|R|} \left(\sum_{i=1}^{|R|} |b_i y| \right)^2 \\ &\leq \frac{1}{|R|} \sum_{i=1}^{|R|} (b_i y)^2 \\ &= \frac{1}{|R|} \|B(\mathcal{R})^T y\|_1^2 \\ &\leq \|B(\mathcal{R})^T y\|_2^2, \end{aligned}$$

and $B(\widetilde{\mathcal{R}}_c)B(\widetilde{\mathcal{R}}_c)^T \leq B(\mathcal{R})B(\mathcal{R})^T$. Similarly, $B(\mathcal{R})B(\mathcal{R})^T \leq B(\widetilde{\mathcal{R}}_d)B(\widetilde{\mathcal{R}}_d)^T$. Noting that $A(\mathcal{G}, \mathcal{R}) = A(\mathcal{G}, \widetilde{\mathcal{R}}_c) = A(\mathcal{G}, \widetilde{\mathcal{R}}_d)$, the controllability gramian consequently has the relationship,

$$\begin{aligned} P(\mathcal{G}, \widetilde{\mathcal{R}}_c) &= \int_0^\infty e^{A(\mathcal{G}, \mathcal{R})\tau} B(\widetilde{\mathcal{R}}_c)B(\widetilde{\mathcal{R}}_c)^T e^{A(\mathcal{G}, \mathcal{R})^T \tau} d\tau \\ &\leq \int_0^\infty e^{A(\mathcal{G}, \mathcal{R})\tau} B(\mathcal{R})B(\mathcal{R})^T e^{A(\mathcal{G}, \mathcal{R})^T \tau} d\tau \\ &= P(\mathcal{G}, \mathcal{R}), \end{aligned}$$

and similarly, $P(\mathcal{G}, \mathcal{R}) \leq P(\mathcal{G}, \widetilde{\mathcal{R}}_d)$. ■

The groundwork is now in place to present bounds for the open loop \mathcal{H}_2 norm for a generic operator pair \mathcal{R} .

Lemma 6 For a graph \mathcal{G} and operator pair \mathcal{R} ,

$$\frac{1}{2|R|} |\mathcal{E}_R| \leq \|G_{\mathcal{G}, \mathcal{R}}(s)\|_2^2 \leq \frac{1}{2} \sum_{v_i \in \pi(\mathcal{E}_R)} \alpha_i E_{\text{eff}}(v_i),$$

where

$$\alpha_i = \sum_{(r_j, v_i) \in \mathcal{E}_R} \delta_j^v,$$

that is, α_i is the sum of the non-operator degrees for each operator attached to v_i .

Proof. From Proposition 5,

$$\left\| G_{\mathcal{G}, \widetilde{\mathcal{R}}_c}(s) \right\|_2^2 \leq \left\| G_{\mathcal{G}, \mathcal{R}}(s) \right\|_2^2 \leq \left\| G_{\mathcal{G}, \widetilde{\mathcal{R}}_d}(s) \right\|_2^2,$$

and

$$\begin{aligned} \text{tr}(P(\mathcal{G}, \widetilde{\mathcal{R}}_c)) &= \text{tr}(B(\widetilde{\mathcal{R}}_c)^T A(\mathcal{G}, \mathcal{R})^{-1} B(\widetilde{\mathcal{R}}_c)) \\ &= \frac{1}{|R|} \text{tr}(B(\mathcal{R}_c)^T A(\mathcal{G}, \mathcal{R})^{-1} B(\mathcal{R}_c)) \\ &= \frac{1}{|R|} \text{tr}(P(\mathcal{G}, \mathcal{R}_c)). \end{aligned}$$

The matrix $M(\widetilde{\mathcal{R}}_d)$ is diagonal with $[M(\widetilde{\mathcal{R}}_d)]_{ii} = \alpha_i$ if $(r_j, v_i) \in \mathcal{E}_R$ and $[M(\widetilde{\mathcal{R}}_d)]_{ii} = 0$ otherwise, and so

$$[M(\widetilde{\mathcal{R}}_d)A(\mathcal{G}, \widetilde{\mathcal{R}}_d)^{-1}]_{ii} = \begin{cases} \alpha_i [A(\mathcal{G}, \mathcal{R}_d)^{-1}]_{ii} & \text{if } v_i \in \pi(\mathcal{E}_R) \\ 0 & \text{otherwise.} \end{cases}$$

Hence,

$$\begin{aligned} \text{tr}(P(\mathcal{G}, \widetilde{\mathcal{R}}_d)) &= \frac{1}{2} \sum_{v_i \in \pi(\mathcal{E}_R)} [M(\widetilde{\mathcal{R}}_d)A(\mathcal{G}, \widetilde{\mathcal{R}}_d)^{-1}]_{ii} \\ &= \frac{1}{2} \sum_{v_i \in \pi(\mathcal{E}_R)} \alpha_i [A(\mathcal{G}, \mathcal{R}_d)^{-1}]_{ii}. \end{aligned}$$

Applying Proposition 2 and the proof of Proposition 4, the proof of the lemma follows. ■

Examining Lemma 6, the lower bound of the open loop \mathcal{H}_2 norm of the network dynamics increases as the ratio of operator edges to operators increases. The upper bound increases with the number of UAVs directly controlled by the operators. The upper bound also increases with the separation of the operators as per the effective resistance discussion for Proposition 4.

An in-depth analysis of $\left\| G_{\mathcal{G}, \widetilde{\mathcal{R}}_d}(s) \right\|_2^2$ was undertaken for a specialized class of graphs, namely, trees \mathcal{T} (Chapman and Mesbahi 2013). To apply some of these

results to more generalized connected graphs, consider any spanning tree \mathcal{T}_s of a connected graph \mathcal{G} . In terms of the electrical resistance analogy, the resistor network corresponding to \mathcal{T}_s is formed by removing resistors from the resistor network corresponding to \mathcal{G} . Rayleigh's monotonicity law states that if the edge resistance in an electrical network is decreased, then the effective resistance between any two agents in the network can only decrease (Bollobás 1998). Consequently, $\left\|G_{\mathcal{G}, \widetilde{\mathcal{R}}_d}(s)\right\|_2^2 \leq \left\|G_{\mathcal{T}_s, \widetilde{\mathcal{R}}_d}(s)\right\|_2^2$, that is, the open loop \mathcal{H}_2 norm of the system with the coordination graph \mathcal{G} , is bounded above by the open loop \mathcal{H}_2 norm system with the coordination graph \mathcal{T}_s corresponding to any of the spanning trees of \mathcal{G} .

82.4 Topology Design

As a group of networked UAVs require only nonphysical interconnections for their coordinated behavior, they have the advantage that their inter-vehicle coordination graph can be *rewired*. This observation leads to an online method for improving network manageability, namely, via a judicious topology design. The goal is to design network topologies that exhibit good control authority. The metric for manageability used in the following analysis is the open loop \mathcal{H}_2 norm of the network dynamics, described in Sect. 82.3.

82.4.1 Constraint Graph

Before continuing, it is important to explore constraints on the underlying graph topology that are prescribed by the swarming application. For all UAVs in the swarm to reach a common consensus, there must be some path connecting each and every UAV along some subset of graph edges, that is, the graph must remain connected for any topology redesign. The nodes within the graph represent the UAVs. As no loss or gain of UAVs is assumed, the number of nodes n remains fixed. An edge $\{v_i, v_j\} \in E$ in the graph \mathcal{G} indicates that UAV v_i is sensing or has communicated the relative information of UAV v_j and vice versa; thus, the total sensing or communication load on the network is $2|E|$, and so fixing the number of edges equates to maintaining this load. Individual UAVs may also have limited sensing or communication capabilities. From a graph-theoretic perspective, this is represented as an upper bound on a node's degree δ_i . Finally, the ability of UAV v_i to perform accurate relative sensing or low-cost communication with UAV v_j is limited by the Euclidean separation of the two UAVs. A *Euclidean-based constraint graph* $\check{\mathcal{G}}_c = (\check{V}, \check{E}_c)$ can be formed where edges exist between UAVs when they lie in each other's sensing range. For topology design, only a subgraph of this constraint graph may be selected.

Figure 82.6a depicts a Euclidean-based constraint graph on 20 nodes. The graph in Fig. 82.6b satisfies the connected Euclidean subgraph constraint with the added global and local load sensing constraints that $|E| \leq 51$ and $\delta_i \leq 7$ for all $v_i \in V$.

Fig. 82.6 Agent graph with operator agents (*squares*). (a) A Euclidean constraint graph $\check{\mathcal{G}}_c = (V, \check{E}_c)$. (b) A connected subgraph of (a) meeting the global and local edge constraints, $|E| \leq 51$ and $\delta_i \leq 7$ for all $v_i \in V$

82.4.2 Network Design Protocol

This section introduces a network design protocol to improve the open loop \mathcal{H}_2 norm of the network. The proposed protocol involves decentralized edge trading (rewiring) between neighboring nodes in the network. The protocol runs over the spanning trees of \mathcal{G} with the objective of increasing $\|G_{\mathcal{G}, \mathcal{R}}(s)\|_2^2$ via increasing $|\mathcal{E}_R|$ and $E_{\text{eff}}(v_i)$ for all $v_i \in \pi(\mathcal{E}_R)$ as illustrated through Lemma 6.

The protocol involves edge trades between neighboring agents executed concurrently and/or in a random agent order while maintaining a connected tree at each iteration. The general procedure is to randomly select a spanning tree \mathcal{T}_s of \mathcal{G} and apply Protocol 1 for some finite number of edge trades and then repeat with a new spanning tree. Within the protocol, an edge removal and subsequent addition is denoted by the notation, \setminus for set minus and \cup for set addition, and the set $\mathcal{I}(v_i)$ contains all nodes that are neighbors of v_i and lie on the shortest path between v_i and any $r_j \in R$. Formally,

$$\mathcal{I}(v_i) := \{v \in \mathcal{N}(v_i) | \exists r \in R, d(v, r) < d(v_i, r)\}.$$

In this direction, the special set of nodes that lie on any of the shortest paths between nodes in \mathcal{R} is defined as the *main path nodes*, that is, those nodes that are neighbors with an operator or with $|\mathcal{I}(v_i)| > 1$. An example of the described notation appears in Fig. 82.7.

The set $\mathcal{I}(v_i)$ can be established locally with a broadcast by the human operator-controlled UAVs, informing their neighbors that they are being directly controlled. This signal can be rebroadcast through neighbors to all UAVs in the swarm, and in doing so, all UAVs are aware of the local directions of the controlled vehicles and more specifically $\mathcal{I}(v_i)$ – their neighbors that are closer to the controlled vehicles set $\pi(\mathcal{E}_R)$. The protocol can be executed on any arbitrary node $v_i \in V$ and requires

Fig. 82.7 Example of protocol notation. The operators are marked with *squares* and the network nodes with *circles*. Arrows on the edges indicate presence of a directed path away from the operators. The set $\mathcal{I}(\cdot)$ is defined for each node as $\mathcal{I}(v_1) = \{r_1, v_2\}$, $\mathcal{I}(v_3) = \{r_2, v_2\}$, $\mathcal{I}(v_2) = \{v_1, v_3\}$, $\mathcal{I}(v_4) = \{v_2\}$, and $\mathcal{I}(v_5) = \mathcal{I}(v_6) = \{v_4\}$. The main path nodes $\{v_1, v_2, v_3\}$ are marked with *solid (red) circles*

Fig. 82.8 (1a)–(1b) Edge swap of Protocol 1 when $|\mathcal{I}(v_i)| = 1$ (condition 1). (2a)–(2b) Edge swap of Protocol 1 when $|\mathcal{I}(v_i)| > 1$ (condition 2). The main path nodes are marked with *solid (red) circles*, and *dotted edges* indicate edges that are removed and added in the protocol

the knowledge of $\mathcal{I}(v_i)$ and $\mathcal{N}(v_i)$ (with the neighborhood defined over $\check{\mathcal{G}}$); hence, the protocol is distributed and decentralized – operating on only local information.

The protocol involves two conditions on the spanning tree: the first pushes nodes toward the main path nodes and the other increases the main path node set. The purpose of both conditions is to increase the degree of operators in R thus increasing $|\mathcal{E}_R|$ and in turn to increase the lower bound in Lemma 6. The second condition's purpose is to increase the effective resistance for nodes in set π (\mathcal{E}_R) and, in doing so, increase the upper bound in Lemma 6. The conditions of the protocol are demonstrated pictorially in Fig. 82.8.

The following lemmas appear in Chapman and Mesbahi (2010), and readers are referred to this paper for the corresponding proofs.

Protocol 1: Increasing open loop \mathcal{H}_2 edge swap

```

foreach Node  $v_i \in V$  do
  if  $\exists v_j, v_k \in \check{V}$  s.t.  $v_j \in \mathcal{I}(v_i), v_k \in \mathcal{N}(v_i) \setminus \mathcal{I}(v_i), \{v_j, v_k\} \notin E$  and  $\{v_j, v_k\} \in \check{E}$  then
     $E \rightarrow E \cup \{v_j, v_k\};$ 
    if  $|\mathcal{I}(v_i)| = 1$  then
       $E \rightarrow E \setminus \{v_i, v_k\};$ 
    else
       $E \rightarrow E \setminus \{v_i, v_j\};$ 
    end
  end
end

```

Lemma 7 Under conditions of Protocol 1, $|\mathcal{E}_R|$ only increases and the graph remains connected.

Lemma 8 For a tree \mathcal{T} , under the second conditions of Protocol 1, $E_{\text{eff}}(v_i)$ for $v_i \in \pi(\mathcal{E}_R)$, monotonically increases.

Lemma 7 has the effect of compressing the network about the main path agents. On the other hand, Lemma 8 adds agents to the main path of \mathcal{T} and in doing so elongates the main path. From a network standpoint, the path between operators is increased. While from an equivalent resistor circuit interpretation, parallel resistors are replaced by series resistors, increasing effective resistance for $v_i \in \pi(\mathcal{E}_R)$. As Protocol 1 iterates over the node set V but involves edges swaps with nodes in set R , then the number of edges attached to nodes in R can only increase.

82.4.3 Topology Design for Wind-Gust Disturbance Rejection

Unpredictable environmental perturbation such as wind gusts is considered one of the main factors that risk a UAV program failure (Drezner et al. 1999). Fulghum (1998) commented that wind could be particularly onerous in cities where buildings produce microbursts.

It has previously been demonstrated that operators applying a *grounded signal* (all operators apply a common constant signal) are able to control the mean consensus value of a wind-gust disturbed system (Chapman and Mesbahi 2013). The following example investigates improving the disturbance rejection for a wind-gust disturbed system via topology design.

82.4.3.1 Wind-Gust Perturbed Model

A vertical wind-gust w_g is not a white noise random signal but has a power spectral density given in Dryden form as (Stevens and Lewis 2003),

$$\Phi_w(\omega) = 2L\sigma^2 \frac{1 + 3L^2\omega^2}{(1 + L^2\omega^2)^2}, \quad (82.8)$$

with frequency in rad/s ω , turbulence intensity σ , and turbulence scale length divided by true airspeed L .

The power spectral density (82.8) can be factored (Stevens and Lewis 2003) as,

$$\Phi_w(s) = H_w(s)H_w(-s),$$

where

$$H_w(s) = \sigma \sqrt{\frac{6}{L}} \frac{s + 1/L\sqrt{3}}{s^2 + 2s/L + 1/L^2}.$$

Now a realization of $H_w(s)$ corresponding to w , a white noise input with zero mean and unit variance W , is given by

$$\begin{aligned} \dot{z}(t) &= \begin{bmatrix} 0 & 1 \\ -\frac{1}{L^2} & -\frac{2}{L} \end{bmatrix} z(t) + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w(t), \\ &= A_w z(t) + B_w w(t), \end{aligned} \quad (82.9)$$

where $z(t) \in \mathbb{R}^2$ denotes the internal states of the vertical wind gust and

$$\begin{aligned} w_g(t) &= \gamma \begin{bmatrix} \frac{1}{L\sqrt{3}} & 1 \end{bmatrix} z(t) \\ &= C_w z(t), \end{aligned} \quad (82.10)$$

where $\gamma = \sigma \sqrt{6/L}$.

The vertical wind model dynamics can now be incorporated into the UAV network dynamics.

For small UAVs and MAVs, it is common that a wind gust has a first-order effect on the vehicle dynamics (Shyy et al. 2007). This means that a wind-gust disturbance to the vehicle dynamics can be replaced with a disturbance on the network dynamics. Due to the close proximity of UAV swarms, the same vertical gust $w_g(t) \in \mathbb{R}$ is assumed to act upon all UAVs in the swarm. The network dynamics is running consensus on a time-varying altitude state $x(t)$, for example, to maintain a common formation height for surveillance and communication benefits. Subsequently, the network dynamics running a perturbed particle model assumes the form

$$\begin{aligned} \begin{bmatrix} \dot{x}(t) \\ \dot{z}(t) \end{bmatrix} &= \begin{bmatrix} A(\mathcal{G}, \mathcal{R})x(t) + B(\mathcal{R})u(t) \\ \dot{z}(t) \end{bmatrix} + \begin{bmatrix} H \\ 0 \end{bmatrix} w_g(t) \\ &= \begin{bmatrix} A(\mathcal{G}, \mathcal{R})x(t) \\ A_w z(t) + B_w w(t) \end{bmatrix} + \begin{bmatrix} B(\mathcal{R}) \\ 0 \end{bmatrix} u(t) + \begin{bmatrix} H \\ 0 \end{bmatrix} C_w z(t) \\ &= \begin{bmatrix} A(\mathcal{G}, \mathcal{R})x(t) \\ A_w z(t) + B_w w(t) \end{bmatrix} + \begin{bmatrix} B(\mathcal{R}) \\ 0 \end{bmatrix} u(t) + \begin{bmatrix} A_z \\ 0 \end{bmatrix} z(t) \\ &= \begin{bmatrix} A(\mathcal{G}, \mathcal{R}) & HC_w \\ 0 & A_w \end{bmatrix} \begin{bmatrix} x(t) \\ z(t) \end{bmatrix} + \begin{bmatrix} B(\mathcal{R}) \\ 0 \end{bmatrix} u(t) + \begin{bmatrix} 0 \\ B_w \end{bmatrix} w(t), \end{aligned} \quad (82.11)$$

where $H = [h_1, \dots, h_n]^T$ and $h_i \in \mathbb{R}$ is a scaling factor specific to UAV i 's gust-vehicle interaction.

It is assumed the operators can measure the altitude of all vehicles with some white measurement noise $v(t) \in \mathbb{R}^n$ with correlation matrix $V \in \mathbb{R}^{n \times n}$. Restating (82.11) in compact form,

$$\begin{aligned} \begin{bmatrix} \dot{x}(t) \\ \dot{z}(t) \end{bmatrix} &= \mathcal{A}_D \begin{bmatrix} x(t) \\ z(t) \end{bmatrix} + \mathcal{B}_D u(t) + G_D w(t) \\ y(t) &= \mathcal{C}_D \begin{bmatrix} x(t) \\ z(t) \end{bmatrix} + v(t), \end{aligned} \quad (82.12)$$

where \mathcal{A}_D , \mathcal{B}_D , and G_D are apparent from (82.11) and $y(t) \in \mathbb{R}^n$ is the operators' observations. As the operators can observe all the followers' states, but not the internal dynamics of the wind gust, then it follows that $\mathcal{C}_D = [I_{n \times n} \ 0_{n \times 2}]$.

82.4.3.2 \mathcal{H}_2 Controller Design

An \mathcal{H}_2 controller will now be designed for wind-gust rejection for the network dynamics. A consequence of Proposition 1 is that, if the underlying network is connected, $A(\mathcal{G}, \mathcal{R})$ has only negative eigenvalues. Examining A_w , $\lambda_i(A_w) = -1/L$ for $i = 1, 2$ and as $L > 0$, it follows that A_w has only negative eigenvalues. Therefore, the system is stabilizable and detectable, so a stabilizing compensator can be formed.

Hence, given a performance measure

$$J = \lim_{t \rightarrow \infty} \mathbb{E} \{x(t)^T Q x(t) + u(t)^T R u(t)\},$$

a compensator that minimizes J can be designed with the form

$$\begin{aligned} \dot{\hat{x}}(t) &= (\mathcal{A}_D - \mathcal{B}_D K_c - K_f \mathcal{C}_D) \hat{x}(t) + K_f y(t) \\ u(t) &= K_c \hat{x}(t), \end{aligned}$$

where $\hat{x}(t)$ is an estimate of $[x(t)^T z(t)^T]^T$, $K_c \in \mathbb{R}^{r \times n}$ is the compensator gain, and $K_f \in \mathbb{R}^{n \times n}$ is the filter gain. The compensator and filter gains satisfy $K_c = R^{-1} \mathcal{B}_D^T P$ and $K_f = S \mathcal{C}_D^T V^{-1}$, and P and S are the solutions of the algebraic Riccati equations,

$$0 = \mathcal{A}_D^T P + P \mathcal{A}_D + Q - P \mathcal{B}_D R^{-1} \mathcal{B}_D^T P$$

and

$$0 = \mathcal{A}_D S + S \mathcal{A}_D^T + G_D W G_D^T - S \mathcal{C}_D^T V^{-1} \mathcal{C}_D S.$$

The corresponding optimal performance cost is then

$$J^* = \text{tr}(P K_f V K_f^T) + \text{tr}(S Q). \quad (82.13)$$

Fig. 82.9 Original network with controlled UAVs marked with squares

Fig. 82.10 Average state and control over time for the compensated (closed loop \mathcal{H}_2 controller) and grounded constant (open loop) control for the wind-perturbed network in Fig. 82.9

For the swarming model (82.12), the stabilizing compensator was applied to a 40-UAV swarm exposed to a vertical wind gust with 3 UAVs directly controlled. The constant parameters of the system have $Q = I_{37 \times 37}$, $R = 10I_{3 \times 3}$, $V = 0.1I_{37 \times 37}$, $H = \mathbf{1}$, $W = 1$, $L = 3.49$, $\sigma = 10$, and initial altitude set as $x(0) = 0$. The network topology is depicted in Fig. 82.9. The performance with respect to the average state and control to maintain a desired altitude ($x(t) = 0$) is compared to the grounded signal control in Fig. 82.10.

Fig. 82.11 (a) Edge constraint graph and (b) resultant leader-follower consensus network after applying Protocol 1 to 50 spanning trees of the graph in Fig. 82.9. The controlled UAVs are marked with *squares*

Fig. 82.12 Average state and control over time for the wind perturbed system corresponding to Fig. 82.9 before and after applying Protocol 1

Protocol 1 is applied to the network topology to improve the effectiveness of the controller. The protocol is restricted to only edges within the constraint graph displayed in Fig. 82.11a and limited to a maximum of 8 neighbors for each noncontrolled UAV. Running the protocol on the graph in Fig. 82.9 over 50 spanning trees, involving 289 edge trades, the final graph displayed in Fig. 82.11b is produced. The resultant leader-follower consensus model has a $\|G_{\mathcal{G}, \mathcal{R}}(s)\|_2^2 = 11.3$ compared to the original system with 4.6. The resultant graph and its response to wind gusts are displayed in Figs. 82.11 and 82.12. The optimal performance cost J^* as defined in (82.13) decreased from 14,815 to 3,265.

82.5 Model Reduction

The \mathcal{H}_2 design framework produces controllers of order at least equal to that of the underlying plant and often higher due to the inclusions of dynamic weights. The corresponding control laws may be too involved with regard to practical implementation and simpler designs are preferred. For this purpose, one can either reduce the order of the plant model prior to controller design or reduce the controller in the final stage, or both. The following section proposes an a priori model reduction method using model truncation but in such a way that the reduced order system corresponds to a new network.

82.5.1 Model Truncation

Model truncation involves partitioning the state vector x into $\begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ where x_2 is the vector of $n-k$ states which will be removed, rearranging the system model such that

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} u$$

$$y = \begin{bmatrix} C_1 & C_2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + Du.$$

A k -th order truncation subsequently produces the approximate model

$$\dot{x}_1 = A_{11}x_1 + B_1u$$

$$y = C_1x_1 + Du,$$

with transfer function $G_a(s) = C_1 (sI - A_{11})^{-1} B_1 + D$. A common error metric is the error between new full model system $G(s)$ and truncated model $G_a(s)$ with respect to the Hankel norm and infinity norm, that is, $\|G(s) - G_a(s)\|_H$ and $\|G(s) - G_a(s)\|_\infty$, respectively. The Hankel and infinity norm of any stable transfer function $E(s)$ is defined as $\|E(s)\|_H := \sqrt{\max_i |\lambda_i(PP_{obs})|}$ and $\|E(s)\|_\infty := \max_w \bar{\sigma}(G(jw))$, where P and P_{obs} are the controllability and observability Gramian of $E(s)$, respectively, and $\bar{\sigma}(\cdot)$ denotes the singular value of a matrix. The optimal k -th order truncation $G_a^H(s)$ with respect to the Hankel norm is

$$\|G(s) - G_a^H(s)\|_H = \sigma_{k+1}, \quad (82.14)$$

where $\sigma_k = \sqrt{\lambda_k(PP_{obs})}$. Another common form of truncation is balance truncation and balanced realization $G_a^B(s)$ which boasts the bound

$$\|G(s) - G_a^B(s)\|_\infty \leq 2(\sigma_{k+1} + \dots + \sigma_n). \quad (82.15)$$

These methods and their corresponding performance guarantees will be used as benchmarks for the following network-based truncation method. For descriptions of these and forms of truncation, see Dullerud and Paganini (2000).

82.5.2 Model Reduction Using Equitable Distance Partitions

The traditional methods of truncation lose characteristics of the underlying network topology. The following proposes a graph-based form of model truncation. The approach is to fuse nodes, reducing the model order, while still maintaining much of the network topology; see Fig. 82.13.

A partition of a graph is the grouping of nodes into subsets called cells. The i -th cell is denoted C_i . An *equitable partition* is one in which each node in C_j has the same number of neighbors in C_i for all i, j . A *distance partition* is one in which each cell is composed of all nodes the same distance from some node v_i . A distance partition over \mathcal{G} is defined with respect to the operators. If each operator is the sole member of a cell, a cell with more than one member exists, and the partition is equitable, then it has been shown that the graph is uncontrollable (Rahmani et al. 2009), and as such there exists a nonempty uncontrollable subspace which can be truncated from the model without introducing any model error. Further it was shown that symmetry within the graph topology with respect to the leader agents induces an equitable partition (Rahmani et al. 2009).

This framework can be extended to generate a graph-based reduced model by fusing together the states of all agents within a cell. Specifically the reduced model's states are

Fig. 82.13 A reduced order network dynamics, full network dynamics, and vehicle dynamics. The operators perceive a more manageable reduced order network dynamics formed by fusing nodes into meta-nodes

$$z_j = \frac{1}{|C_j|} \sum_{v_i \in C_j} x_i,$$

for all j , that is, the average state value within the cell. For the case where the partition is an *equitable distance partition* with respect to some r_i , then the same partition will be generated if it was calculated with respect to any r_j . As mentioned above, this model reduction has exactly the same input-output characteristics as the full state system, that is, no model error is introduced. This method for model reduction was introduced for a single leader in Martini et al. (2008). As most leader-follower consensus systems do not have an equitable distance partition, the partition depends on the selection of the leader r_i that defines it. To remove this dependence and provide equal contribution from all operators, the distance partition is modified to a new form dubbed an *operator partition*. This new partition is formally defined as follows.

Definition 9 An operator partition is composed of cells such that all nodes are initially designated to operator cells \overline{C}_j , where nodes who share the same closest operator are grouped together, that is, $\overline{C}_j = \{v_i : r_j = \operatorname{argmin}_k d(r_k, v_i)\}$. If nodes are equidistant between a set of operators, then membership in one of the corresponding operator cells is randomly chosen. Each leader cell \overline{C}_j is then distance partitioned with respect to their corresponding operator node r_j to form operator partition cells.

The proposed model reduction procedure involves fusing the states of all agents within each of the operator partition cells. In the case where the network contains an equitable distance partition, then combinations of the operator partition cells form the distance partition cells. Consequently, the operator partition model reduction would not introduce modeling errors. The strength of this model reduction process is that it exploits the structural components of the graph which are close to being symmetric, introducing only small modeling errors corresponding to ignored asymmetries.

The reduced order model has system matrices

$$A_r = STA(\mathcal{G}, \mathcal{R}) T^T S \in \mathbb{R}^{n_r \times n_r}$$

$$B_r = STB(\mathcal{R}) \in \mathbb{R}^{n_r \times r}$$

$$C_r = T^T S \in \mathbb{R}^{n \times n_r},$$

where $S \in \mathbb{R}^{n_r \times n_r}$, n_r are the number of cells in the operator partition, $[S]_{ii} = \frac{1}{\sqrt{|C_i|}}$, $T \in \mathbb{R}^{n_r \times n}$ and $[T]_{ij} = 1$ if $v_i \in C_j$ and $[T]_{ij} = 0$ otherwise.

Graphically, $\overline{A} = TA(\mathcal{G}, \mathcal{R}) T^T$ and $\overline{B} = TB(\mathcal{R})$ correspond to the state matrix of the reduced order graph $\overline{\mathcal{G}} = (\overline{V}, \overline{E})$. This can be formed by fusing the nodes of $\check{\mathcal{G}}$, forming *meta-nodes*, corresponding to the operator partition and reweighting the edges accordingly. Therefore, each node in $\overline{\mathcal{G}}$ corresponds to a fused cell, and the

weight on edge $(v_i, v_j) \in \bar{E}$, \bar{w}_{ij} , is equal to the number of edges between nodes in C_i and in C_j in $\check{\mathcal{G}}$.

The interpretation of A_r and B_r is a graph with self-loops and can be formed by reweighting the edges of $\bar{\mathcal{G}}$ from \bar{w}_{ij} to w_{ij} such that

$$w_{ij} = \begin{cases} \frac{1}{\sqrt{|C_i||C_j|}} \bar{w}_{ij} & v_i, v_j \notin R \\ \frac{1}{\sqrt{|C_i|}} \bar{w}_{ij} & \text{otherwise.} \end{cases}$$

For the self-loops, one has

$$\begin{aligned} w_{ii} &= \frac{1}{|C_i|} \sum_{v_j \neq v_i} \bar{w}_{ij} - \sum_{v_j \neq v_i} w_{ij} \\ &= \frac{1}{|C_i|} \sum_{v_j \neq v_i} \bar{w}_{ij} - \frac{1}{\sqrt{|C_i|}} \left(\sum_{v_j \notin R \cup \{v_i\}} \frac{1}{\sqrt{|C_j|}} \bar{w}_{ij} + \sum_{v_j \in R} \bar{w}_{ij} \right) \end{aligned}$$

Among the benefits of this type of reduction is a simple graphical approach to model reduction, compared to traditionally more numerically intensive model

Fig. 82.14 Proposed model reduction graph $\bar{\mathcal{G}}$ for network in Fig. 82.9. The reduced weighted graph corresponding to A_r and B_r with operator modes (*squares*). Edges from a meta-node to itself (a self-loop) are denoted by a *circle* around the meta-node

Fig. 82.16 Average state and control over time for the wind-perturbed system corresponding to Fig. 82.9 with original H_2 controller and controller partition reduced model (Fig. 82.11)

reduction techniques, for example, balanced residualization, as well as the potential to apply graph-theoretic analysis on the reduced model.

82.5.3 Model Reduction for Wind-Gust Disturbance Rejection

Revisiting the wind-gust example of Sect. 82.4.3, the proposed graph-based model reduction method can be performed on the original graph in Fig. 82.9 to produce a

lower-order more manageable graph for the operators to manipulate. A lower-order \mathcal{H}_2 controller can then be constructed based on this reduced model.

The operator partition model reduction method, when applied to the original network, reduces the order of the system from 37 to 7. The reduced graph corresponding to A_r and B_r is displayed in Fig. 82.14. The singular value and impulse response for a selected agent with respect to each of the controls are compared to the full state and reduced state systems in Fig. 82.15. Applying the norm metrics, then $\|G(s) - G_a(s)\|_H = 0.45$ and $\|G(s) - G_a(s)\|_\infty = 2.57$ compared to the benchmarks (82.14) and (82.15) with $\|G(s) - G_a^H(s)\|_H = 0.03$ and $\|G(s) - G_a^B(s)\|_H \leq 0.11$. The reduced model was used to produce an \mathcal{H}_2 controller, and its performance was compared to the full state \mathcal{H}_2 controller in Fig. 82.16.

Conclusion

This chapter presents network-theoretic approaches for the design of efficient models, interfaces, and topologies of the network for UAV swarming. A UAV swarm can be decomposed into a two-component hierarchical structure where the network dynamics drives the vehicle dynamics and in turn is influenced by the human operators. This two-component hierarchical model of the UAV swarm allows topological elements and algorithms to be employed to manage the swarm's performance and dynamics. The open loop \mathcal{H}_2 norm was analyzed for the network dynamics as a metric to quantify its performance. With this metric, the number of neighbors of the controlled UAVs and spacing of these UAVs were highlighted as characteristics of manageable swarms. An adaptive rewiring protocol based on the spanning trees of the graph was described for the use in the online design of networks for swarming with human operators. The protocol is decentralized across the UAVs in the swarm, increases the open loop \mathcal{H}_2 norm, and consequently produces effective interfaces for the human operators. Network properties pertaining to symmetry and node partitioning provided a network-centric method for model reduction. The method is a simple graphical approach involving fusing UAV nodes to form reduced order meta-nodes. The result is a lower-order model that corresponds to a manageable network for the operators to manipulate. The topology rewiring protocol and model reduction method were applied to UAV swarms perturbed by wind gusts with improved operator manageability and wind-gust rejection, to demonstrate the versatility of this work.

Abstract

A team of unmanned aerial vehicles (UAVs) with limited communication and sensing ranges, communication delays, and finite resources are deployed to search and destroy targets in a given region. The targets can be static or moving.

To detect the targets, the UAVs perform a search task. When a target is detected, a coalition of UAVs, that has sufficient combined resources to destroy the target, must be formed. This coalition is to be determined, in a decentralized manner, by the UAVs communicating over a time and space varying communication network formed by UAVs in motion. In this chapter, a communication protocol to search for potential coalition members over a dynamic UAV network and a strategy for a UAV coalition to track and destroy moving targets is developed. The proposed mechanisms are validated through simulations. The effects of communication ranges and delays as well as the scalability of the proposed schemes with change in number of targets and UAVs are studied. The results show that it is beneficial to search for potential coalition members over a wide diameter in the UAV network when the communication delay is less, while it is more advantageous to determine a coalition from among the immediate neighbors in the presence of significant communication delay.

83.1 Introduction

Nowadays, several applications which are inaccessible and dangerous to human life are performed using unmanned aerial vehicles (UAVs). The capability of UAVs to deploy weapons, perform sensing operations, and act as communication relays has pushed the envelope of UAV applications covering missions like surveillance, search and rescue, border patrol, fire monitoring, target search and destroy, pipeline monitoring, communication relay, data mule, etc. Typically, these missions can be performed by a single UAV, in which case, the missions take more time to complete and the system is not robust to malfunctions. To enhance the mission performance in terms of robustness and mission completion time, deployment of multiple UAVs is desirable. The team of multiple UAVs must coordinate with each other to reap the benefits of a team. Therefore, there is a need to develop efficient cooperative algorithms to maximize the UAV team's performance.

Depending on the type of application, the coordination mechanism between the UAV team members varies. For example, in formation control problems, the coordination between UAVs is in maintaining constant distance and angle with respect to the neighbors. For surveillance problems, the cooperation between UAVs is to jointly cover a region while ensuring minimal area overlap. Yet another type of coordination is required in distributing tasks between multiple UAVs. The problem of task allocation between UAVs is combinatorial by nature. There are several types of task allocations depending on the task requirements and UAV capabilities. Gerkey and Mataric (2004) categorized multiple robot task allocation problems as single robot–single tasks (SR-ST), multiple robot–single tasks (MR-ST), single robot–multiple tasks (SR-MT), and multiple robot–multiple tasks (MR-MT). In this chapter, a MR-MT task allocation problem is considered where several UAVs need to search and destroy targets in a region.

In a task allocation problem, if the complete information about the targets (their locations and resources) and the UAV are known a priori, then the task allocation

problem can be solved using standard optimization techniques such as linear programming (LP), integer programming, and mixed-integer linear programming (MILP). However, this is rarely the case in a realistic mission scenario where the UAVs have limited sensing and communication ranges, delays in communication, kinematic constraints, and limited resources that deplete with use. In most cases, the target locations may not be known a priori. Moreover, the targets may be in motion and may require multiple resources to be destroyed. Determining task allocation solutions considering all the realistic constraints is highly complex and challenging. Hence, certain assumptions are made to obtain solutions under a given scenario. For example, several solutions have been developed with assumptions like all UAVs can communicate with each other, UAV resources are unlimited, and a single UAV alone can destroy a target. Nygard et al. (2001) developed a network flow optimization model that uses a linear programming method to allocate UAVs to targets. This approach assumes global communication between UAVs. The network flow model has been further extensively studied by Schumacher et al. (2003a,b) for wide area search munitions with variable path lengths and assignment with timing constraints. Chandler et al. (2003) explored various techniques like iterative network flow, auctions, LP, and MILP methods for multiple UAVs in an environment where the planning and allocation tasks are strongly coupled. Alighanbari et al. (2003) developed a task allocation algorithm for multiple UAVs using MILP to minimize the mission completion time while taking loitering time constraints into account. Schumacher et al. (2003a) developed a task allocation approach taking the arrival time constraints into account. They solve a single MILP problem that provides the optimal solution. Further, Shima and Schumacher (2009) considered the possibility of performing several tasks on the target before it can be destroyed completely. They developed a task allocation scheme using genetic algorithms for allocating tasks to multiple UAVs. On similar lines, Kingston and Schumacher (2005) develop a MILP-based solution to assign multiple UAVs to track and prosecute moving targets. Turra et al. (2004) developed a task allocation algorithm based on area assignment to consider moving targets.

When the constraint of limited communication range with delays is considered, several of the task allocation schemes, described above, fail to produce efficient results. The effect of communication delays on task allocation using an iterative network flow model is studied in Mitchell et al. (2003). Dionne and Rabbath (2007) developed an algorithm for decentralized task allocation in the presence of intermittent and asynchronous communication links, where the task allocation algorithm is formulated as a linear programming problem based on the information received from other agents. Lemaire et al. (2004) developed a task allocation scheme for multiple UAVs based on a contract net protocol taking limited communication constraints into account. To improve mission efficiency using auctions with limited communication, Sujit and Beard (2007) developed a sequential auction task allocation scheme where a single agent can be assigned to multiple targets.

There exists only a few works in the literature that consider the need to form a sub-team of UAVs to destroy a target. This sub-team is called a coalition, and the problem of determining a coalition is the coalition formation problem which is

NP-Hard (Shehory 1998). Kingston and Schumacher (2005) addressed this problem with the assumption of global communication. Vig and Adams (2006) developed a coalition scheme – RACHNA – where the tasks act as agents and perform the function of an auctioneer for gathering bids and thus determining the required coalition. Parker and Tang (2006) present a coalition formation scheme where a coalition leader robot broadcasts the existence of a task and other robots reply by providing their availability. The leader robot evaluates all possible coalitions and sends an accept decision to the robots that it considers suitable to be part of coalition. In the above approaches, the robots do not face a situation where the communication network can be broken during the coalition formation process since the robots can stop and form a static network until the coalition formation process is completed.

In a complete decentralized setup, a set of UAVs communicate with each other to form a coalition to engage a target. Due to limited communication ranges and constant motion, some of the UAVs may get disconnected from the network during the coalition formation process. If a disconnected member happens to be part of the determined coalition, then it cannot be informed about its requirement in the coalition. Hence, the coalition becomes invalid, and a new coalition has to be formed. Thus, determining a coalition in dynamic environments is very challenging. Scerri et al. (2005) determined potential team members using an algorithm that takes advantage of the “small world” property of large networks. Vanzin and Barber (2006) proposed a mechanism of finding potential members for a coalition based on the TCP protocol. However, both the approaches do not consider the possibility of communication delays and moving targets.

From the description of above articles, taking all the realistic constraints on UAVs and targets for a search and destroy mission into account is a complex task to accomplish. In this chapter, a novel mechanism to determine coalitions for moving targets taking all these constraints into account is developed. The only assumption is that the UAVs do not collide with each other while performing the mission. The chapter is organized as follows: In Sect. 83.2, the coalition formation problem is described. Section 83.3 gives a low complexity algorithm for coalition formation. The communication protocol employed in determining potential coalition members over a dynamic network is described in Sect. 83.4. The proposed algorithm is evaluated using Monte Carlo simulations in Sect. 83.5. Section 83.6 concludes this chapter with a brief summary.

83.2 Problem Formulation

83.2.1 Problem Scenario and Approach

Consider a search and destroy mission using N heterogeneous UAVs. The UAVs can carry n types of resources in limited numbers. Some of these resources are consumable, that is, the resources deplete with use, while others like sensors do not deplete. Each UAV is identified by its unique token number U_i , $i = 1, \dots, N$

assigned prior to the start of the mission and the resource capability vector of U_i is denoted by R^{U_i} of the form

$$R^{U_i} = (R_1^{U_i}, \dots, R_n^{U_i}), \quad i = 1, \dots, N$$

where $R_p^{U_i}$, $p = 1, \dots, n$ represents the number of type- p resources held by UAV U_i . Assume that there are M targets (some static and some in motion) whose positions and the resource requirements are unknown a priori. The target resource requirement vector is represented as

$$R^{T_j} = (R_1^{T_j}, \dots, R_m^{T_j}), \quad j = 1, \dots, M$$

where $R_q^{T_j}$, $q = 1, \dots, m$ represents the quantity of type- q resources required to destroy the target T_j and, without loss of generality, it can be assumed that $m \leq n$.

The UAVs have limited sensor range (r_s) and communication range (r_c). Typically, the communication ranges are higher than the sensing ranges; hence, it is assumed that $r_c > 2r_s$. This assumption ensures that multiple UAVs within the communication ranges of each other do not form multiple coalitions for the same target. The agents carry out a search task to detect targets. It is assumed that the agents use a heading search strategy where the UAV moves along a given heading until it crosses the boundary of the region of interest. At the boundary, it turns back into the operational region with some other heading direction. This process is continued until a target is found. When U_i detects a target T_j , as shown in Fig. 83.1, it assumes the role of a coalition leader and broadcasts the target resource requirement vector (R^{T_j}). It is assumed that the coalition leader can ascertain the type of resources required to destroy the target. The UAVs in the search region, that are within the communication range of U_i , possessing at least one of the required resources to destroy the target T_j will respond to U_i with their cost and resource capabilities (agent U_2 , U_5 , and U_6 in Fig. 83.1). Often, the resources of the immediate neighbors is not sufficient, in which case, the leader's broadcast must be passed on to the neighbors of the neighbors of U_i . The message passing between the UAVs occurs with delays. Thus, the coalition leader has to find potential members for its coalition over a dynamic ad hoc network subject to communication delays. Details on a robust mechanism to determine the coalition partners is described in Sect. 83.4.

83.2.2 Objective and Constraints

Assume that the UAV team of N agents takes τ time units to destroy all the targets. The mission time τ depends on the time taken to detect the targets, which in turn depends on the performance of the search strategy, and the time taken to

Fig. 83.1 The UAV U_i detects a target T_j and initiates a coalition formation process through a network formed by UAVs U_i and U_2 to U_7

form coalitions and destroy each detected target. The objective is to accomplish the mission in minimum time. That is, the global objective is

$$\min \tau \quad (83.1)$$

where the minimization is over all possible search strategies, prosecution sequences, and coalitions. Here, τ is bounded above by the sum of τ_s and $\sum_{j=1}^M \tau_c^{T_j}$, where τ_s is the search time and $\tau_c^{T_j}$ represents the time taken by the coalition to destroy the target T_j once it is detected. The mission time τ is not equal to but bounded by the above sum as some of the targets may be destroyed simultaneously. It is to be noted that the search time, τ_s , implicitly depends on the coalition formation strategies. This is because the choice of coalition will decide the UAVs that are free to carry out the search task. For example, for a given target, out of two coalitions with the same prosecution time, the coalition with smaller size will lead to more UAVs being available for search, which may ultimately lead to a reduction in the total search time. Also, note that the prosecution time, $\tau_c^{T_j}$, in turn, depends on the search strategy as the UAVs available for coalition formation, once T_j is detected, depends on the number of UAVs available within the communication range which, in turn, depends on the search deployment strategy. Thus, the global cost is a function of intertwined search and coalition formation strategies. The global objective can be achieved from Eq. (83.1) by (a) minimizing the time taken by the coalitions to destroy each target, that is,

$$\min \tau_c^{T_j}, \quad j = 1, \dots, M \quad (83.2)$$

where the minimization is over all possible coalitions, and (b) minimizing the size of coalitions formed to destroy it. Thus, the task of a coalition leader is to form a coalition such that (i) the target is destroyed in minimum time and (ii) the coalition contains minimum number of UAVs. The objective (i) (minimizing the time-to-attack the target) is a desirable quantity in achieving the objective given in Eq. (83.2), and the objective (ii) (which is to minimize coalition size) ensures that the UAVs distribute their search effort so that the targets are detected quickly and the mission is accomplished faster.

The coalition leader which forms a coalition to destroy a target is the UAV which detected the target. The role of the coalition leader U_i that detected target T_j is to form a coalition $\mathcal{C}(U_i, T_j)$, with combined resources $R^{\mathcal{C}(U_i, T_j)} \geq R^{T_j}$, to destroy T_j taking into account the objectives (i) and (ii). Let the set of all UAVs, the potential coalition members, that responded to the coalition formation request of U_i to destroy target T_j be denoted by $\mathcal{PC}(U_i, T_j)$. Let $\mathcal{D}(U_i, T_j) = \{D_U^{T_j} : U \in \mathcal{PC}(T_j, U_i)\}$ represent the set of earliest times of arrival for the UAVs in the set of potential coalition members, and $D_U^{T_j}$ denotes the earliest time of arrival (ETA) of the UAV U at the location of target T_j using Dubins curves (Dubins 1957). The ETA is used as the cost metric. To determine a coalition, the coalition leader solves the following optimization problem:

$$\arg \min_{\mathcal{C}'(U_i, T_j) \subseteq \mathcal{PC}(U_i, T_j)} \left(\max_{U \in \mathcal{C}'(U_i, T_j)} D_U^{T_j} \right) \quad (83.3)$$

$$\text{subject to } \left(\sum_{U \in \mathcal{C}'(U_i, T_j)} R_p^U \right) \geq R_p^{T_j}, \quad \text{for all } p = 1, \dots, m \quad (83.4)$$

The set $\mathcal{C}(U_i, T_j)$, the solution to the above optimization problem, represents the smallest coalition which satisfies Eq. (83.4). That is, if $\mathcal{C}''(U_i, T_j) \subseteq \mathcal{PC}(U_i, T_j)$ is another set which is a solution to Eqs. (83.3) and (83.4), then $|\mathcal{C}(U_i, T_j)| \leq |\mathcal{C}''(U_i, T_j)|$. The set obtained as a solution to the above optimization problem satisfies the objectives (i) and (ii). It is to be noted that the optimum value of the objective function in Eq. (83.3) is the earliest time at which all the members of the coalition, $\mathcal{C}(U_i, T_j)$, can arrive at the target T_j , which is equal to $\tau_c^{T_j}$, the time taken by the coalition to destroy T_j . Therefore, solving the optimization problem in Eqs. (83.3) and (83.4) for every target will minimize the objective function given in Eq. (83.2). The minimum time (objective (i)) for all the UAVs in a coalition to arrive at the target is determined by that UAV which has the highest ETA to the target. Since both the smallest coalition and the coalition that can destroy the target in minimum time needs to be determined simultaneously, the objective function is coupled. This coupling makes the optimization problem nontrivial and unsuitable for solution using standard techniques. In this chapter, previously developed coalition formation algorithms are used to determine coalitions that

are close to optimal and consume low overhead (Manathara et al. 2011). For completeness, a brief description of the algorithms is provided in Sect. 83.3.

The coalition leader forms the coalition in a decentralized manner which has significant advantages over centralized solution concepts. The coalition formation algorithms determine a set of agents that need to attack the target. The coalition members arrive at the target using Dubin's shortest path and deploy their resources at the target location. When all the agents in the target coalition deploy their resources, the target is assumed to be destroyed. However, in the case of moving targets, the target needs to be tracked and the target location information needs to broadcast to other agents in the coalition. Once the target is in the sensing range of an agent, the agent deploys the resource and tracks it until it is within the sensing range of the next coalition member. The attacking and tracking of the target with handshaking mechanism is described in Sect. 83.3.

The UAVs are subjected to kinematic constraints preventing instantaneous course changes. Assume that the autopilots of the UAVs hold a constant altitude and ground speed. The kinematics of the i th UAV is therefore modeled using first order kinematics as

$$\begin{aligned}\dot{x}_i &= v_i \cos \psi_i, \\ \dot{y}_i &= v_i \sin \psi_i, \\ \dot{\psi}_i &= k(\psi_i^d - \psi_i), \quad i = 1, \dots, N\end{aligned}\tag{83.5}$$

where x_i and y_i are the UAV location, ψ_i is its heading, ψ_i^d is the desired heading, v_i is the ground speed, and k is autopilot gain. The heading rate to be constrained within bounds. That is,

$$-\omega_{\max} \leq \dot{\psi}_i \leq \omega_{\max}, \quad i = 1, \dots, N\tag{83.6}$$

Some of the targets are assumed may be moving and can change their heading randomly, but this change is bounded by a maximum turn rate. The kinematic model of the target T_j is

$$\begin{aligned}\dot{x}_j^T &= v_j^T \cos \psi_j^T \\ \dot{y}_j^T &= v_j^T \sin \psi_j^T \\ \dot{\psi}_j^T &= \beta \dot{\psi}_{\max}^T, j = 1, \dots, M\end{aligned}\tag{83.7}$$

where v_j^T is the velocity of the target T_j , ψ_j^T is its heading, $\dot{\psi}_{\max}^T$ is the maximum turn rate, and β takes values ± 1 randomly for intervals of random durations as time evolves. The velocities of all the targets are assumed to be less than the velocities of any of the UAVs. After a target is attacked by a UAV, if it is not completely destroyed, then the target velocity is reduced by a random factor. This reduction

is to simulate the fact that after the resources are deployed by a UAV, the target capability reduces. Hence, the new target velocity after prosecution by a UAV is given by \hat{v}_j^T which is strictly less than v_j^T .

83.3 Coalition Formation

Once a UAV detects a target, it acts depending on its resource state and the resource requirement of the target. Figure 83.2 shows two different states (S_1 and S_2) and how the UAV makes a coalition. The sequence of actions carried out during these states are described below.

Coalition Leader Has All the Required Capabilities (S1) In this case, UAV U_i detects target T_j that requires R^{T_j} resources and $R_p^{U_i} \geq R_p^{T_j}$ for all $p = 1, \dots, m$. If U_i is not already a part of another coalition, then U_i would attack target T_j without requesting a coalition with other UAVs. This is a special case of coalition formation where only one UAV comprises of the coalition. The UAV determines the route to travel using Dubins curves (Dubins 1957) and then proceeds toward the target as shown by the state S_1 in Fig. 83.2.

Coalition Leader Has Partial Resources or No resources (S2) U_i assumes the role of coalition leader and broadcasts the information about the target, that is, its location and required resources, to the other UAVs. The UAVs that have at least one of the types of required resources will send their cost to arrive at the target (ETA) and their available resource vector. The coalition leader considers all the responses and determines whether a coalition can be formed. If a coalition cannot be formed, then it sends a “discard coalition” broadcast as shown in Fig. 83.2; otherwise, it will form a coalition and broadcast the coalition information. The rejected agents will discard their potential interest in the coalition and continues to perform their search task. During this process, the potential members who announced their availability for coalition will be in a wait state to receive information from the coalition leader. The complete sequence of actions that happen during the coalition formation for a target by the coalition leader as well as by other UAVs is shown in Fig. 83.2.

The coalition leader has to solve the optimization problem described by Eqs. (83.3) and (83.4) to determine the coalition members. Previously, in Manathara et al. (2011), two coalition formation algorithms were developed: (i) polynomial time coalition formation algorithm (PTCFA – which is suboptimal) and (ii) optimal coalition formation algorithm (OCFA). Both the algorithms use a two-stage mechanism to produce solutions that have low computational complexity. In Manathara et al. (2011), it is shown that PTCFA performs similar to OCFA with lower computational complexity. In the simulations presented later, PTCFA was used and hence PTCFA is described briefly below.

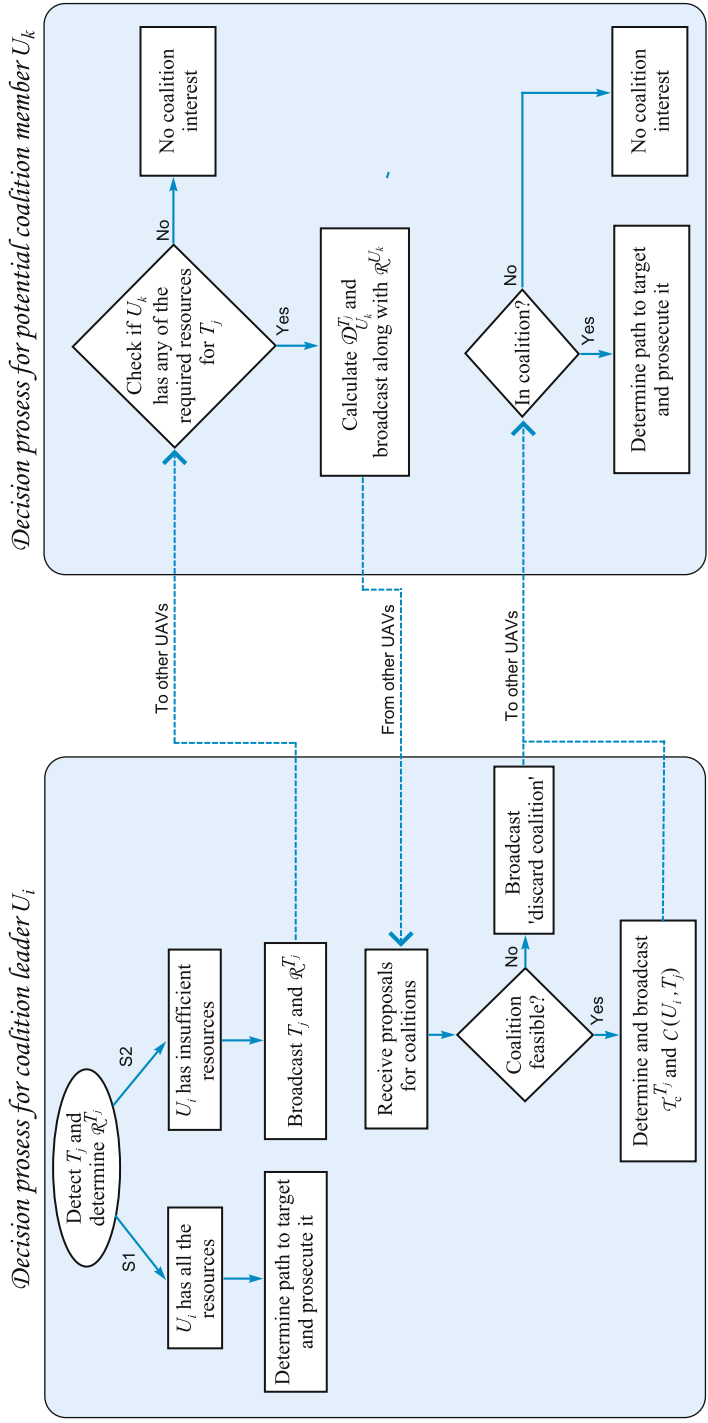

Fig. 83.2 Sequence of events during coalition formation

83.3.1 Polynomial Time Coalition Formation Algorithm (PTCFA)

Determining the smallest coalition that would successfully destroy the target in minimum time can be accomplished in two stages. In the first stage, a set of UAVs with required total resources that can achieve the minimum time requirement is determined. Then the obtained set of UAVs are pruned to achieve the minimum member coalition in the second stage. The process to achieve this task is given in Algorithms 1 and 2.

Assume that UAV U_i is the coalition leader and detected a target T_j that requires R^{T_j} resources. Algorithm 1 begins by initializing the coalition set to empty and the coalition resources to zero (line 1). First, the responses of the potential coalition members are sorted in the ascending order of their ETA to target (line 3). The algorithm takes one UAV (U_k) at a time (line 5) from the ordered list, includes U_k in the coalition $\mathcal{C}(U_i, T_j)$ (line 6), and updates the coalition resource vector $R^{\mathcal{C}(U_i, T_j)}$ (line 7) and the coalition time $\tau_c^{T_j}$ (line 8). Then it checks whether the target resource constraint is met (line 9). If the constraint is not met, then the process of including the next agent and its resources and verifying the resource constraint continues until the target resource constraint is met or the UAVs in the sorted potential coalition member set is exhausted in which case a feasible coalition is not formed (line 18). Once the resource constraint is met, the algorithm returns the feasible coalition $\mathcal{C}(U_i, T_j)$ and the coalition time $\tau_c^{T_j}$ (line 16).

Algorithm 1 First stage of the PTCFA

Input: Potential coalition members $\mathcal{PC}(U_i, T_j)$ and their ETAs $\mathcal{D}(U_i, T_j)$

Output: Coalition $\mathcal{C}(U_i, T_j)$ and coalition time $\tau_c^{T_j}$

```

1:  $\mathcal{C}(U_i, T_j) = \emptyset$  and  $R^{\mathcal{C}(U_i, T_j)} = \mathbf{0}$ 
2: Stage 1:
3:  $[\mathcal{D}_{sorted}, \mathcal{PC}_{sorted}] = \text{sortAscending}(\mathcal{D}(U_i, T_j), \mathcal{PC}(U_i, T_j))$ 
4: for  $l = 1$  to  $|\mathcal{PC}(U_i, T_j)|$  do
5:    $U_k \leftarrow \mathcal{PC}_{sorted}(l)$ 
6:    $\mathcal{C}(U_i, T_j) \leftarrow \text{append } U_k$ 
7:    $R^{\mathcal{C}(U_i, T_j)} \leftarrow R^{\mathcal{C}(U_i, T_j)} + R^{U_k}$ 
8:    $\tau_c^{T_j} \leftarrow \mathcal{D}_{sorted}(l)$ 
9:   if  $R_p^{\mathcal{C}(U_i, T_j)} \geq R_p^{T_j}$ , for all  $p$  then
10:     break
11:   else
12:     continue
13:   end if
14: end for
15: if  $R_p^{\mathcal{C}(U_i, T_j)} \geq R_p^{T_j}$ , for all  $p$  then
16:   return  $\mathcal{C}(U_i, T_j)$  and  $\tau_c^{T_j}$ 
17: else
18:   return No feasible coalitions
19: end if
```

Algorithm 2 Second stage of the PTCFA

Input: Minimum time coalition $\mathcal{C}(U_i, T_j)$ from Algorithm 1

Output: Pruned coalition $\mathcal{C}(U_i, T_j)$

```

1: Stage 2:
2: for  $l = 1 : |\mathcal{C}(U_i, T_j)|$  do
3:    $U_k \leftarrow \mathcal{C}(U_i, T_j)(l)$ 
4:    $\bar{R}^{C(U_i, T_j)} \leftarrow R^{C(U_i, T_j)} - R^{U_k}$ 
5:   if  $\bar{R}^{C(U_i, T_j)} \geq R_p^{T_j}$ , for all  $p$  then
6:      $\mathcal{C}(U_i, T_j) \leftarrow \mathcal{C}(U_i, T_j) \setminus U_k$ 
7:      $R^{C(U_i, T_j)} \leftarrow \bar{R}^{C(U_i, T_j)}$ 
8:   end if
9: end for
10: return  $\mathcal{C}(U_i, T_j)$ 

```

Algorithm 1 will always ensure a coalition with minimum time to target. This is proved in Manathara et al. (2011). Once the minimum time coalition is formed by Algorithm 1, then those members in the minimum time coalition whose resources are not required to form a coalition with smaller size must be pruned. This process is carried out by using Algorithm 2. The algorithm checks for each UAV $U_k \in \mathcal{C}(U_i, T_j)$ in the coalition formed by Algorithm 1, whether the resources of U_k are required for the coalition or not by removing its resources from $R^{C(U_i, T_j)}$ (lines 4 and 5). If the resources of U_k are not required, then the UAV U_k is removed from $\mathcal{C}(U_i, T_j)$ (line 7) and its resources are deducted from $R^{C(U_i, T_j)}$ (line 7). This process is carried out for all the UAVs $U_k \in \mathcal{C}(U_i, T_j)$. The Algorithms 1 and 2 together form the two-stage polynomial time coalition formation algorithm (PTCFA).

83.3.2 Target Prosecution Maneuvers

The environment contains static and moving targets. The procedure involved in prosecuting a static target is different from that of a maneuvering target.

83.3.2.1 Procedure to Prosecute a Static Target

In this case, the coalition strikes the target based on their ETA. The UAV with the smallest ETA attacks the target first and then continues to perform other tasks. After that, the UAV with the second lowest ETA will attack. This process continues until the last UAV in the coalition strikes the target and destroys it completely. The sequence in which the coalition members arrive at the target location is based on the ascending order of their ETAs to the target.

83.3.2.2 Procedure to Prosecute a Maneuvering Target

Unlike the static target, destroying a moving target with random maneuvers is difficult and requires cooperation between the coalition members. Since the target

moves in random directions, an attack and track mechanism is used. Once the target is attacked, depending on the resources deployed, it is either completely destroyed or its velocity is reduced by a random factor which represents a slower moving target after suffering some casualty. The process involved in destroying a maneuvering target is described below.

Assume that a coalition consisting of $N' \leq N$ is formed. In this case, the coalition leader continues to track the target until it directly communicates with the first UAV of the formed coalition. The coalition leader updates the information of the target to the approaching coalition member. Based on this information, the coalition member updates its heading continuously until it detects the target. Once the coalition member detects the target, the coalition leader relinquishes its role to track and monitor the target and switches itself to a search task. This process of handshaking is required because the coalition member does not know the target location accurately because of the target's random heading behavior.

Once the coalition member detects the target, it tracks the target and strikes. When resources are deployed on the target, its velocity is reduced randomly. After deploying the resources, the coalition members continue to track the target. When the next coalition member is within the communication range, the coalition member currently tracking the target updates the information of the target so that the arriving member can update its direction. When the second agent detects the target, the first relinquishes its tracking role to perform other tasks. This process continues until all the coalition members strike the target, finally destroying it.

83.3.3 Resource Removal

When a UAV attacks a target, it deploys some of its resources. The quantity of resources deployed depends on the quantity of resources required by the target at that instant in time. At any time t , if the required target resources are R^{T_j} and the p th resource is $R_p^{T_j}$, then the new resources required by the target after UAV resource deployment is $R_p^{T_j} = \max(R_p^{T_j} - R_p^{U_i}, 0)$. That is, the UAVs use a greedy approach, where the UAVs deploy all the available required resources when they prosecute the target. There is no exchange of the resources between the agents.

Although the coalition formation process developed above is simple, when implemented over a dynamic network, like the one consider in this chapter, highly nontrivial situations arise which need to be addressed effectively. For example, an intermediate UAV can fail to communicate a decision to a required UAV or by the time the coalition decision is declared, a potential coalition member can be out of communication range. To address such situations, there is a need to design behaviors that will either enable the agent to make its decision smoothly whenever such events occur, or avoid these situations altogether. The second strategy is adopted here and explained in detail below.

83.4 Finding Potential Coalition Members Over a Dynamic Network

The UAVs need to form coalitions over a time-varying network, and the success of forming a feasible coalition depends heavily on the communication protocol employed. The coalition formation process, as described before, involves the following communications (refer Fig. 83.2): (i) broadcast of the coalition leader seeking the participation of other UAVs in the coalition to be formed to destroy a target that it detected, (ii) message from potential coalition members about their willingness to participate in that coalition, and (iii) broadcast from coalition leader about the success/failure of the coalition formation process. When the UAVs have limited communication ranges, these communications have to be done over a time-varying network. This problem can be mitigated by finding a subnetwork, that is invariant for the time period of the coalition formation process, over which the communications happen.

83.4.1 Communication Protocol

In the network, a UAV will receive information from another UAV (say, a coalition leader) through intermediate UAVs called relay nodes. For example, in Fig. 83.1, the UAV U_7 receives information about target T_j from U_i through the information path $U_i \rightarrow U_2 \rightarrow U_3 \rightarrow U_7$, where the UAVs U_2 and U_3 act as the relay nodes rebroadcasting the message from U_i . This method of communication between wireless nodes is referred to in the literature as “flooding” (Obraczka et al. 2001; Williams and Camp 2002). To mimic a real-world wireless network, a delay is associated with each message hop – transmission of message from one UAV to another – called the hop delay denoted by Δ_{hop} . The hop delay includes the queuing delay, the message processing time at a relay node, and the propagation delay, which are the usual delays associated with a standard wireless network. The wireless communication standard – the IEEE 802.11 MAC (medium access control) protocol – handles broadcast packets by sending it to all the neighbors as soon as the carrier is sensed free (IEEE-SA Standards Board 2007). However, it does not use any collision detection to ensure the successful delivery of the broadcast packets. There are some schemes (Alagar et al. 1995; Tang and Gerla 2001; Chen and Huang 2005) that ensure reliable MAC designs for broadcast transmission but add overhead to the MAC layer. The UAVs are assumed to use one such protocol and the hop delay will include the associated overheads. The value of Δ_{hop} can be considered a constant taking the value of the estimated maximum possible delay in the network (Lamport 1984). For the above example, the UAV U_7 would receive the message from U_i within $3\Delta_{\text{hop}}$ seconds as the message from U_i has to make 3 hops to reach U_7 .

A message broadcast by a UAV flows through the network as it is rebroadcast by relay nodes. To prevent the message from floating around in the network indefinitely, thus reducing the bandwidth of the network, the notion of time-to-live (TTL) is used for a message – a notion used in packet switching (Clark 2003) in the Internet

Protocol. The TTL of a message is considered to be the maximum number of hops that it is allowed to make before it is abandoned (not rebroadcast) by the nodes in the network and specify it in terms of maximum number of hops (H_{\max}) a message can make in a network. The TTL concept is implemented as follows. Each message has in its body a hop counter, H , which is initially set to H_{\max} . Whenever a relay UAV rebroadcasts the message, H is reset to $H - 1$. If $H = 0$, then the message is not rebroadcast by a relay UAV and thus gets abandoned.

A UAV that acts as a relay node keeps a log of every message that it rebroadcasts. If it receives a message that is already in the log, it will not be rebroadcast. This is to prevent clogging the network with messages that are already broadcast. For example, in Fig. 83.1, U_2 gets message from U_i which it broadcasts. It will also receive the same message as rebroadcast by U_6 later. However, this will be ignored by U_2 as it has already broadcast that message. The log of a broadcast message is kept until the TTL of the message.

To determine a coalition, the coalition leader requires the following information from the potential members: (a) earliest time of arrival (ETA) at the target and (b) resources available for target prosecution. However, since some of the targets are nonstationary and the network has propagation delays, there is an ambiguity about the procedure for calculation of ETA. In order to determine ETA in a consistent manner, inspiration is drawn from the way contracts are carried out for tasks in real life. An excellent example of this can be the task of “call for papers” for a conference. The conference committee will broadcast the task with the submission deadline, the deadline for acceptance/rejection notification, and the final submission deadline. Thus, there exists deadlines for every part of the process to accomplish the task. Similarly, the coalition leader uses intermediate deadlines to receive the information and to form coalitions. The coalition leader will broadcast the availability of the target along with the deadline for proposal submission, the deadline to receive decisions, and the deadline to destroy the target. The coalition leader will also broadcast the exact time at which the coalition members are required to start the execution maneuver. The time at which a coalition member is expected to start its prosecution maneuver is called the go-ahead time, denoted by $\tau_G^{T_j}$. A potential coalition member uses this information to estimate its ETA to the target.

To determine coalition over a dynamic network, a set of agents whose communication graph exists for the coalition formation process period must be found. This is achieved as follows. A UAV agrees to be a relay node for a message it received only if it is going to be in the communication range of the UAV from which it received the message for the entire coalition formation period. Every message contains the information on the latest time by which the coalition formation process should end. For a coalition formation process for target T_j , this time is the same as the go-ahead time $\tau_G^{T_j}$. All the UAVs are assumed to have synchronized clocks. A potential coalition member shows interest in a coalition only if it remains in the communication range of the UAV from which it received the message until $\tau_G^{T_j}$. This behavior ensures a subnetwork that is invariant over the period of coalition formation.

The go-ahead time is determined by the coalition leader as a time which is greater than the time required for the entire coalition formation process. If H_{\max} is the maximum number of allowed hops for a message with a hop delay of Δ_{hop} associated with each hop, then the coalition request, the response to this request, and the message on coalition membership together take at most $3H_{\max}\Delta_{\text{hop}}$ seconds to propagate over the network. Each potential coalition member is given a time window of Δ_w seconds before they respond to a coalition participation request from a coalition leader. This will give the potential coalition members time to consolidate the requests and respond to the appropriate coalition leader (coalition leader with highest token number). The coalition leader takes a time of Δ_c seconds to form a feasible coalition. Thus, the total coalition process is upper bounded by $3H_{\max}\Delta_{\text{hop}} + \Delta_w + \Delta_c$. The coalition leader, therefore, can choose the go-ahead time, $\tau_G^{T_j}$, as $3H_{\max}\Delta_{\text{hop}} + \Delta_w + \Delta_c$.

From the above discussion, it is clear that the time for proposal submission by potential coalition members is $2H_{\max}\Delta_{\text{hop}} + \Delta_w$ seconds after the dispatch of the coalition participation request. A potential coalition member U_k , if it has any resource required to prosecute the target, estimates its position at time $\tau_G^{T_j}$ called its go-ahead location, denoted by $G_{U_k}^{T_j}$. It then broadcasts its ETA to target from $G_{U_k}^{T_j}$ and its resource capability vector. The coalition leader determines a feasible coalition using PTCFA and the message is broadcast. The UAVs in coalition reach their respective go-ahead locations ($G_{U_k}^{T_j}$) and take a Dubins path to arrive at target T_j . On the other hand, the rejected UAVs continue their previous task. If a coalition leader cannot form a feasible coalition for a target, it waits for a specified time (a value of 5 s is used in simulations) before a coalition formation request is broadcast again.

Coalition leader U_i broadcasts the request in the form

$$\langle U_i, T_j, \tau_G^{T_j}, H \rangle$$

where $\tau_G^{T_j}$ is the go-ahead time, T_j represents the location of the target, its heading and speed at $\tau_G^{T_j}$, and H is the hop counter which is set to H_{\max} by the coalition leader. The presence of H_{\max} in the message will help the potential coalition member to set the initial value of the hop counter H for the proposal message that it is sending back to a coalition leader. The information on $\tau_G^{T_j}$, apart from being useful for a potential coalition member to calculate its ETA to target in a consistent way, enables the intermediate UAVs to decide whether to be relay nodes and potential coalition members and tells the relay nodes when to delete the message from the log to save space.

A typical response of a potential coalition member, U_k , is of the form

$$\langle U_k, U_i, R^{U_k}, \tau_{U_k}^{T_j}, \tau_G^{T_j}, H \rangle$$

where R^{U_k} is the resource vector of U_k , $\tau_{U_k}^{T_j}$ is its ETA to target, and H is the hop counter for the message. Similar to the case of broadcast from the coalition leader, the $\tau_G^{T_j}$ information will help a receiving UAV to decide whether to be a relay node.

The decision process and the communication protocol during a coalition formation process, within a group of UAVs with limited communication ranges executing a search and destroy task, is given in Fig. 83.3. Although, the coalition leader, the relay nodes, and the potential coalition members are shown separately in the figure for clarity, every UAV, including the coalition leader, acts as both a relay node as well as a potential coalition member.

83.5 Simulation Results

In this section, the performance of the coalition formation algorithm for UAVs performing a search and destroy mission is studied via simulations. Initially, an example is presented to show how the coalition formation is carried out and then Monte Carlo simulation results are presented. Through Monte Carlo simulations, the effects of the network protocol parameters like maximum number of allowed hops (H_{\max}) and hop delay Δ_{hop} on the performance of the search and destroy mission are studied in detail.

For all the simulations presented, the UAVs are assumed to have a maximum turn rate of 20 deg/s. The following behavior for a maneuvering target is considered in simulations: it has an initial velocity, the magnitude of which is less than that of all UAVs. It moves forward for a random period of time bounded above by 5 s and then takes a turn randomly either to left or right with a turn radius of 100 m for a random time interval in the range of 0–3 s. This process is repeated several times till the target gets destroyed or till the end of the simulation. After being hit by a UAV, the velocity of a target reduces by a random amount and it does a turn maneuver either to left or right for a random time duration which is less than 3 s. A UAV that is tracking a maneuvering target communicates with the other UAVs, at every 1 s interval, to provide the information of the updated position of the target.

83.5.1 Example Scenario

Consider a scenario with five UAVs and two moving targets in a bounded region of $2,000 \times 2,000$ m as shown in Fig. 83.4a. The target resource requirements are $R^{T_1} = (1, 2, 1)$ and $R^{T_2} = (2, 1, 3)$. The targets have constant speeds of 13.06 and 17.2 m/s with initial headings of 335° and 240° , respectively. The resource capabilities of the UAVs are $R^{U_1} = (1, 0, 1)$, $R^{U_2} = (2, 1, 1)$, $R^{U_3} = (1, 2, 0)$, $R^{U_4} = (1, 2, 1)$, and $R^{U_5} = (0, 1, 1)$. The UAVs have constant speeds of 50 m/s. Figure 83.4a shows the initial placement of the UAVs and the targets. The circles around the UAVs represent the sensor ranges of the vehicles, and the lines

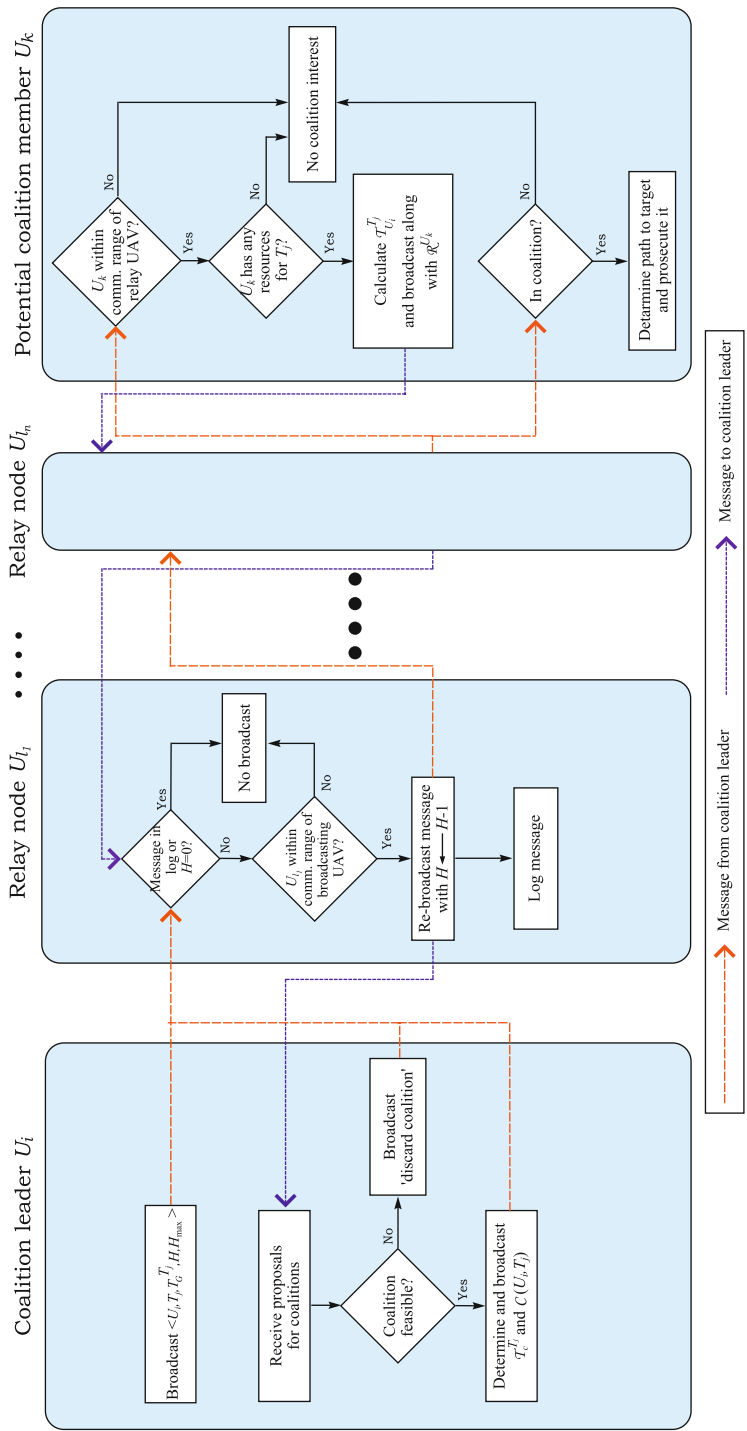

Fig. 83.3 Decision process and communication protocol for coalition formation of UAVs with limited communication ranges

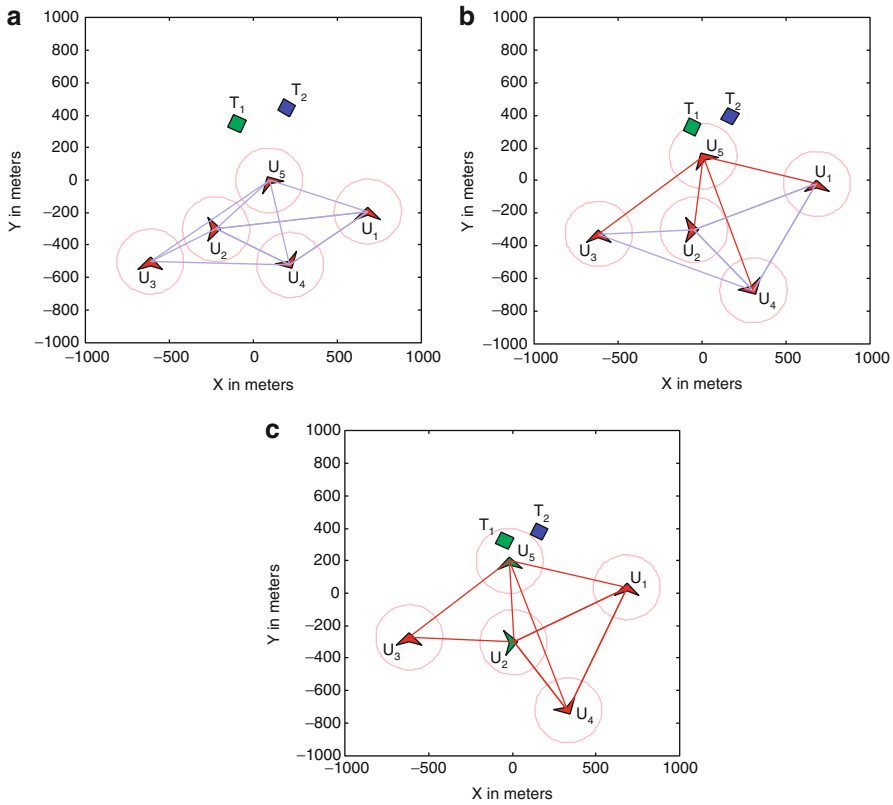

Fig. 83.4 (a) Initial positions of the UAVs and the targets. (b) UAV U_5 detects target T_1 at time $t = 3.6$ s and broadcasts the proposal. (c) A coalition consisting of U_5 and U_2 is formed to destroy target T_1 at time $t = 4.7$ s

connecting the vehicles denote the communication links between them. For this example, the sensor range is 200 m and the communication range is 1,000 m for all UAVs. The maximum number of allowed hops for a message is 2 and $\Delta_{\text{hop}} = 0.1$ s, $\Delta_w = 2\Delta_{\text{hop}}$, and $\Delta_c = 0.3$ s.

The sequence of events during the simulation is as follows. At time $t = 3.6$ s, U_5 detects T_1 (as shown in Fig. 83.4b), and since it does not have enough resources, it broadcasts the proposal for coalition. The UAV U_5 sets the go-ahead time as $\tau_G^{T_1} = 4.7$ s. Figure 83.4b shows all the UAVs are in the communication range of U_5 . The coalition leader U_5 determines a coalition $\mathcal{C}(U_5, T_1) = \{U_5, U_2\}$ at $t = 4.1$ s and sends the decision at $t = 4.2$ s. However, the target execution maneuver starts at $t = 4.7$ s, which is the same as $\tau_G^{T_1}$, as shown in Fig. 83.4c. The agent U_5 will direct its motion toward T_1 and periodically sends the position information of T_1 to U_2 , for aiding U_2 to close in on T_1 .

As the mission progresses, at $t = 5.3$ s, U_5 detects T_2 and sends out a coalition request. Since U_5 and U_2 have not yet completed their task of executing T_1 , they

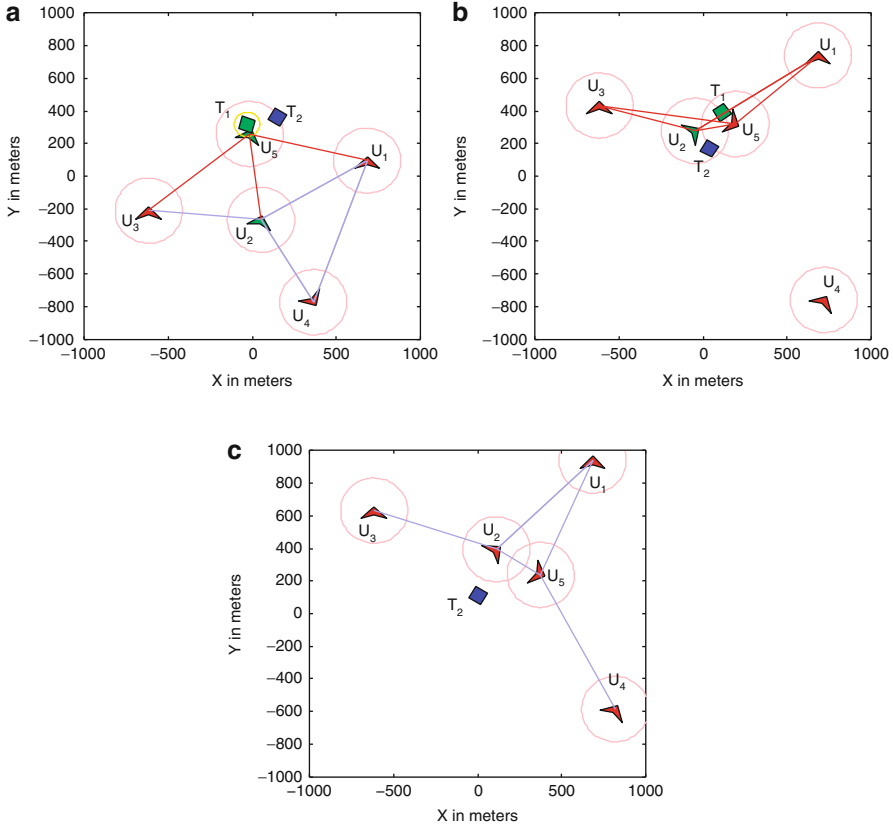

Fig. 83.5 (a) U_5 deploys resources on T_1 and continues to track it. U_5 also detects T_2 and tries to form an unsuccessful coalition due to lack of sufficient resources. (b) U_2 detects T_1 in the sensor range and U_5 releases itself from tracking T_1 . (c) U_2 deploys its resources on T_1 and destroys it completely

cannot yet be the part of the coalition formed to destroy T_2 . The combined resources of the UAVs U_1 , U_3 , and U_4 are $(3, 4, 2)$ and the required resource to destroy T_2 is $R^{T_2} = (2, 1, 3)$. As the combined quantity of the third type of resource of the UAVs available for coalition is less than the target requirement, a coalition cannot be formed. At time $t = 6$ s, U_5 deploys its resources on T_1 (as shown in Fig. 83.5a) and continues to track T_1 until T_1 is in the sensor range of U_2 , as shown in Fig. 83.5b. At time $t = 21.4$ s, U_2 deploys its resources on T_1 to destroy the target completely as shown in Fig. 83.5c.

By the time T_1 is destroyed, T_2 has moved away from the sensor range of all the agents as seen in Fig. 83.5c and the agents continue to search for T_2 . At time $t = 59.6$ s, U_4 detects T_2 and initiates a coalition formation proposal as shown in Fig. 83.6a. The coalition leader U_4 determines a coalition $\mathcal{C}(U_4, T_2) = \{U_4, U_1, U_2\}$ at time $t = 60.7$ s (as shown in Fig. 83.6b). The agent U_4 attacks T_2 and deploys its

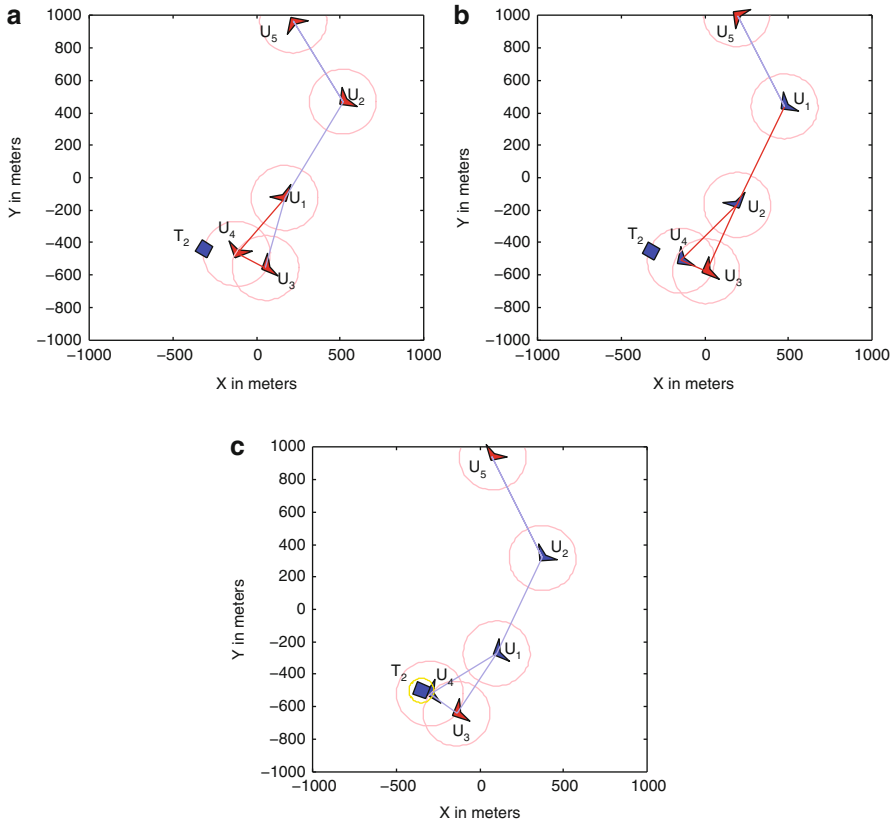

Fig. 83.6 (a) U_4 detects T_2 at $t = 59.6$ s. (b) U_4 forms a coalition $\{U_4, U_1, U_2\}$ for T_2 at time $t = 60.7$ s. (c) U_4 attacks T_2 at $t = 65.3$ s and continues to track it

resources at $t = 65.3$ s (as shown in Fig. 83.6c) and continues to track T_2 . Once T_2 is in U_1 's sensor range, U_4 releases the tracking tasks and U_1 strikes T_2 at $t = 70.5$ s (as shown in Fig. 83.7a). After U_1 's strike, U_1 tracks the target until U_2 detects the target in its sensor range as shown in Fig. 83.7b. Then U_2 tracks the target and strikes it to accomplish the mission as shown in Fig. 83.7c at time $t = 81.3$ s.

The above sequence of events for the sample scenario shows how the agents determine coalitions and the process involved in tracking randomly maneuvering targets and destroying them.

83.5.2 Effect of Varying Number of UAVs and Targets

The performance of the coalition formation algorithm with increase in the number of UAVs used for the search and destroy mission is studied in this section.

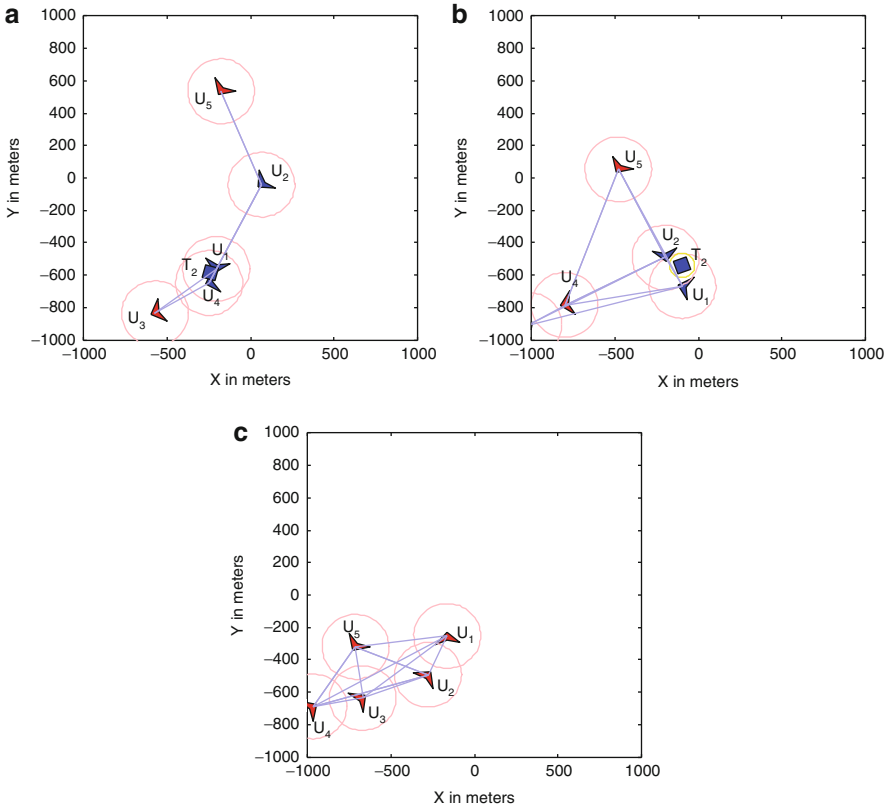

Fig. 83.7 (a) U_1 strikes T_2 at $t = 70.5$ s. (b) T_2 is in the sensor range of U_2 . (c) U_2 strikes T_2 at time $t = 81.3$ s to destroy it and complete the mission

The performance is measured in terms of the time required for mission completion. The parameters used for the simulation are as follows. A bounded region of $1,000 \times 1,000$ m is considered for simulations. The sensor range is 150 m and the communication range is 300 m. The maximum number of allowed hops for a message is 3 and $\Delta_{\text{hop}} = 0.1$ s, $\Delta_w = 0.2$ s, and $\Delta_c = 0.3$ s. The UAVs have fixed but different velocities in the range 10–20 m/s randomly chosen at the start of each simulation. To start with, every target has a fixed velocity randomly chosen between 0 and 10 m/s. The target behavior is similar to that described in the beginning of this section. Also, if the target is near the boundary of the search region, the UAV that detected it will track the target until it comes within the region of interest and then a coalition request is made. If a UAV that is part of a coalition detects a target on its way to prosecution of some other target, then it broadcasts this information to nearby UAVs. Those UAVs that receive this message moves to the region where the target was detected. This leads to a kind of directed search that will aid a quicker prosecution of targets which otherwise would have to be detected again.

Fig. 83.8 Variation of mission time with increase in number of UAVs for various number of targets

The mission time is defined as the time taken to destroy all the targets within the region of interest. The simulation is done for a maximum simulation time of 1,500 s. If the mission is not complete (i.e., all the targets are not destroyed) within that time, then the mission time is deemed to be 1,500 s. The targets are assumed to have three type of resources. The quantity of each type is a random integer between 0 and 3. The UAVs also have similar resource distribution. However, if the total UAV resources are not enough to destroy the target, then resources are added to UAVs before the start of the mission so that the mission is feasible. The above setting is also used for rest of the simulations.

Figure 83.8 gives the total mission time, that is, the time required to find and destroy all the targets, as a function of the number of UAVs used in the mission. Cases where the number of target are 5, 10, and 15 are considered. The results reported are averages over 100 Monte Carlo runs with different initial positions and orientations of UAVs and targets. As seen in the figure, for a fixed number of targets, the time to destroy all the targets decreases as the number of UAVs deployed increases.

83.5.3 Effect of Varying Communication Range

The effect of change in UAV communication ranges on the completion time of the search, and destroy mission is studied in this section. Simulation settings are the same as described above except for the communication range which is varied. The results obtained are shown in Fig. 83.9. As expected, the mission performance increases with increase in communication ranges of UAVs. This is because, with

Fig. 83.9 Variation of mission time with increase in communication range of UAVs for a mission with 10 UAVs and 10 targets

Fig. 83.10 Variation of mission time with increase in maximum hops allowed for 10 and 20 UAVs prosecuting 10 targets

more communication range, it is possible for the coalition leader to interact with more number of UAVs leading to a higher chance of a successful coalition being formed. At very high values of communication range, a UAV will be able to communicate with all other UAVs without the need for a relay agent, and then the problem becomes equivalent to that with global communication.

83.5.4 Effect of Hop Delay and Max-Hops

The goal of this experiment is to study the effects of communication delays and number of maximum allowed hops for a message in the network on the mission performance. The simulation setting is the same as described before.

Figure 83.10 shows the variation of average mission time (averaged over 100 runs) taken by 10 and 20 UAVs to destroy 10 targets with respect to H_{max} . Next, the

effect of increase in H_{\max} for a given $\Delta_{\text{hop}} = 0.1$ s is studied. Consider the change in mission time for H_{\max} varying from 1 to 5 as shown in Fig. 83.10. With increase in H_{\max} , the mission time decreases. This is because, as the network depth is more, the coalition leader can get more potential coalition members than being restricted to only its immediate neighbors as in the case for low value of H_{\max} say, $H_{\max} = 1$, and hence will be able to make feasible coalitions that can destroy the target quicker. However, further increasing H_{\max} will result in a slight degradation of performance. The degradation in performance occurs as the employed communication protocol requires a subnetwork that is invariant throughout the coalition formation period. Since it is harder to find a wider network (higher H_{\max}) that stays invariant for a specified time period, the mission time increases with H_{\max} and even more so in the case where Δ_{hop} is high (for the cases presented in Fig. 83.10, $\Delta_{\text{hop}} = 0.1$ s). Thus, the degradation in mission performance with increase in H_{\max} will be more prominent for high Δ_{hop} . This effect is clearly seen in Fig. 83.11 where the combined effect of H_{\max} and Δ_{hop} is captured. The figure shows the change in mission time for a search and destroy task with 10 UAVs and 10 targets with respect to maximum number of allowed hops for different values of communication delay. Note the degradation of mission performance for the cases where $\Delta_{\text{hop}} = 0.5$ and 1 s when the number of maximum allowed hops is more than 3.

Figure 83.12 shows the effect of communication delay on the mission completion time for search and destroy missions with 10 and 20 UAVs and 10 targets. As seen from the figure, the mission time increases with increase in communication delay. This is because an increase in communication delay will cause an increase in the coalition formation period. Since the communication protocol depends on finding a subnetwork that has an invariant topology throughout the coalition formation process, it becomes harder to find such a network under higher communication

Fig. 83.11 Effect of hop delay Δ_{hop} and maximum number of allowed hops H_{\max} on mission performance (different curves correspond to $\Delta_{\text{hop}} = 0.1, 0.5$, and 1 s)

Fig. 83.12 Variation of mission time with increase in communication delay for 10 and 20 UAVs prosecuting 10 targets

delays. This results in the inability of coalition leader to find potential members to form feasible coalitions leading to higher mission completion times.

From these studies, it can be concluded that the hop delay in the network and the selection of H_{\max} are important for the performance of the mission in terms of the mission completion time. Also, note that all the simulations had UAVs with different speed which shows the efficacy of the algorithm for use with heterogeneous UAVs.

83.6 Conclusions

In this chapter, a coalition formation algorithm for UAVs having limited communication ranges with associated communication delays is presented. A novel mechanism is developed to determine potential coalition members in a dynamic network formed by UAVs moving around. The UAVs in the coalition, sequentially, use a track and strike method to deploy their resources on the moving target. The effect of communication delay and the maximum number of allowed hops for a message in the network to determine potential coalition members for a coalition is studied. The results showed that if the delay is large, then a coalition formed from the immediate neighbors are sufficient for a good performance in terms of mission completion time. Under smaller delays, the simulations show that including neighbors up to a few hops will increase performance, and any additional increase in hop count will degrade performance. In these studies, collision avoidance among the UAVs is not included. Thus, an important aspect of extending the problem lies in including collision avoidance into the UAV system, and to study how the UAVs will alter their routes to avoid collisions while tracking and striking the target. It will be interesting to investigate the performance of the multiple UAV search and destroy mission under such a situation.

Abstract

This chapter investigates how to control and coordinate teams of unmanned aerial vehicles (UAVs) to provide protection to convoys of ground vehicles. This is a rich yet canonical problem when coordinating multiple UAVs in that coordinated movements, task assignments, and resource balancing must all be performed for a successful completion of the mission. Time-optimal paths for providing convoy

protection to stationary ground vehicles are presented, and these algorithms are extended to moving ground vehicles. The assignment problems, associated with dispatching UAVs from the convoy to inspect and clear potential threats, are moreover discussed.

84.1 Introduction

Airplanes can be used to provide close air support or large-scale area surveillance for ground convoys in unknown and potentially dangerous environments. Wide-spread use of unmanned ground vehicles (UGVs) to conduct tasks in these environments has necessitated the design of practical approaches to effectively control and coordinate multiple UAVs to provide coverage, surveillance, tracking, and convoy protection for the UGVs (see, e.g., Beard et al. 2006; Cruz et al. 2007; Girard et al. 2004; Grocholsky et al. 2006; Lee et al. 2003; Spry et al. 2005). This chapter discusses this problem, which can be decomposed into two subproblems. The first problem involves the design of coordinated UAV maneuvers to ensure the ground convoy is protected. The second problem concerns how to assign and dispatch UAVs from the convoy to clear potential threats in such a way that the fuel consumption is balanced across the team of UAVs.

84.1.1 Problem 1: Time-Optimal Protection Paths

UAVs often use onboard Electro-optical/infrared cameras in order to obtain information about surrounding areas. In many surveillance applications with small UAVs (e.g., Morris and Holden 2000; Quigley et al. 2005), the motion of the camera is typically decoupled from that of the UAV, using a gyro-stabilized camera platform that keeps the camera pointing in the same direction regardless of the motion of the UAV. This approach provides the UAV with stable images even under high-frequency oscillations associated with the UAV itself. Hence, the assumption is made that the onboard camera always points down and, as such, the UAV monitors a circular disk on the ground.

To solve the problem of providing coordinated protection maneuvers, an optimal approach is adopted for path planning and coordination of multiple UAVs. The UAVs are modeled as Dubins vehicles flying at constant altitude. Limited ranges of sensors onboard the UAVs, together with their kinematic constraints, might make it impossible to provide coverage to the ground vehicles with a single UAV. In this case, it is of interest to find the best path for an individual UAV so that it can monitor the ground vehicles for the longest time and then coordinate the UAVs in such a way that the ground vehicles are visible to at least one UAV at any given time, as illustrated in Fig. 84.1.

A Dubins vehicle is a planar vehicle with bounded turning radius and constant forward speed. L.E. Dubins was the first to give a characterization of time-optimal trajectories for such a vehicle using geometric methods (Dubins 1957). Shortest-path problems for Dubins vehicles have been since studied extensively

Fig. 84.1 UAVs providing convoy protection to UGVs. The UAVs are assumed to be kinematically restricted by their minimum turning radius R . The sensors onboard the UAVs also have limited range and are assumed to be able to observe a disk of radius r on the ground

(see Agarwal et al. 1998; Boissonnat et al. 1994; Dubins 1961, for example). A Dubins vehicle that can move backward was studied by Reeds and Shepp (1990), and the shortest-path problem for a Reeds-Shepp vehicle was further studied and classified by Souères and Laumond (1996). Walsh et al. (1994) found optimal paths using quadratic cost functions for a Dubins airplane in $SE(2)$, $SO(3)$, and $SE(3)$. McGee et al. (2005) obtained time-optimal paths for Dubins vehicles in constant wind. Dubins vehicles have moreover been used as a simplified model to describe planar motions of UAVs in Savla et al. (2008). Chitsaz and LaValle (2007) extend the Dubins' model from $SE(2)$ to $SE(2) \times \mathbb{R}$ to account for altitude changes and gave a characterization of the time-optimal trajectories for this model based on the final altitude.

Optimal trajectories of a Dubins vehicle are often constructed using motion primitives (see Belta et al. 2007; Frazzoli et al. 2005; Hauser et al. 2006, for example). For point-to-point minimum-time transfer problems, it has been shown that the optimal solutions are curves consisting of only three motion primitives: line segments and circular arcs turning maximally to the left and to the right (see Dubins 1957; Lavalle 2006; Souères and Boissonnat 1998). The optimal paths for the point-to-point minimum-time transfer problem are characterized by sequences of these three motion primitives. This chapter extends this to the case of stationary convoy protection, where resulting time-optimal paths are characterized by sequence of only two motion primitives (maximally turning left and turning right) and do not include any line segments. In fact, this chapter draws upon the results in Ding et al. (2009). Similar to many previous time-optimal path-planning work (e.g., Boissonnat et al. 1994; Chitsaz and LaValle 2007; Ding et al. 2009; McGee et al. 2005; Souères and Laumond 1996; Souères and Boissonnat 1998), it makes use of Pontryagin's Minimum Principle to derive optimal trajectories.

When addressing this problem, the first case under investigation is when the convoys are stationary, and global optimal paths are found for a single UAV that maximize the coverage time, that is, the time the UAV spends with the convoy being visible. It is then shown how to coordinate a group of UAVs to provide continuous coverage of the convoys and the minimum number of UAVs required to achieve continuous convoy protection for all time, as well as how to extend these results to moving rather than stationary ground convoys.

Dubins vehicles flying at constant altitude with unit speed (The unit speed assumption is justified since the results describe paths which are invariant under different forward speeds.) and minimum turn radius of R can be modeled as

$$\begin{cases} \dot{x} = \cos(\theta) \\ \dot{y} = \sin(\theta) \\ \dot{\theta} = \omega, \end{cases} \quad (84.1)$$

where x and y are the position of the UAV in the x - y plane at the altitude the UAV is flying and ω is the angular velocity of the vehicle. The angular velocity is bounded by the inverse of the minimum turn radius R of the vehicle, that is, $\omega \in [-\frac{1}{R}, \frac{1}{R}]$. The state of the system be given by $q(t) = [x(t), y(t), \theta(t)]^T$.

As already stated, it is assumed that the cameras onboard the UAVs can monitor a disk of radius r on the ground (see Fig. 84.1 for an illustration of this scenario). That is, it is assumed that the onboard camera is attached to a gyro and is always looking down, regardless of the bank and pitch angles of the UAV. A gimbaled camera system is commonly used in UAV surveillance applications to decouple camera from dynamics of the plane (see, e.g., Morris and Holden 2000; Quigley et al. 2005). In addition, to simplify the problem, the ground convoys are considered to be points located at the centroid of the convoys in the x - y plane. Hence, successful convoy protection is defined as being achieved when the centroid of the UGVs is visible to at least one of the UAVs at any time. Or, in other words, convoy protection is provided by the UAV if the horizontal distance between the UAV and the centroid of the UGVs is less than or equal to r .

The disk of observation and its radius r certainly depend on the altitude of the UAV, and the angular range of the camera but to ensure quality of observation and successful protection, cameras or sensors onboard the UAV usually have narrower field of view than the UAV's turning radius. This is especially true for cameras and sensors that carry out tasks using computer vision algorithms, which require certain level of image resolution. In these cases, $R > r$, and if the UGVs are stationary, then a single UAV is not capable of providing convoy protection to the ground vehicles indefinitely, and a control strategy is needed to optimize the time in which convoy protection is achieved. This can be seen by drawing a circle of radius r using the position of the centroid of UGVs as the center. If there is only one UAV, then due to the fact that $R > r$, the UAV will eventually fly out of this circle no matter where it starts.

Note that in case of static convoys, if $R \leq r$, then the convoy protection problem is trivial since it can be solved by using a single UAV flying on a circular path of

radius R with the center being the centroid of the ground vehicles. In this case, convoy protection is provided for all time using only one UAV.

In this chapter, the problem of controlling and coordinating UAVs is considered, with the task of the UAVs being that of providing convoy protection for both stationary UGVs and UGVs moving on a straight line. In both cases, it is assumed that $R > r$. Let the *convoy circle* denote a disk of radius r centered at the centroid of the UGVs. Using the convoy circle, it can be seen that convoy protection is achieved if the ground track of at least one UAV is present inside the convoy circle at any time. Because of the kinematic constraint (turning radius R of the UAV), the UAVs are required to be coordinated so that they collectively provide continuous convoy protection while individual UAVs enter and leave the convoy circle.

84.1.2 Problem 2: Assigning and Dispatching UAVs

In the convoy protection problem, being able to have the UAVs track the UGVs is not enough. Sometimes UAVs need to be dispatched in order to clear potential threats. In fact, given a single UAV and N known threats that must be cleared, together with a cost associated with traversing between the threats, the problem of selecting the order in which the threats should be visited (and cleared) is a variant of the well-studied traveling salesperson (TSP) problem (Burkard 2002; Garey and Johnson 1979). Unfortunately, TSP is a NP-hard problem, that is, there are no polynomial (in the number of threats)-time algorithms that can solve the problem. As a consequence, *any attempt at tackling the full-fledged TSP using limited computational resources is doomed to failure*. The reason for this computational intractability is that, in order to solve the TSP problem, one has to establish the order in which the threats are visited. If, on the other hand, this order is a priori given, the problem would already be solved.

If there are multiple UAVs (as is the case in the convoy protection scenario under consideration here), the complexity of the TSP problem is reduced if the number of UAVs is greater than or equal to the number of threats (including both known and pop-up threats). The reason for this is that one ends up with a so-called matching problem (Pardalos et al. 1994), where one simply has to decide which threat should be visited by which UAV. And, since there are no threats left unvisited after all UAVs have visited one threat, there is again no ordering of the threats that must be decided upon. The matching problem can be solved in cubic time (in the number of threats) using the Hungarian algorithm (Kuhn 1955), as is done, for example, in Ji et al. (2006) and Moore and Passino (2005). If there are fewer UAVs than threats, then the NP-hardness result still applies (Arsie et al. 2009; Pavone et al. 2009), and this is the situation (fewer UAVs than threats) that can be expected in real-world operations.

Numerous algorithms for approximating and addressing the TSP problem in a computationally tractable manner have been proposed. These algorithms typically fall under two categories, namely, (1) greedy algorithms (Beard et al. 2002; Psaraftis 1988; Richards et al. 2002; Schumacher et al. 2003), where each agent is trying

to locally maximize and minimize a cost based solely on the instantaneous cost rather than over the whole time horizon, and (2) auction-based and game theoretic algorithms (Arslan et al. 2007), where the agents get to “bid” on which tasks they want to be assigned to. In the greedy case, the solution is clearly suboptimal, even though it was shown in Arsie et al. (2009) and Pavone et al. (2009) that asymptotically (as the number of threats approach infinity), the solution gets to within a constant factor of the optimal solution. Auction-based solutions, on the other hand, typically require a significant amount of information to be shared by the agents, and despite this increase in shared information and the required communication bandwidth, the inherent complexity of the problem remains the same. As such, auction-based methods may provide some guidance as to finding suboptimal solutions, but they do not, unfortunately, overcome the complexity issue and they come with an increased communications overhead. Solutions that fall in between these two approaches were presented in Ponda et al. (2010), where decentralized suboptimal solutions were obtained by focusing on the feasibility of the solution over limited time horizons rather than the minimization of any particular cost function, and in Northrop Grumman, where the assignment and allocation problems were addressed for more specialized surveillance missions. This last approach (as exemplified by Northrop Grumman and Ponda et al. 2010) is one that will be followed in this chapter in that the special structure of the convoy protection problem will be leveraged to obtain good suboptimal solutions to an intractable problem.

The convoy protection problem is *not* a standard TSP (single or multi-UAV) problem even though it shares some of the same features. The two main differences are:

- Threat dynamics: The threats are not given all at once. Instead, they show up throughout the mission, and as a consequence, the problem must be resolved whenever a new threat appears.
- Overall cost: The cost to be minimized is not the total distance traveled or the total fuel consumed by the team of UAVs. Instead, it needs to reflect the fact that the fuel consumption should be balanced among the different UAVs, since success of convoy protection mission depends on participation of all UAVs in convoy protection effort. As such, it is a min-max cost in that what must be minimized is the fuel consumption of the UAV who has to expend the most fuel.

As a consequence of these considerations, the convoy protection problem is still NP-hard, and in order to be able to still solve it in a resource-constrained environment, some simplifying assumptions must be made. However, one can take the explicit *structure* of the convoy protection problem into account when making these assumptions.

A1 Bounded number of threats: At any given time, only a fixed number of threats will be considered (e.g., roadside bombs). Even though no a priori upper limit is placed on the number of threats that may appear, the algorithm will be restricted to only consider the closest M threats, where M is a fixed number. Without further assumptions, this will still make the complexity factorial in M , which may be a large number (depending on what M is), but at least, it is bounded.

- A2 *One-dimensional threat distribution*: As the convoy is moving along an established route, for example, a road, only threats on (or close to) the road will be considered. As such, the threats will be placed along a one-dimensional path, and they will be encountered sequentially. The result is that the order in which the threats are cleared is already given in that the closest threat is cleared first.
- A3 *Not all threats must be cleared*: The objective of the convoy protection algorithm is to ensure that the convoy is not endangered by any threats. There are two ways in which this can be achieved. The first is by clearing threats, as previously discussed. However, one can also replan the path the convoy takes in order to produce a detour around a threat. This will be done if the threat cannot be cleared in time which allows for threats to be ignored that would otherwise require too much fuel to be cleared.

These three assumptions will allow for a polynomial-time algorithm for solving the assignment aspect of the overall convoy protection problem.

84.2 Optimal Convoy Protection Maneuvers

84.2.1 Single UAV Time-Optimal Paths

The first problem to consider is the problem of using one UAV to provide convoy protection to some stationary UGVs for the maximum amount of time, which is equivalent of finding the longest feasible path inside the convoy circle. What needs to be determined is both the optimal path for a single UAV starting at a fixed initial condition and the optimal path if the UAV is allowed to pick the initial condition (position and heading) when entering the convoy circle.

Fix the origin of the x - y plane at the centroid of the UGVs. A maximum-time, optimal control problem with state constraint $x^2 + y^2 - r^2 \leq 0$ and input constraint $|w| \leq \frac{1}{R}$ is then obtained. Furthermore, it can be assumed that the UAV starts at a point on the state constraint boundary (convoy circle). This assumption does not limit the generality of the result, since, if the UAV starts inside the convoy circle, Bellman's Principle of Optimality can be used to obtain the optimal path for the UAV by integrating backward in time.

To facilitate the analysis, it is useful to impose an extra terminal manifold constraint. Since the optimal solution always has the terminal state (henceforth denoted as the exit state) on the boundary of the state constraint set (exiting the convoy circle), the terminal constraint of being on the convoy circle when exiting is enforced. To simplify, the following notation is introduced: $q_T := q(T)$ and $[x_T, y_T, \theta_T] := [x(T), y(T), \theta(T)]$. The terminal manifold can then be defined as the set of states that satisfy

$$M(q_T) = x_T^2 + y_T^2 - r^2 = 0. \quad (84.2)$$

The optimal control problem is given by

Problem 84.2.1

$$\min_{\omega(t)} J = \int_0^T -1 dt, \quad (84.3)$$

subject to the dynamics of (84.1) with a given initial condition $q(0)$, the input constraint

$$-\frac{1}{R} \leq \omega(t) \leq \frac{1}{R}, \quad (84.4)$$

the state constraint

$$x(t)^2 + y(t)^2 - r^2 \leq 0 \quad (84.5)$$

$$x(0)^2 + y(0)^2 - r^2 = 0, \quad (84.6)$$

and the terminal manifold constraint

$$M(q(T)) = x(T)^2 + y(T)^2 - r^2 = 0. \quad (84.7)$$

This problem is henceforth denoted as $\Pi_{q(0)}$.

When solving this problem, one immediately should exclude initial conditions that generate no paths entering the convoy circle. This occurs when the initial heading $\theta(0)$ points away from the convoy circle. The set of initial conditions Λ that are considered for the optimization problem are thus given by

$$\Lambda = \left\{ q = [x, y, \theta]^T : x^2 + y^2 = r^2, \text{ and } -\frac{\pi}{2} < \theta - \text{atan2}(y, x) < \frac{\pi}{2} \right\}. \quad (84.8)$$

The set Λ is called the feasible entry set. For simplicity of notation, it is assumed that all angles are taken modulo 2π .

$\Pi_{q(0)}$ is an optimal control problem with both input and state inequality constraints. Optimal control problem with state inequality constraints is usually hard or impossible to solve explicitly. Fortunately, in this problem, due to the special structure of the state inequality constraint (84.5), there are only two points on the state trajectory where the constraint is active. These two states correspond to when the UAV is entering and exiting the convoy circle. Due to this special structure, an auxiliary state is used to handle the state constraint. Define $\xi(x^2 + y^2 - r^2)$ as an inverted Heaviside function:

$$\xi(x^2 + y^2 - r^2) = \begin{cases} 0 & : x^2 + y^2 - r^2 \leq 0 \\ 1 & : \text{otherwise.} \end{cases} \quad (84.9)$$

Define a new state τ as

$$\dot{\tau}(t) = (x^2 + y^2 - r^2)^2 \xi(x^2 + y^2 - r^2). \quad (84.10)$$

The state of the UAV is then augmented as $\bar{q}(t) = [q(t), \tau(t)]^T$. Assuming that $\tau(0) = 0$ and imposing the terminal constraint that $\tau(T) = 0$, it follows that $\dot{\tau}(t) = 0, \forall t \in [0, T]$, since $\dot{\tau}(t) \geq 0, \forall t \in [0, T]$. Hence,

$$\tau(t) = 0, \forall t \in [0, T]. \quad (84.11)$$

Note that the terminal constraint $\tau(T) = 0$ enforces the state inequality constraint (84.5). Using this auxiliary state τ , the state inequality constraint is transformed into an equivalent terminal constraint. When there is no ambiguity, it is assumed that the state constraint (84.5) is satisfied and $q(t)$ is still referred to as the state trajectory.

The Hamiltonian for this optimal control problem is

$$\begin{aligned} \mathcal{H} = & -1 + \lambda_1 \cos \theta + \lambda_2 \sin \theta + \lambda_3 \omega \\ & + \lambda_4 (x^2 + y^2 - r^2)^2 \xi (x^2 + y^2 - r^2), \end{aligned} \quad (84.12)$$

where $\lambda = [\lambda_1, \dots, \lambda_4]^T$ are the costates. The costates satisfy the following differential equations in the time interval $[0, T]$:

$$\begin{aligned} \dot{\lambda}_1 &= -\frac{\partial \mathcal{H}}{\partial x} = -2x\lambda_4(x^2 + y^2 - r^2)\xi(x^2 + y^2 - r^2), \\ \dot{\lambda}_2 &= -\frac{\partial \mathcal{H}}{\partial y} = -2y\lambda_4(x^2 + y^2 - r^2)\xi(x^2 + y^2 - r^2), \\ \dot{\lambda}_3 &= -\frac{\partial \mathcal{H}}{\partial \theta} = \lambda_1 \sin \theta - \lambda_2 \cos \theta, \\ \dot{\lambda}_4 &= -\frac{\partial \mathcal{H}}{\partial \tau} = 0. \end{aligned}$$

When the state constraint (84.5) is satisfied, the last term in the Hamiltonian (84.12) does not contribute since $\lambda_4(x^2 + y^2 - r^2)^2 \xi(x^2 + y^2 - r^2) = 0, \forall t \in [0, T]$, and thus the Hamiltonian becomes

$$\mathcal{H} = -1 + \lambda_1 \cos \theta + \lambda_2 \sin \theta + \lambda_3 \omega. \quad (84.13)$$

The necessary optimality condition from the Pontryagin's Minimum Principle states that

$$\begin{aligned} \mathcal{H}(\bar{q}^*(t), \lambda^*(t), \omega^*(t), t) &\leq \mathcal{H}(\bar{q}^*(t), \lambda^*(t), \omega(t), t), \\ \forall \omega(t) &\in \left[-\frac{1}{R}, \frac{1}{R} \right], t \in [0, T], \end{aligned} \quad (84.14)$$

where $\bar{q}^*(t)$ denotes the optimal augmented state trajectory, $\lambda^*(t)$ denotes the optimal costate trajectory corresponding to $\bar{q}^*(t)$, and $\omega^*(t)$ is the optimal control.

Using the necessary optimality condition (84.14) on the Hamiltonian equation (84.13), one can see that the optimal control $\omega^*(t)$ is a function of the costate $\lambda_3^*(t)$:

$$\omega^*(t) = \begin{cases} -\frac{1}{R}, & \text{if } \lambda_3^*(t) > 0 \\ \frac{1}{R}, & \text{if } \lambda_3^*(t) < 0 \\ \text{undetermined,} & \text{if } \lambda_3^*(t) = 0. \end{cases} \quad (84.15)$$

Thus, it can be seen that when $\lambda_3^*(t) > 0$, the optimal control is maximum turning right and when $\lambda_3^*(t) < 0$, the optimal control is maximum turning left. When $\lambda_3^*(t) = 0$ for a finite time interval, then any control $\omega(t) \in [-\frac{1}{R}, \frac{1}{R}]$ satisfies the Minimum Principle, and the finite time interval when this case arises is called a singular interval (for discussions on singular intervals for optimal control problems, see any standard text on optimal control, such as Kirk 2004). Hence, the optimal control is in the form of bang-bang (if there is no singular interval) or bang-off-bang (if there are singular intervals). And if there is a singular interval for $\Pi_{q(0)}$, then it is necessary that there exists a time interval $[t_1, t_2]$ such that $\lambda_3(t) = 0$ and $\dot{\lambda}_3(t) = 0$ for all $t \in [t_1, t_2]$. For Dubins vehicles with dynamics specified in Eq. (84.1), singular intervals result in line segments as part of the optimal path, and as a consequence, line segments are usually part of the optimal paths for shortest-path (or minimum-time) Dubins vehicle problems.

Definition 84.2.1 For a state trajectory $q(t), t \in [0, T]$ satisfying the state constraint (84.5), if the costate trajectory $\lambda_3(t)$ and corresponding input $\omega(t)$ satisfy the control strategy (84.15), then $q(t)$ is referred to as a *candidate optimal trajectory* (COT).

Pontryagin's Minimum Principle states that being a COT is a necessary condition for being an optimal solution, and assuming that a trajectory $q(t)$ is a COT but only its terminal state q_T is given, the entire trajectory $q(t)$, its corresponding costate trajectory $\lambda(t)$ satisfying the necessary optimality condition (84.14), and the control $\omega(t)$ satisfying the optimal control strategy (84.15) can all be uniquely determined from the terminal state q_T , as is shown in Ding et al. (2009, 2010). In fact, in Ding et al. (2010), it was shown that an optimal trajectory cannot contain both a circular arc and a line segment. In addition, the COT can be either a line through the origin or a curve consisting of circular arcs of radius R . Hence, if the optimal control is not constant, then it can only change between $\omega = -\frac{1}{R}$ and $\omega = \frac{1}{R}$, since there is no singular interval in that case. Henceforth, the term *switching time* is used for the time instant when the control law switches between $\omega = -\frac{1}{R}$ and $\omega = \frac{1}{R}$. Furthermore, a switching point in a state trajectory is defined as the state when the controller switches.

For a number of terminal conditions q_T , the corresponding COTs are shown in Fig. 84.2. For all of these terminal conditions, x - y coordinates of the terminal state

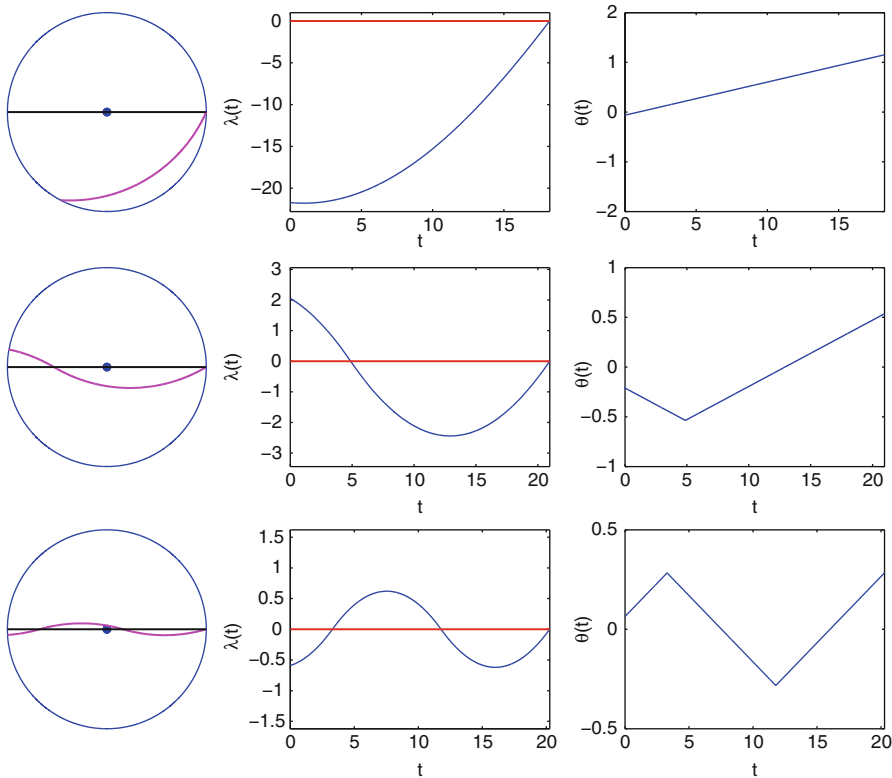

Fig. 84.2 A number of COTs are plotted for different exit angles θ_T resulting in different number of switchings. The *left plots* are the COTs in x - y plane, the *middle plots* are the costates λ_3 , and the *right plots* are the angles $\theta(t)$. The first, second, and third rows correspond to the cases when this is 0, 1, and 2 switchings, respectively

are fixed at $[r, 0]^T$ (hence $\psi_T = 0$), but the exit angle θ_T is allowed to vary. The path in the x - y plane $[x(t), y(t)]$, costate $\lambda_3(t)$, and angle $\theta(t)$ are plotted from left to right.

An unusual aspect of this problem is that, unlike the Dubins vehicle shortest-path problem, the optimal paths for Problem 84.2.1 do not in fact contain line segments, as shown in Ding et al. (2010), even though such maneuvers do constitute valid COTs. Additionally, it can be shown (Ding et al. 2010) that the optimal paths never switch more than once, which leads to the following key result when characterizing the best protection paths:

Theorem 84.2.1 *For any initial condition $q(0)$, the optimal solution to Problem 84.2.1 is a UAV trajectory that does not switch more than once and that does not contain any straight line segments.*

Based on this theorem, the set of optimal motion primitives does not contain the motion of going straight. As such, two motion primitives $\{\mathbf{L}, \mathbf{R}\}$ are defined, where \mathbf{L} and \mathbf{R} motion primitives turn the vehicle maximally to the left and right, respectively. Furthermore, since the optimal trajectory only switch once, there are only four possible sequences of the $\{\mathbf{L}, \mathbf{R}\}$ motion primitives, namely,

$$\{\mathbf{L}, \mathbf{R}, \mathbf{LR}, \mathbf{RL}\}, \quad (84.16)$$

where \mathbf{LR} stands for turning left then right and \mathbf{RL} for turning right then left. The actual optimal paths can now be determined directly from the costate equations. In fact, since there are only four possibilities for the motion sequences in an optimal trajectory, it is easy to determine the global optimal path for any initial condition. A set of optimal paths for initial conditions with heading $\theta(0) = \frac{\pi}{2}$ are shown in Fig. 84.3. Figure 84.3 also shows the optimal switching surface on which switchings are optimal, and it can be observed that when a switching is needed for the optimal trajectory, the switching point, the origin, and the exit point are on the same line.

Fig. 84.3 A number of optimal state trajectories with initial heading $\frac{\pi}{2}$. The optimal switching points are plotted together to form the optimal switching surface. In this case, $R = 1.5r$. The *dashed paths* correspond to optimal paths. If $x(0) \in (-\frac{r^2}{R}, 0]$, then \mathbf{LR} is optimal. If $x(0) \in [0, \frac{r^2}{R})$, then \mathbf{RL} is optimal. If $x(0) \in [\frac{r^2}{R}, r)$, then \mathbf{L} is optimal. Otherwise, \mathbf{R} is optimal. The optimal switching points are plotted together to form the optimal switching surface. The *solid path* corresponds to the initial condition that $x(0) = -\frac{r^2}{R}$. This path and the path where $x(0) = \frac{r^2}{R}$ are equal in length and longer than all other optimal paths with the same initial heading

By rotating the initial state until the initial heading is $\frac{\pi}{2}$, the switching surface in Fig. 84.3 provides a control law which produces the optimal trajectory for any given initial condition. Now, this result is extended to address a perhaps more important problem: finding the optimal path inside the convoy circle with initial condition free to choose.

Problem 84.2.2

$$\min_{q(0)} J^*(q(0)), \quad (84.17)$$

where $J^*(q(0))$ is the solution of Problem 84.2.1 ($\Pi_{q(0)}$), with the initial state $q(0)$.

Let the optimal initial condition be denoted by $q^*(0)$; hence,

$$q^*(0) = \arg \min_{q(0)} J^*(q(0)). \quad (84.18)$$

The optimal path with this initial condition will be referred to as a globally (To clarify, the word *globally* is used here not within the context of local or global optimality. The solutions obtained for Problem 84.2.1 are global optimal trajectories each corresponds to a fixed initial condition. A globally optimal path in this chapter is defined as the longest path over all feasible initial conditions.) optimal path. $q^*(0)$ will be called an optimal entry state. It is apparent that any rotation of this state around the origin is also an optimal entry state. Hence, the globally optimal paths and optimal entry states are not unique. The set of optimal entry states, denoted by \mathbb{Q}^* , can be exactly determined by noting that optimal paths with optimal entry points do *not* switch. Instead, they are given by maximal left/right inputs while the entry point, the center of the convoy circle, and the exit point are located on the same line, as found in Ding et al. (2010).

84.2.2 Multi-UAV Convoy Protection

Due to kinematic constraint of the UAVs ($r < R$), it is impossible for one UAV to provide complete convoy protection for a group of UGVs. In this situation, multi-UAV coordination is required in order to successfully carry out convoy protection. The previous section laid out the groundwork to achieve optimal convoy protection by a group of UAVs. In particular, the set of optimal initial conditions that produces a set of globally time-optimal trajectory was characterized. It can moreover be shown that these optimal trajectories specify not only a path inside the convoy circle but also a path for a single UAV to come back to the convoy circle without changing direction. As shown in Fig. 84.4, this path constitutes a circle of radius R , and part of the path is a globally optimal path inside the convoy circle.

Definition 84.2.2 The circular paths of radius R entering and exiting the convoy circle at states located on the same line as the center of the convoy circle are referred to as the optimal convoy protection paths.

Figure 84.4 shows three examples of optimal convoy protection paths, and it is straightforward to show the following key result:

Theorem 84.2.2 *Over all simple closed paths of a single UAV, the optimal convoy protection paths each maximizes the ratio of the length inside the convoy circle over its total length.*

Intuitively, an optimal convoy protection path maximizes the coverage ratio because it is the quickest path to come back to the convoy circle, always reenters optimally, and repeats as a limit cycle. And, to ensure that all the UAVs maximize their time providing convoy protection, their paths should be set to the optimal convoy protection paths such as the ones shown in Fig. 84.4. In order to achieve successful convoy protection, it is required that the UGVs are visible to at least one UAV at all time. Thus, one can establish a lower bound on the number of UAV required to provide successful convoy protection for all time based on the length of the optimal convoy protection paths.

Fig. 84.4 Three optimal convoy protection paths are shown. They maximize the time spent inside the convoy circle over the time outside of the convoy circle. The *smaller dashed circle* is the convoy circle, and the *larger dotted circles* are optimal convoy protection paths. The *solid curve* is the past trajectories of the UAV. One can see that the key to coordinate the UAVs for optimal continuous convoy protection is to fly individual UAVs on optimal convoy protection paths and space them out so that there is at least one UAV inside the convoy circle for all time

Corollary 84.2.3 *Given the convoy circle of radius r for the UGVs and minimum turning radius R for the UAVs, the minimum number of UAVs needed to provide convoy protection for all time is*

$$N = \left\lceil \frac{\pi}{\arcsin(\frac{r}{R})} \right\rceil, \quad (84.19)$$

where $\lceil \cdot \rceil$ denotes the ceiling function.

Assume that there is N UAVs and they can start at an optimal initial condition $q^*(0) \in \mathbb{Q}^*$, the UAVs need to space themselves evenly in terms of the time entering the convoy circle. This can be achieved by slowing down and speeding up with respect to the other UAVs so that the i th UAV enters the convoy circle at time $\frac{2\pi R}{N}i$. This strategy is possible since the optimal paths derived for this problem remain the same for UAVs of any speed (instead of unit speed).

84.2.3 Moving Convoy Protection

In this section, the focus is shifted to a convoy protection strategy for moving UGVs. Again, it is assumed that the location of the UGVs is represented by their centroid as a point. Instead of being static, the case is considered where this point is moving in a constant direction with a constant and bounded speed.

Denote the speed of the UGVs as V_G . The UGVs are assumed to be moving in a constant heading of angle ϕ . The UAV speed is again normalized to 1. Hence, the UAVs follow the dynamics in Eq. (84.1), and their states are denoted by $[x, y, \theta]^T$. The UAVs are assumed to be capable of flying with faster speed than the UGVs (this agrees with current state of technologies in terms of speed of unmanned ground vehicles versus UAVs). Hence, it is assumed that $V_G \leq 1$.

Now, a control strategy is proposed with a corresponding lower bound V_G^* so that if the speed of the UGVs is in this bound ($V_G \in [V_G^*, 1]$), then one UAV is guaranteed to provide convoy protection for all time. Inspired by the motion primitives defined in the static convoy protection problem, the motion of the UAV is fixed to a sequence of maximally left and right turns, that is, $\mathcal{M} = \{\mathbf{L}, \mathbf{R}, \mathbf{L}, \mathbf{R}, \dots\}$ or $\mathcal{M} = \{\mathbf{R}, \mathbf{L}, \mathbf{R}, \mathbf{L}, \dots\}$. It is assumed that the UAV and UGVs are initially on top of each other; that is, the initial x - y coordinate of the UGVs is $[x(0), y(0)]^T$. Define the angle between the heading of the UGVs and initial heading of the UAV as β . Hence, $\beta = \phi - \theta(0)$. Again, to simplify notations, it is assumed that all angles are taken modulo 2π .

The motion switches between \mathbf{L} and \mathbf{R} every time the paths of UAV and UGVs intersect. With this control strategy, the path of the UAV and the UGVs intersects every time the UAV flies for a circular arc of angle 2β . An example of the trajectory of the UAV and the UGVs is shown in Fig. 84.5. The initial motion primitive of the motion sequence \mathcal{M} depends on β . If $\beta \in [0, \pi)$, then the path of the UGVs

Fig. 84.5 Example trajectory of a UAV providing convoy protection for the UGVs with the proposed control strategy. The *solid curve* is the path of the UAV. The *dashed line* is the path of the UGVs. The *dashed circle* is the convoy circle. The angle of the circular arc for each motion primitive is 2β . In this case, $\beta \in [0, \frac{\pi}{2}]$

is to the left of the initial heading of the UAV and the first motion primitive is **L**; otherwise, the first motion primitive is **R**. The following discussion focuses on the case when $\beta \in [0, \pi)$ and the motion sequence is $\mathcal{M} = \{\mathbf{L}, \mathbf{R}, \mathbf{L}, \mathbf{R}, \dots\}$, since if $\beta \in (-\pi, 0]$, then the path of the UAV is symmetric to the path corresponding to the angle of $-\beta$.

It is desirable to control the UAV to meet the UGVs periodically. This goal can be achieved by carefully choosing the initial heading of the UAV based on the speed of the UGVs. If the UAV executes the proposed control strategy, then it flies for a circular arc of angle 2β for each motion primitive in \mathcal{M} . Assume that the UAV meets with the UGVs at the end of each motion primitive. For each motion primitive, the UAV travels for a distance of $2R\beta$ and the UGVs travel for a distance of $2R\sin(\beta)$. Since the UAV is unit speed, $V_G 2R\beta = 2R\sin(\beta)$, and therefore $V_G = \frac{\sin(\beta)}{\beta}$. In other words:

Lemma 84.2.4 Assume that the UGVs move with constant speed V_G and heading ϕ , and the UAV starts at the same position as the UGVs with the initial heading $\theta(0)$. $\beta = \phi - \theta(0)$. Assume that $\beta \in [0, \pi)$ and hence $\mathcal{M} = \{\mathbf{L}, \mathbf{R}, \mathbf{L}, \mathbf{R}, \dots\}$. Then if the UAV executes the proposed control strategy, and $V_G = \frac{\sin(\beta)}{\beta}$, then the UAV and the UGVs meet at the end of each motion primitive.

Note that if the UGVs travel with the same speed as the UAV, that is, $V_G = 1$, then from Lemma 84.2.4, it follows that $\beta = 0$. In this case, the UAV will fly exactly on top of the UGVs. Using Lemma 84.2.4, one can thus obtain the lower bound for the speed of UGVs to achieve perpetual convoy protection with the proposed strategy.

Theorem 84.2.5 Using the proposed control strategy, one UAV is sufficient to provide continuous convoy protection for all time, if V_G is bounded below by V_G^* , where

Fig. 84.6 For each execution of one motion primitive, there are two segments of the path corresponding to two circular arcs of angle γ^* , so that the distance between the UAV and the UGVs is less or equal to r when the UAV is on these segments. In this figure, the *dashed curve* is the path of the UAV, and the *solid curves* are the segments of the path in which convoy protection is provided. The UAV and the convoys are drawn at the times when the UAV enters and exits these segments

$$V_G^* = \frac{\sqrt{2rR - r^2}}{R \arccos\left(1 - \frac{r}{R}\right)}. \quad (84.20)$$

When $V_G < V_G^*$, convoy protection cannot be provided with a single UAV, and one needs to coordinate multiple UAVs to provide perpetual convoy protection. Using a similar approach as in the static convoys, case, it is possible to determine the minimum number of UAVs required. In this case, on the path of each execution of one motion primitive, there are two segments of the path when the distance between the UAV and the UGVs is less than or equal to r . Positions of UAV and UGVs and hence their distance can be uniquely characterized by the arc angle γ as $d(\gamma)$. Convoy protection is provided by one UAV for two circular arcs of angle γ^* for each execution of one motion primitive, where $d(\gamma^*) = r$. Refer to Fig. 84.6 for an example.

Similar to the multi-UAV coordination approach in the previous section, one can use a timing strategy to schedule the UAVs such that, at any time, one of the UAVs is inside the convoy circle. First, note that the minimum number of UAVs required to provide continuous convoy protection can be obtained by the following corollary, which directly follows from the fact that, for each motion primitive, the length of the path in which one UAV stays inside the convoy circle is $2R\gamma^*$, while the length of the entire path for the motion primitive is $2R\beta$.

Corollary 84.2.6 *Using the proposed control strategy, if $V_G < V_G^*$, then the minimum number of UAVs needed to provide continuous convoy protection for all*

Fig. 84.7 Example of using two UAVs to provide continuous convoy protection using the proposed strategy. In this figure, the *dashed curves* are the paths of the UAVs, and the *solid curves* are the segments of the paths in which convoy protection is provided. In this case, every time one UAV exits the convoy circle, the other UAV is inside the convoy circle. This is always true if $N = \lceil \frac{\beta}{\gamma^*} \rceil = 2$ and the times when the UAVs synchronize with the UGVs are spaced out

time is $N = \lceil \frac{\beta}{\gamma^*} \rceil$, where $\lceil \cdot \rceil$ denotes the ceiling function. γ^* can be obtained by solving a nonlinear equation $d(\gamma^*) = r$, and β is obtained from V_G ($V_G = \frac{\sin(\beta)}{\beta}$).

Figure 84.7 shows how one can schedule the UAVs to provide continuous convoy protection for all time. The key is to synchronize the position of the UGVs with individual UAVs at different times, so that when one UAV exits the convoy circle, there is at least one UAV inside the convoy circle and it is on the segment of its path in which the distance to the UGVs is less or equal to r .

84.3 The Assignment Problem

Now that suitable maneuvers have been obtained for making the UAV team fly over the ground convoy, the next issue concerns what UAVs should be dispatched from the convoy in order to investigate and potentially clear threats. To address this issue, one must solve the so-called assignment problem. The assignment problem is one of the fundamental problems in combinatorial optimization. In the setting of a UAV team providing ground convoy protection to a number of UGVs, it is important that the task is allocated to the right UAV and a certain cost objective is optimized. For the convoy protection mission scenario, the UGVs are traveling along a nominal path. The task of the UAVs is to provide protection to the ground vehicles, while clearing threats as they emerge in front of the path of the UGVs.

A natural choice for the cost objective is to balance the fuel consumptions of the UAVs. In a realistic convoy protection scenario, the fuel carried by each UAV is limited. By balancing the fuel consumption among the UAVs, the duration in

which all UAVs remain operational is being maximized. Therefore, the maximum fuel consumption among the UAVs will be used as the cost function when designing the scheduling and task allocation algorithm for the UAVs (see e.g., Egerstedt 2011).

To formulate the problem in a mathematical setting, one first needs to provide a model for the overall mission of the UGVs and the possible threats. Furthermore, since the convoy protection problem is highly related to the TSP problem, as already discussed, a number of simplifying assumptions are made in order to lower the complexity of the problem. This is of paramount importance as the algorithm must run repeatedly on a computationally limited resource in order to respond to pop-up threats.

In Sect. 84.1.2, a number of assumptions were discussed, and here, these assumptions are related to their impact on the formulation of the assignment problem. Assumption A2 simply says that the UGVs follow a set path. This is a realistic assumption as the UGV is expected to follow roads or other easily traversable structures in the environment. Along the nominal convoy path, there are a number of threats that the UAVs must survey and possibly clear. The threats are classified into two categories. One category of threats are *persistent*. These are threats that the UGVs must avoid since they cannot be cleared by the UAVs. And, as per Assumption A3, one also wants to allow for the possibility of threats not being cleared if they cannot be surveyed by a UAV in time. In fact, it is assumed that the UAV-UGV team can only detect the threats up to a distance D away from the location of the UGVs, and as a consequence of Assumption A1, the threat density is such that no more than a given number M of threats can appear within this distance at any given time. But, if a threat pops up in front of the UGVs within distance D and if all available UAVs are dispatched beyond the threat, clearing of the threat may not be possible. If this is the case, they will be treated as persistent threats. In both of these cases (inspected persistent threats and threats that cannot be inspected in time), the path of the UGVs will be replanned to avoid the threats.

The other category of threats are *nonpersistent*, in which case the threats are removed after being checked by the UAVs. Regardless of the type, all threats must, if possible, be checked and surveyed by the UAVs, and the threat category cannot be established without a UAV inspecting the location of the threat. If a UAV does not get to a threat in time, it will be treated as a persistent threat and, as such, force a replanning of the UGV convoy.

In order to formulate the assignment problem, the UGV convoy vehicles are modeled as single-point masses moving along a one-dimensional (not necessarily straight) path as shown in Fig. 84.8. The UAVs are either flying alongside the UGVs (meaning they are at the same position along the path) or they can fly ahead of the UGVs. As they fly ahead of the UGVs, they do not have to follow the path. Instead, they are assumed to follow the Euclidean shortest distance to the target location. Hence, for this model, the motion of the UGVs is viewed as moving along a one-dimensional corridor which, as already discussed, allows one to establish an order among the threats which significantly cuts down on the complexity of the problem. At the same time, this is a realistic assumption that does not significantly limit the applicability of the proposed method.

Fig. 84.8 The assignment problem model

With this model, the assignment algorithm does not consider the kinematic constraints of the UAVs and UGVs, and the UAVs are assumed to be able to change direction and turn around while checking threats. At time t , the position of the UGV team is denoted to be $x_g(t)$. The positions of the individual UAVs are denoted as $x_i(t)$, where $i \in \mathcal{I}$ denotes the index of the individual UAVs and \mathcal{I} is the set of all UAV indices.

It is assumed that the team can detect threats for a distance of D in front of the UGVs. Hence, only threats contained in this window are known to the UGV-UAV team. At time t , it is assumed that there are $N(t)$ threats in this range. The locations of threats are assumed to be fixed, and they are denoted as $\tau_j, j = 1, 2, \dots, N(t)$. The sequence of the known threats at time t is denoted as $\bar{\tau}(t) = [\tau_1, \tau_2, \dots, \tau_{N(t)}]$. This known threat sequence has time-varying length $N(t)$. $N(t)$ increases when a pop-up threat is detected and decreases when a threat is cleared. Note that all threats (pop-up or not) are in front of the UGVs on the intended path.

Furthermore, let the total number of threats be denoted by N (where, for notational convenience, the explicit dependence on t is suppressed, as will be done in the remaining chapter), and the sequence of all threats is denoted as

$\bar{\tau} = [\tau_1, \tau_2, \dots, \tau_N]$. The overall mission of the UAVs is to clear all the threats. If any of the threats are hostile after being checked out by a UAV, then the path taken by the UGVs is replanned, the problem is re-initialized, and the assignment algorithm is restarted.

Naturally, when the UAV is checking a threat, it should fly with a higher speed than when it is cruising along with the UGVs. The velocity of the UGV team is assumed to be V_g . It is assumed that when the UAVs are flying alongside the UGVs, they fly with the same speed V_g . However, when they are assigned to clear a threat or coming back after clearing a threat, they fly with the speed V_a . Throughout this chapter, it is assumed that $V_a > V_g$.

Let the starting time of the overall mission be denoted by t_0 and the time when all N threats are cleared by T . It should be noted that since the aim is to develop a real-time algorithm to select and assign the UAVs to clear the threats, the only information available at time t is the $N(t)$ threats within range D , and the assignment algorithm only uses this information to make decisions.

The problem is to devise algorithms to dispatch the UAVs to clear all upcoming threats while balancing the fuel consumptions of the UAVs. The accumulated fuel consumption of i th UAV at time t is denoted as $f_i(t)$. $f_i(t)$ is considered to be the state of the UAVs, and they are known. It should be noted that at the beginning of the mission, the accumulated fuel consumption of all the UAVs is 0; hence, $f_i(t_0) = 0, \forall i$. With this information, one can formulate the UAV assignment problem.

Problem 84.3.1 *Design an algorithm that assigns UAVs such that the maximum fuel consumption among the UAVs is minimized when all threats $\bar{\tau}$ are cleared. That is, solve the optimization problem:*

$$\min_{\Pi} \max_{j \in \mathcal{I}} \{f_j(T)\}, \quad (84.21)$$

where Π is a assignment algorithm that maps from time to \mathcal{I} .

84.3.1 Selection Policy and Task Allocation Algorithm

In this section, an algorithm is introduced that assigns the UAVs based on their current level of accumulated fuel consumption. The algorithm uses an optimization-based selection policy that selects (and assigns) one threat to one of the UAVs when an event triggers. Events that trigger the reevaluation of the selection policy can be one of the following:

1. A threat is cleared by any of the assigned UAV.
2. A pop-up threat is detected.

In other words, the selection policy is only reevaluated when the known threat sequence $\bar{\tau}(t)$ is modified. In order to allow real-time execution of the algorithm,

the optimization problem needed for the selection policy is chosen so that it can be solved quickly online. In order to reduce the problem from NP-hard to polynomial complexity, only the closest threat is considered when an event triggers. This does not cause inefficiency in clearing multiple threats since each time a threat is cleared, the selection policy is reevaluated. The position of the closest threat is denoted by $\tau \in \mathbb{R}^2$. Hence,

$$\tau = \min_{j \in \{1, 2, \dots, N(t)\}} \tau_j. \quad (84.22)$$

The selection policy is a function that maps time t to the set of the UAVs (\mathcal{I}), and it is the solution of an optimization problem. This optimization policy is based on computing the fuel consumption associated with letting a UAV clear the target threat (τ) and returning to the convoy. Even though this may actually not be what is done (as new threats are constantly reconsidered), the resulting algorithm minimizes the accumulated fuel consumption over all other assignments assuming that the assigned UAV will return to the convoy after the threat is inspected. Here, it is taken into account that the UGVs are moving constantly along the path with speed V_g and that the closest threat τ may be a pop-up threat.

As fuel consumption is at the heart of the assignment costs, one needs to establish an appropriate model for this consumption. Although the developed algorithm must be quite general and should not rely on any particular choice of fuel model, the fuel consumption rate at any given moment is a nonlinear function of the UAV's speed, weight, and altitude. Therefore, the fuel consumption rate of the i th UAV at time t is given by

$$\frac{df_i(t)}{dt} = Q(v(t), w(t), h(t)), \quad (84.23)$$

where $v(t)$, $w(t)$, and $h(t)$ are the UAVs speed, gross weight, and altitude at time t , respectively.

When an event triggers at time t , the following optimization problem is solved:

$$P_1(t) = \arg \min_{i \in \mathcal{I}} \left\{ \max_{j \in \mathcal{I}} \left\{ f_j(t) + \begin{cases} Q(V_a, w^*, h^*)T_i(t), & \text{if } j = i \\ Q(V_a, w^*, h^*)S_j(t) + Q(V_g, w^*, h^*)(T_i(t) - S_j(t)), & \text{if } j \neq i \end{cases} \right\} \right\}. \quad (84.24)$$

The optimization problem is a min-max problem. $T_i(t)$ represents the time for i th UAV to clear the threat and return to the UGVs (with speed V_a). If the j th UAV is not assigned, $S_j(t)$ represents the time it takes for it to return to the UGVs (with speed V_a). $T_i(t) - S_j(t)$ therefore represents the time for the j th UAV to fly alongside the UGVs with speed V_g until the assigned UAV flies back. If the UAV j is flying alongside the UGV at time t , then $x_j(t) = x_g(t)$ and $S_j(t) = 0$. Hence, the quantity

Fig. 84.9 The operation of the selection policy. In this example, the threat is not a pop-up

$$f_j(t) + \begin{cases} Q(V_a, w^*, h^*)T_i(t), & \text{if } j = i \\ Q(V_a, w^*, h^*)S_j(t) + Q(V_g, w^*, h^*)(T_i(t) - S_j(t)), & \text{if } j \neq i \end{cases} \quad (84.25)$$

represents the accumulated fuel consumption of the j th UAV, assuming UAV i is assigned.

It is important to note here that the convoy protection problem formulation, along with the corresponding task assignment algorithm presented in this section, is independent of how the quantities $T_i(t)$ and $S_j(t)$ are computed for a specific operational scenario. In the experiments, these quantities were computed assuming piecewise-linear convoy path defined by a series of waypoints. As shown in Fig. 84.9, $P_1(t)$ assigns the UAV so that the UAV with most accumulated fuel consumed after the clearance of the threat is minimized.

Min-max problems are generally hard to solve, and the complexity of computing $P_1(t)$ is $O(|\mathcal{I}|^2)$, where $|\mathcal{I}|$ is the number of UAVs. However, under certain design choices of UAV speeds V_a and V_g , weight w^* , and altitude h^* , one can reduce the optimization problem to one that has $O(|\mathcal{I}|)$ (linear) complexity. The assumption needed for this is that it is more costly in terms of fuel consumption to be inspecting a threat than to remain with the convoy. And, under this assumption, one can rewrite the assignment problem in the following manner:

Lemma 84.3.1 *If UAV speeds V_a and V_g , gross weight w^* , and altitude h^* are chosen such that*

$$Q(V_a, w^*, h^*) > Q(V_g, w^*, h^*), \quad (84.26)$$

then the optimization problem $P_1(t)$ can be solved by solving another optimization problem:

$$P(t) = \arg \min_{i \in \mathcal{I}} \{f_i(t) + Q(V_a, w^*, h^*)T_i(t)\}. \quad (84.27)$$

Hence, $P(t) = P_1(t)$.

This reformulation is useful in that it actually allows one to solve the assignment problem directly. To describe in words, $P(t)$ assigns the UAV so that, after the threat

is cleared and returned to the UGVs, the total fuel consumed for the assigned UAV is minimum over all the UAVs. The projected time for the clearance of the threat is $T_i(t)$, where i denotes the assigned UAV. It should be noted that during this time, the UGVs have moved forward by $V_g T_i(t)$ distance.

Based on this reformulation, one can in fact formulate the corresponding task allocation algorithm which uses the above selection policy.

Algorithm: Task Allocation Algorithm

Initialize: Set t_0 .

Iterate: until end of mission.

If an event is triggered:

1. Update $\bar{\tau}(t) = [\tau_1, \tau_2, \dots, \tau_{N(t)}]$.
2. Find $\tau = \min_{j \in \{1, 2, \dots, N(t)\}} \tau_j$.
3. Solve $i^* = P(t)$ in Eq. (84.27) and use the solution i^* as the assignment for the i th UAV to clear τ .

Wait until another event is triggered.

An illustration of the intended operation is depicted in Fig. 84.10a–f. The UAVs will follow the ground vehicles in a set formation. If a threat is detected, a UAV will be assigned that will balance fuel usage among the UAVs, to clear the threat and return to the formation.

84.4 Experimental Results

To demonstrate the practical aspects of the proposed algorithms as well as to show that they can indeed be successfully deployed in an operational environment characterized by numerous computational and communications limitations, the algorithms were implemented on a test bed consisting of both UAVs and UGVs.

The experiment consists of a mission that incorporates all details highlighted in this chapter. The mission is structured as follows:

1. The UGVs are given a set of waypoints which define a path to be taken through the (possibly hostile) environment. All UAVs are assigned to protect the convoy by flying over it while maintaining some spacing from one another.
2. Once a possible threat has been identified, the projected fuel consumption for each UAV is computed, which in turn dictates which UAV to dispatch so as to balance fuel consumption.
3. The chosen UAV flies over to visit the threat, while the remaining UAVs remain with the convoy.
4. After the threat is neutralized (cleared), the assigned UAV returns to protect the convoy.
5. In the event that a threat cannot be neutralized (is persistent), the UAV signals the convoy to replan its path to avoid the threat.

Fig. 84.10 Simulation of three UAVs executing the convoy protection algorithm. (N is the number of UAVs along the UGV convoy.) (a) UAVs forming a formation of $N = 3$. (b) UAVs in $N = 3$ formation. (c) A UAV is splitting. (d) UAVs form new $N = 2$ formation. (e) A UAV is rejoining. (f) UAVs return to a formation of $N = 3$

The plots in Fig. 84.12 show the recorded trajectories of the UAVs and convoy during the experiment. In particular, Fig. 84.12a shows both UAVs performing convoy protection by flying above the UGVs as they follow their intended path. Notice that the UAVs maintain a safe separation from one another. A photograph of this operation is shown in Fig. 84.11a.

Figure 84.12c shows the UAVs detecting a persistent threat which blocks the intended path of the convoy. The UAVs execute the task allocation algorithm to determine which UAV should be dispatched so as to balance fuel consumption. When the dispatched UAV determines that the threat is persistent, the UAV informs

Fig. 84.11 Photos showing the convoy protection and threat neutralization as carried out by the hardware platform. (a) Two UAVs protect the convoy while maintaining spacing from one another. (b) One UAV is dispatched to visit a threat, while the other remains with the convoy

Fig. 84.12 Plots showing the trajectories of UAVs and the convoy which it protects as both a nonpersistent and persistent threat are encountered. (a) Two UAVs perform convoy protection on UGVs. (b) A UAV is dispatched to clear a nonpersistent threat. (c) A UAV identifies a persistent threat and the convoy replans its path

the convoy that it must replan its path so as to avoid the threat. Afterward, the UAV returns to the convoy, and the UGVs proceed in following the recomputed path to safely reach their destination.

To further illustrate effects of convoy path replanning, Fig. 84.13a shows the originally intended path of the convoy corresponding to the trajectories in Fig. 84.12a, b. Meanwhile, Fig. 84.13b shows the recomputed path taken by the convoy so as to avoid the persistent threat.

To validate that the task allocation algorithm performs as expected, a separate experiment was conducted in which 16 threats were presented to the convoy over an extended period of time. Figure 84.14 shows the fuel consumption of the two UAVs over this time and marks when a UAV is dispatched to clear a threat. As seen in the plot, the algorithm successfully determines which UAV to dispatch when a threat is encountered such that the fuel consumption is balanced among the two UAVs over time. This oftentimes results in the same UAV being dispatched multiple times consecutively so as to clear threats that are located within its vicinity.

Abstract

Recent years have witnessed great advancements in the science and technology for unmanned aerial vehicles (UAVs), for example, in terms of autonomy, sensing, and networking capabilities. This chapter surveys algorithms on task assignment and scheduling for one or multiple UAVs in a dynamic environment, in which targets arrive at random locations at random times, and remain active until one of the UAVs flies to the target’s location and performs an on-site task. The objective is to minimize some measure of the targets’ activity, for example, the average amount of time during which a target remains active. The chapter focuses on a technical approach that relies upon methods from queueing theory, combinatorial optimization, and stochastic geometry. The main advantage of this approach is its ability to provide analytical estimates of the performance of the UAV system on a given problem, thus providing insight into how performance is affected by design and environmental parameters, such as the number of UAVs and the target distribution. In addition, the approach provides provable guarantees on the system’s performance with respect to an ideal optimum. To illustrate this approach, a variety of scenarios are considered, ranging from the simplest case where one UAV moves along continuous paths and has unlimited sensing capabilities, to the case where the motion of the UAV is subject to curvature constraints, and finally to the case where the UAV has a finite sensor footprint. Finally, the problem of cooperative routing algorithms for multiple UAVs is considered, within the same queueing-theoretical framework, and with a focus on control decentralization.

85.1 Introduction

This chapter discusses current solution approaches for the design of cooperative control and task allocation strategies for networks of unmanned aerial vehicles (UAVs). The focus is on *uncertain* and *dynamically changing environments*, in which new task requests are generated in real time, and on routing algorithms with performance guarantees, as opposed to heuristic algorithms.

As a motivating example, consider the following scenario: a team of unmanned aerial vehicles (UAVs) is responsible to investigate possible threats over a region of interest. As possible threats are detected, by intelligence, high-altitude, or orbiting platforms, or by ground sensor networks, one of the UAVs must visit its location and investigate the cause of the alarm in order to enable an appropriate response if necessary. Performing this task may require the UAV not only to fly to the possible threat’s location but also to spend additional time on site. The objective

is, in general, to minimize the average time between the appearance of a possible threat and the time one of the UAVs completes the close-range inspection task. In a variation of this problem, which will be referred to as persistent patrolling, the UAVs must detect possible threats using limited-range onboard sensors. Other variations may include priority levels or time windows during which the inspection task must be completed.

In order to perform the required mission, the UAVs (or, more in general, mission control) need to repeatedly solve three *coupled* decision-making problems:

1. *Task allocation among the UAVs*: Which UAV shall pursue each task? What policy is used to assign tasks to UAVs?
2. *Service scheduling for each UAV*: Given the list of tasks to be pursued, what is the most efficient ordering of these tasks?
3. *Loitering paths*: What should UAVs without pending assignments do?

In general, the combined problem, which one can refer to as dynamic vehicle routing, falls within the class of heterogeneous, stochastic (possibly distributed) decision-making problems with uncertain information, with additional complexity stemming from the differential and algebraic constraints on the UAV motion and the local sensing of the environment. This problem is generally *intractable*, and solution approaches have been devised that look either at heuristics algorithms or at approximation algorithms with some guarantee on their performance.

The chapter is structured as follows. Section 85.2 presents an overview of current solution approaches for UAV routing in uncertain and dynamic environments. First, the differences and commonalities between static and dynamic UAV routing problems are discussed. Then, some of the main classes of algorithms used in the relevant literature are introduced, namely, heuristic algorithms (without performance guarantees), as well as online algorithms and spatial queueing theory (which provide guaranteed approximations to optimal performance). Section 85.3 considers in some detail the application of spatial queueing theory to some prototypical scenarios, involving a single UAV. The main motivation is to show how to model a specific UAV routing problem within this framework and how to solve it. Section 85.4 considers the same scenarios, extending the theory to the case of multiple UAVs. Finally, Sect. 85.5 summarizes the chapter.

85.2 Approaches for UAV Routing in Dynamic Environments

The objective of this section is to first discuss the differences between static and dynamic environments and then to present a broad overview of current solution approaches. Broadly speaking, there are three main approaches available in the literature to tackle such dynamic vehicle routing problems. The first approach relies on heuristic algorithms. In the second approach, called “online algorithms,” routing policies are designed to minimize the worst-case ratio between their performance and the performance of an optimal offline algorithm which has a priori knowledge of the entire input sequence. In the third approach, the routing problem is embedded within the framework of queueing theory, and routing policies are designed to minimize typical queueing-theoretical cost functions such as the expected time

the tasks remain in the queue. Since the generation of tasks and motion of the vehicles is within an Euclidean space, one can refer to this third approach as spatial queueing theory.

85.2.1 Static and Dynamic Vehicle Routing

In the recent past, considerable efforts have been devoted to the problem of how to cooperatively assign and schedule tasks that are defined over an extended geographical area (Arslan et al. 2007; Alighanbari and How 2008; Beard et al. 2002; Moore and Passino 2007; Smith and Bullo 2009). In these papers, the main focus is in developing distributed algorithms that operate with knowledge about the task locations and with limited communication between robots. However, the underlying mathematical model is *static*, in that no new tasks arrive over time, and fits within the framework of the static vehicle routing problem, whereby (i) a team of m vehicles is required to service a set of n tasks in a two-dimensional space; (ii) each task requires a certain amount of on-site service; (iii) the goal is to compute a set of routes that minimizes the cost of servicing the tasks; see Toth and Vigo (2001) for a thorough introduction to this problem. In general, most of the available literature on routing for robotic networks focuses on static environments and does not properly account for scenarios in which dynamic, stochastic, and adversarial events take place.

The problem of planning routes through service tasks that arrive *during* a mission execution is known as the “dynamic vehicle routing problem” (abbreviated as the DVR problem in the operations research literature). There are two key differences between static and dynamic vehicle routing problems. First, planning algorithms should actually provide *policies* (in contrast to preplanned routes) that prescribe how the routes should evolve as a function of those inputs that evolve in real time. Second, dynamic tasks (i.e., tasks that arrive and vary over time) add *queueing phenomena* to the combinatorial nature of vehicle routing. In such a dynamic setting, it is natural to focus on steady-state performance instead of optimizing the performance for a single task. Additionally, system stability in terms of the number of waiting tasks is an issue to be addressed (Fig. 85.1).

Fig. 85.1 An illustration of *dynamic routing problems* for a robotic system. From left to right: (i) tasks are generated, (ii) vehicles are assigned to tasks and select routes, (iii) new tasks appear, requiring an update to assignments and routes

85.2.2 Heuristic Algorithms

A naïve, yet reasonable approach to devise an heuristic algorithm (i.e., an algorithm without performance guarantees) would be to adapt classic queueing policies to spatial queueing systems. However, perhaps surprisingly, this adaptation is not at all straightforward. For example, policies based on a First-Come First-Served discipline, whereby tasks are fulfilled in the order in which they arrive, are unable to stabilize the system for all stabilizable task arrival rates, in the sense that under such policies, the average number of tasks grows over time without bound, even though there exist other policies that would maintain the number of tasks uniformly bounded (Bertsimas and van Ryzin 1991).

The most widely applied approach is to combine static routing methods (e.g., VRP-like methods or heuristic methods such as nearest neighbor or genetic algorithms) and sequential re-optimization, where the re-optimization horizon is chosen heuristically. (A similar approach, incidentally, is at the core also of the approximation algorithms presented in the following sections.) However, the joint selection of a static routing method and of the re-optimization horizon in presence of UAV and task constraints (e.g., differential motion constraints, or task priorities) makes the application of this approach far from trivial. First, one can show that an erroneous selection of the re-optimization horizon can lead to pathological scenarios where no task *ever* receives service (Pavone 2010). Second, direct application of VRP-like methods might lead to infeasible paths for vehicles with differential motion constraints. Additionally, performance criteria in dynamic settings commonly differ from those of the corresponding static problems. For example, in a dynamic setting, the time needed to complete a task may be a more important factor than the total vehicle travel cost.

85.2.3 Online Algorithms

An online algorithm is one that operates based on input information available up to the current time. Thus, these algorithms are designed to operate in scenarios where the entire input is not known at the outset, and new pieces of the input should be incorporated as they become available. The distinctive feature of the online algorithm approach is the method used to evaluate an algorithm's performance, which is called *competitive analysis* (Sleator and Tarjan 1985). In competitive analysis, the performance of an online algorithm is compared to the performance of a corresponding offline algorithm (i.e., an algorithm that has a priori knowledge of the entire input) in the worst-case scenario. Specifically, an online algorithm is c -competitive if its cost on *any* problem instance is at most c times the cost of an optimal offline algorithm:

$$\text{Cost}_{\text{online}}(I) \leq c \text{Cost}_{\text{optimal offline}}(I), \quad \forall \text{ problem instances } I.$$

In the recent past, several dynamic vehicle routing problems have been successfully studied in this framework, under the name of the online traveling repairman

problem (Irani et al. 2004; Jaillet and Wagner 2006; Krumke et al. 2003), and many interesting insights have been obtained. However, the online algorithm approach has some disadvantages. First, competitive analysis is a *worst-case* analysis; hence, the results are often overly pessimistic for normal problem instances. Moreover, in many applications, there is some probabilistic problem structure (e.g., distribution of the inter-arrival times, spatial distribution of future tasks, distribution of on-site service times), that can be advantageously exploited by the vehicles. In online algorithms, this additional information is not taken into account. Second, competitive analysis is used to bound the performance relative to the optimal offline algorithm, and thus it does not give an absolute measure of performance. In other words, an optimal online algorithm is an algorithm with minimum “cost of causality” in the worst-case scenario, but not necessarily with the minimum worst-case cost. Finally, many important real-world constraints for DVR, such as time windows, priorities, differential constraints on vehicle’s motion, and the requirement of teams to fulfill a task, “have so far proved to be too complex to be considered in the online framework” (Golden et al. 2008, p. 206). Some of these drawbacks have been recently addressed by Van Hentenryck et al. (2009) where a combined stochastic and online approach is proposed for a general class of combinatorial optimization problems and is analyzed under some technical assumptions.

85.2.4 Spatial Queueing Theory

Spatial queueing theory embeds the dynamic vehicle routing problem within the framework of queueing theory and overcomes some of the limitations of the online algorithm approach; in particular, it allows to take into account several real-world constraints, such as time constraints and priorities. The name *spatial queueing theory* stems from the fact that the generation of the tasks and the motion of the servers (i.e., UAVs) happens in a metric space. This chapter concentrates on an algorithmic approach to spatial queueing theory whose objective is to *synthesize* an efficient control policy, whereas in standard queueing theory, the objective is usually to *analyze* the performance of a specific policy. Within this context, an efficient policy is one whose *expected* performance is either optimal or within a constant factor of the optimum. Specifically, the expected performance of a policy is the expected value of the performance over all possible inputs (i.e., task arrival sequences). A policy performs within a constant factor κ of the optimum if the ratio between the policy’s expected performance and the optimal expected performance is upper bounded by κ .

In order to make the model tractable, tasks are usually considered “statistically independent,” and their arrival process is assumed stationary (with possibly unknown parameters). These assumptions, however, can be unrealistic in some scenarios, in which case the online algorithms approach may represent a better alternative. Pioneering work in this context is that of Bertsimas and van Ryzin (1991, 1993a, b), who introduced queueing methods to solve the simplest DVR problem

(a vehicle moves along straight lines and visits tasks whose time of arrival, location, and on-site service are stochastic; information about task location is communicated to the vehicle upon task arrival); see also the earlier related work (Psaraftis 1980). Recently, by integrating ideas from dynamics, combinatorial optimization, teaming, and distributed algorithms, this approach has been applied to scenarios with complex models for the tasks such as time constraints, service priorities, and translating tasks; problems concerning robotic implementation such as adaptive and decentralized algorithms, complex vehicle dynamics, limited sensing range, and team forming; and even integration of humans in the design space; see Bullo et al. (2011) and references therein.

An interesting feature of this approach is that the performance analysis of these algorithms usually yields scaling laws for quality of performance in terms of mission parameters. These scaling laws can serve as useful guidelines for operators to select mission parameters when feasible (e.g., number of UAVs, sensing range) to provide a desired quality of service.

85.3 Spatial Queueing Theory: The Single-Server Case

This section presents the basic ideas and tools for an algorithmic approach to spatial queueing theory (more details can be found in, e.g., Bullo et al. 2011). This approach consists of three main steps, namely, development of a spatial queueing model, establishment of fundamental limitations of performance, and design of algorithms with performance guarantees. More specifically, the formulation of a model entails detailing four main aspects:

1. A model for the *dynamic* component of the environment: This is usually achieved by assuming that new events are generated (either adversarially or stochastically) by an exogenous process.
2. A model for targets/tasks: Tasks are usually modeled as points in a physical environment distributed according to some (possibly unknown) distribution, might require a certain level of on-site service time, and can be subject to a variety of constraints, for example, time windows and priorities.
3. A model for the UAVs and their motion: Besides their number, one needs to specify whether the UAVs are subject to algebraic (e.g., obstacles) or differential (e.g., minimum turning radius) constraints, sensing constraints, and fuel constraints. Also, UAVs might be able to communicate directly only with other UAVs (or static nodes) that lie within a certain radius, or might not have any communication capability (e.g., when cheap micro UAVs are used, or stealthiness is required). Finally, the control could be centralized (i.e., coordinated by a central station) or decentralized.
4. Performance criterion: Examples include the minimization of the waiting time before service, loss probabilities, and expectation-variance analysis.

Once the model is formulated, one seeks to characterize fundamental limitations of performance (in the form of lower bounds for the best achievable cost); the purpose of this step is essentially twofold: it allows to quantify the degree of optimality of

a routing algorithm and provides structural insights into the problem. As for the last step, the design of a routing algorithm usually relies on a careful combination of static routing methods with sequential re-optimization. Desirable properties for the static methods are as follows: (i) the static problem can be solved (at least approximately) in polynomial time, and (ii) the static method is amenable to a statistical characterization (this is essential for the computation of performance bounds). Formal performance guarantees on a routing algorithm are then obtained by quantifying the ratio between an upper bound on the cost delivered by that algorithm and a lower bound for the best achievable cost. Such a ratio, being an estimate of the degree of optimality of the algorithm, should be close to one and possibly independent of systems's parameters (i.e., a *constant factor* guarantee, as defined in Sect. 85.2).

In the remainder of this section, three problems will be considered, all involving only one UAV (the server in the queueing model: in the remainder of this chapter, the terms “server” and “UAV,” as well as “task” and “target,” will be used interchangeably). In the first problem, the UAV moves along continuous paths and visits targets whose time of arrival, location, and on-site service are stochastic; information about target location is communicated to the UAV upon target arrival. In the second problem, the motion of the UAV is subject to differential constraints, but still the UAV has full knowledge of newly arrived targets. Finally, in the third problem, the information available to the UAV is limited, that is, the UAV is not aware of a target's existence or location upon its arrival time but must first detect it using onboard sensors.

The purpose of these examples is twofold: on the one hand, to provide some concrete examples about how to apply spatial queuing theory to devise UAV routing algorithms in dynamic settings, on the other hand, to provide guidelines for UAV routing in a variety of scenarios of interest. The case of multi-UAV coordination will be addressed in the next section.

85.3.1 UAV Routing with No Motion Constraints and Unlimited Sensing

Consider a basic scenario where one UAV moves along continuous paths (with no differential constraints, e.g., on the curvature) and visits spatially localized targets whose time of arrival, location, and on-site service are stochastic; information about target location is communicated to each UAV upon target arrival. This problem has been studied in the literature as the dynamic traveling repairman problem (DTRP) in Bertsimas and van Ryzin (1991) and can be summarized as follows:

85.3.1.1 The Single-Server DTRP Problem

In a geographical region \mathcal{Q} of area A , a dynamic process generates spatially localized tasks. The process generating tasks is modeled as a spatiotemporal Poisson process, that is, (i) the time between each pair of consecutive events has an exponential distribution with intensity $\lambda > 0$, and (ii) upon arrival, the locations

of tasks are independently and uniformly distributed in \mathcal{Q} . The location of the new tasks is assumed to be immediately available to the UAV. The UAV provides service in \mathcal{Q} , flying at constant speed v ; the UAV is assumed to have unlimited fuel and task-servicing capabilities. Each task requires an independent and identically distributed amount of on-site service with finite mean duration $\bar{s} > 0$. A task is completed when the UAV moves to its location and performs its on-site service. The objective is to design a *routing policy* that maximizes the quality of service delivered by the UAV in terms of the average steady-state time delay \bar{T} between the generation of a task and the time it is completed (in general, in a dynamic setting, the focus is on the quality of service as perceived by the “end user,” rather than, e.g., fuel economies achieved by the UAV). Other quantities of interests are the average number \bar{N} of tasks waiting to be completed and the waiting time \bar{W} of a task before its location is reached by a UAV. These quantities, however, are related according to $\bar{T} = \bar{W} + \bar{s}$ (by definition) and by Little’s law, stating that $\bar{N} = \lambda \bar{W}$, for stable queues (Little 1961).

One comment is in order: the queueing models used to model UAV routing problems are inherently different from traditional, nonspatial queueing models. In particular, one might be tempted to consider the queueing model for the single-server DTRP as a standard $M/G/1$ queue (where M stands for Poisson arrival process, G indicates that the service times are identically and *independently* distributed according to a general distribution, and 1 is the number of servers). The main reason is that in UAV routing, the “service time” has both a *travel* and an *on-site* component. Although the on-site service requirements are “statistically” independent (by assumption), the travel times generally are not.

85.3.1.2 Stability

Before proceeding further, it is necessary to ensure the stability of the system. The system is considered stable if the expected number of waiting tasks is uniformly bounded at all times, or equivalently, that tasks are removed from the system at least at the same rate at which they are generated. In the case at hand, the time to complete a task is the sum of the time to reach its location (which depends on the routing policy) plus the time spent at that location in on-site service (which is independent of the routing policy). Since, by definition, the service time is no shorter than the on-site service time \bar{s} , then a weaker necessary condition for stability is $\varrho := \lambda \bar{s} < 1$; the quantity ϱ measures the fraction of time the UAV is performing on-site service. Remarkably, it turns out that this is also a sufficient condition for the single-server DTRP; note that this stability condition is independent of the size and shape of \mathcal{Q} and of the speed of the vehicle.

85.3.1.3 Lower Bounds

To derive lower bounds, the main difficulty usually consists in bounding (possibly in a statistical sense) the amount of time spent to reach a target location. The derivation of these bounds becomes simpler in asymptotic regimes, that is, looking at cases when $\varrho \rightarrow 0^+$ and $\varrho \rightarrow 1^-$, which are often called “light load” and “heavy load” conditions, respectively.

For example, consider first the case in which $\varrho \rightarrow 0^+$ (light load regime). The median of \mathcal{Q} is defined as the point that minimizes the expected distance to a random point sampled uniformly from \mathcal{Q} ; this distance can be written as $H_1^* \sqrt{A}$, where H_1^* is a constant that only depends on the shape of \mathcal{Q} (see also Appendix A.1). Assuming that the UAV would have enough time to return to the median location before the appearance of each new task (in other words, assuming light load conditions), the expected system time can be lower bounded as

$$\bar{T} \geq \frac{H_1^* \sqrt{A}}{v} + \bar{s} \quad (\text{as } \varrho \rightarrow 0^+).$$

Consider now the case in which $\varrho \rightarrow 1^-$ (heavy load). Let \bar{D} be the average travel distance per task for some routing policy. By using arguments from geometrical probability (independent of algorithms), one can show that $\bar{D} \geq \beta_2 \sqrt{A} / \sqrt{2N}$ as $\varrho \rightarrow 1^-$, where β_2 is a constant that will be specified later. As discussed, for stability, one needs $\bar{s} + \bar{D}/v < 1/\lambda$. Combining the stability condition with the bound on the average travel distance per task, one obtains

$$\bar{s} + \frac{\beta_2 \sqrt{A}}{v \sqrt{2N}} \leq \frac{1}{\lambda}.$$

Since, by Little's law, $\bar{N} = \lambda \bar{W}$ and $\bar{T} = \bar{W} + \bar{s}$, one finally obtains (recall that $\varrho = \lambda \bar{s}$)

$$\bar{T} \geq \frac{\beta_2^2 A}{2} \frac{\lambda}{v^2 (1 - \varrho)^2} + \bar{s}, \quad (\text{as } \varrho \rightarrow 1^-).$$

This lower bound allows to draw the following conclusions for the single-server DTRP: (i) the condition $\varrho < 1$ is also sufficient for stability, and (ii) the quality of service, which is proportional to $1/(1 - \varrho)^2$, degrades much faster as the target load increases than in a nonspatial queueing systems (where the growth rate is proportional to $1/(1 - \varrho)$).

85.3.1.4 Routing for the Single-Server DTRP

Consider the following routing policy for the single-server DTRP, based on a partition of \mathcal{Q} into $p \geq 1$ subregions $\{Q_1, Q_2, \dots, Q_p\}$ of equal area A/p . Such a partition can be obtained, for example, as sectors centered at the median of \mathcal{Q} . Define a cyclic ordering for the subregion, such that, for example, if the vehicle is in region Q_i , the “next” region is Q_j , where j follows i in the cyclic ordering (in other words, $j = (i + 1) \bmod p$).

1. If there are no outstanding targets, move to the median of the region \mathcal{Q} .
2. Otherwise, visit the “next” subregion; subregions with no tasks are skipped. Compute a minimum-length path from the UAV's current position through all the outstanding tasks in that subregion. Complete all tasks on this path, ignoring new tasks generated in the meantime.
3. Repeat.

In the above policy, two static optimization methods are applied, depending on whether or not there are outstanding tasks. Computing the median of \mathcal{Q} is a standard problem in geometric optimization (see Appendix A.1). The problem of computing the shortest path through a number of points is related to the well-known traveling salesman problem (TSP). While the TSP is a prototypically hard combinatorial problem, it is well known that the Euclidean version of the problem is very easy to approximate; see Appendix B.1 for more details. Furthermore, the length $\text{ETSP}(n)$ of a Euclidean TSP through n points independently and uniformly sampled in \mathcal{Q} is known to satisfy the following property:

$$\lim_{n \rightarrow \infty} \text{ETSP}(n)/\sqrt{n} = \beta_2 \cdot \sqrt{A}, \quad \text{almost surely,}$$

where $\beta_2 \approx 0.712$ is a constant; this is the same constant that appears in the lower bound for \bar{T} . The convergence to this limit is very fast: Larson and Odoni (1981) report that for “fairly compact and fairly convex” regions, the estimate $\text{ETSP}(n) \approx \beta_2 \sqrt{nA}$ is within a few percent from the true value for as few as 15 points.

It can be shown (see, e.g., Bertsimas and van Ryzin 1993a) that, using the above routing policy, the average system time \bar{T} satisfies

$$\bar{T} = \frac{H_1^* \sqrt{A}}{v} + \bar{s}, \quad (\text{as } \varrho \rightarrow 0^+),$$

$$\bar{T} \leq \gamma(p) \frac{A}{v^2} \frac{\lambda}{(1 - \varrho)^2} + \bar{s}, \quad (\text{as } \varrho \rightarrow 1^-),$$

where $\gamma(1) = \beta_2^2$ and $\gamma(p) \rightarrow \beta_2^2/2$ for large p . These results critically exploit the statistical characterization of the length of an optimal TSP tour. Hence, the proposed policy achieves a quality of service that is arbitrarily close to the optimal one, in the asymptotic regimes of light or heavy load.

While the simple policy stated above is provably optimal in light and heavy load, in the sense that no policy can provide a strictly lower system time, several variations have been proposed that improve the performance in other scenarios or operating conditions, at the expense of some additional complexity in implementation and analysis. The interested reader can find more information in Bullo et al. (2011) and references therein.

85.3.2 UAV Routing with Motion Constraints and Unlimited Sensing

In this section, the complexity of the single-server DTRP problem is increased, by imposing differential constraints on the trajectories that the UAV can follow.

85.3.2.1 The Single-Server Dubins DTRP Problem

In this version of the problem, the task generation process and performance metrics are assumed to be the same as in the standard DTRP problem. On the other hand, the UAV is modeled as a non-holonomic vehicle, constrained to move on the plane at

constant speed v , along paths of bounded curvature. In particular, the instantaneous radius of curvature is constrained to be no less than ρ . This model is often referred to as the Dubins vehicle, in recognition of Dubins' work in computing minimum-length paths for such model (Dubins 1957), and is typically considered appropriate to model the kinematics of UAVs (Chandler et al. 2000; Beard et al. 2002). The UAVs are assumed to be identical and have unlimited range. In the course of this chapter, the term *Dubins frame* shall be used to refer to a coordinate frame with the origin attached to the Dubins vehicle and its first axis aligned with the vehicle's velocity vector. For simplicity, the region \mathcal{Q} will be assumed to be a rectangle of height H and width W , with $H < W$, and $WH = A$. The on-site service time will be assumed to be identically zero, for example, as in flyby requests. This version of the DTRP will be henceforth called the Dubins DTRP.

85.3.2.2 Lower Bounds

The lower bounds from the basic case still hold. Note that in this case, since $\bar{s} = 0$, the load is entirely determined by λ : in the light-load case $\lambda \rightarrow 0^+$, and in the heavy-load case $\lambda \rightarrow +\infty$. So, for example, the light-load lower bound is

$$\bar{T} \geq H_1^*/v, \quad (\text{as } \lambda \rightarrow 0^+).$$

For the heavy-load case, it is possible to derive a lower bound specific to the Dubins DTRP. Let $\bar{D}_\rho(n)$ be the expected distance along a Dubins path, between a UAV situated in the interior of \mathcal{Q} and the closest among n points independently and uniformly sampled from \mathcal{Q} . Reachability arguments show that, for large n ,

$$\bar{D}_\rho(n) \geq \bar{\gamma}_D \left(\frac{\rho A}{n} \right)^{1/3},$$

where $\bar{\gamma}_D = \frac{3}{4} \sqrt[3]{3}$. In the case $\bar{s} = 0$, stability requires $\bar{D}_\rho(\bar{N})/v \leq 1/\lambda$, and Little's condition states that $\bar{N} = \lambda \bar{T}$. Hence, for large λ ,

$$\frac{1}{\lambda} \geq \frac{\bar{D}_\rho(\bar{N})}{v} \geq \bar{\gamma}_D \left(\frac{\rho A}{\lambda \bar{T}} \right)^{1/3} \frac{1}{v},$$

and finally

$$\bar{T} \geq \bar{\gamma}_D^3 \frac{\rho A}{v^3} \lambda^2, \quad (\text{as } \lambda \rightarrow +\infty).$$

85.3.2.3 Routing for the Single-Server Dubins DTRP Problem

Consider the following routing policy for the single-server Dubins DTRP problem. As in the case of the "standard" single-server DTRP, the policy is based on a partition of \mathcal{Q} . However, in this case, the partition is computed through a tiling of the plane into "beads" of length

Fig. 85.2 (a) Construction of the “bead.” The figure shows how the upper half of the boundary is constructed and the bottom half is symmetric. (b) Bead tiling of the plane, with the beads aligned with the width of \mathcal{Q}

$$\ell = \min \left\{ \frac{7 - \sqrt{17}}{4} \left(1 + \frac{7\pi\rho H}{3A} \right)^{-1} \frac{v}{\lambda}, 4\rho \right\},$$

aligned along the width direction of \mathcal{Q} ; see Fig. 85.2. All beads with a nonempty intersection with \mathcal{Q} are ordered in a cyclic fashion, in such a way that beads sharing a cusp are adjacent in the ordering. The beads are constructed in such a way that a Dubins vehicle arriving at point p_- (refer Fig. 85.2) with heading toward point p_+ can service at least one target anywhere inside the bead and reach point p_+ with the same heading as it had when it arrived at point p_- . This feature allows the Dubins vehicle to service at least one target per bead in a cyclic fashion.

1. If there are no outstanding targets, loiter on a circular trajectory of radius ρ about the median of the region \mathcal{Q} . The direction of loitering is irrelevant and can be chosen in such a way that the loitering circle is returned to in minimum time after servicing the target.
2. Otherwise, visit beads in order, servicing at least one target per nonempty bead. Shortcuts skipping empty beads can be taken, as long as the cyclic ordering of the beads is preserved.
3. Repeat.

In the light-load case, in which most of the time there are no outstanding tasks, it is clear that the above policy attempts to replicate the policy used in the basic case, with no differential constraints. In the heavy-load case, the construction of the beads and their cyclic ordering ensure that (i) the number of beads in \mathcal{Q} is proportional to λ^3 , and hence the rate at which tasks are generated within a single bead is proportional to λ^{-2} , and (ii) the length of the cycle is proportional to λ^2 , hence the rate at which the UAV is able to complete tasks within a single bead (at least once per cycle), is proportional to λ^{-2} . Indeed, the proposed policy is able to stabilize the system and in fact provides a provable constant-factor approximation to the optimal system time.

Summarizing, it can be shown that, using the stated policy, the average system time \bar{T} satisfies

$$\bar{T} \leq \frac{H_1^* \sqrt{A} + 7/3\pi\rho}{v}, \quad (\text{as } \lambda \rightarrow 0^+),$$

and

$$\bar{T} \leq 71 \frac{\rho A}{v^3} \left(1 + \frac{7}{3}\pi \frac{\rho}{W}\right)^3 \lambda^2, \quad (\text{as } \lambda \rightarrow +\infty).$$

In other words, the performance of the stated policy is approximately optimal in light load if the minimum turning radius ρ is negligible with respect to \sqrt{A} . In the heavy-load case, the policy is provably stabilizing and is within a constant factor of the optimum.

85.3.3 UAV Routing with Limited Sensing Capabilities

In some applications, UAVs are not aware of new tasks upon their arrival; rather, the UAVs must search for and detect the tasks with limited-range onboard sensors before being able to complete them. This section is devoted to this problem, which can be called *persistent patrolling* problem.

85.3.3.1 The Persistent Patrolling Problem (PPP)

In this version of the problem, the task generation process and performance metrics are the same as in the DTRP problem, as well as the model for the motion of the UAVs, which can fly at constant speed along any continuous path, with no differential constraints imposed. However, the UAVs are not aware of the location of new tasks until they detect them using limited-range onboard sensor. For the sake of simplicity, the sensing region of a UAV is modeled as a disk of radius σ centered at the position of the UAV. Other shapes of the sensor footprint can be considered with minor modifications to specifics of the algorithms, without affecting their performance significantly. The analysis will focus on the case in which σ is small when compared to the region \mathcal{Q} (or, more precisely, to a characteristic length, e.g., \sqrt{A}). Also, in order to highlight some interesting aspects of the problem, the task generation process will be modeled with a nonuniform spatial distribution, described by a probability density function φ supported on \mathcal{Q} .

This problem is related to the well-studied problem of optimal search (Stone 1975). However, the fact that tasks are dynamically generated changes the problem in a fundamental way. In particular, new tasks may be generated in areas that have already been explored, hence requiring the UAV to return to previously visited locations. Problems of this nature have been studied, for example, in Song et al. (2010), considering uniform distribution of tasks; however, standard sweep methods do not work well if φ is not uniform. Motivated by search, patrolling, or foraging applications, other works such as (Mathew and Mezic 2009; Mesquita

2010; Cannata and Sgorbissa 2011) give algorithms that ensure that the distribution of the UAV (over time) asymptotically matches a given distribution, often taken to be the distribution of an underlying stochastic process. However, as discussed in the following, for the case at hand, the desired spatial distribution of the UAV's position is dependent on, but not equivalent to, the spatial distribution φ of tasks.

85.3.3.2 Lower Bounds

The problem will be discussed with a focus on the case in which $\sigma \rightarrow 0^+$, that is, the sensing range is very small, and hence search time is the main factor determining the system time. It can be shown that in this case

$$\bar{T} \geq \frac{1}{4v\sigma} \left(\int_{\mathcal{Q}} \sqrt{\varphi(q)} dq \right)^2 + \bar{s}.$$

Since $\left(\int_{\mathcal{Q}} \sqrt{\varphi(q)} dq \right)^2 \leq \int_{\mathcal{Q}} \varphi(q) dq = 1$ (e.g., by Jensen's inequality), any nonuniformity in the task distribution is beneficial in terms of detection time and should be exploited by the patrolling UAV.

85.3.3.3 Routing for the Single-Server PPP

In the case in which the density φ is uniform, the optimal patrolling strategy consists of following a “lawnmower pattern,” that is, a cyclic path that allows the vehicle's footprint to cover all of \mathcal{Q} . For small σ (i.e., ignoring boundary effects), and uniform φ , this achieves the lower bound on the system time and is hence optimal.

The case in which φ is not uniform, the design of a good patrolling strategy is more involved. As in previous cases, a routing policy can be designed based on an appropriate partition of the environment. For simplicity of exposition, assume that the distribution φ is piecewise constant, that is, there is a partition $\{\mathcal{Q}_1, \mathcal{Q}_2, \dots, \mathcal{Q}_l\}$ of \mathcal{Q} such that $\varphi(q) = \varphi_i$ for all $q \in \mathcal{Q}_i$, $i = 1, \dots, l$. Further partition each subregion \mathcal{Q}_i into $p_i = \lceil \bar{p}/\sqrt{\varphi_i} \rceil$ tiles of equal area, $i = 1, \dots, l$, where \bar{p} is a number that is large enough that the values $\bar{p}/\sqrt{\varphi_i}$ are well approximated by integers. Define a cyclic ordering of the subregions \mathcal{Q}_i and cyclic orderings of the p_i tiles within each subregion, $i = 1, \dots, l$. Each of these ordering defines uniquely the “next” subregion (or tile), given the current subregion (or tile).

1. If any outstanding tasks have been revealed, use the single-server DTRP routing policy to complete these tasks.
2. Otherwise, move to the “next” tile in the “next” subregion, and sweep this tile using a lawnmower pattern. (The initial tile and subregion can be chosen arbitrarily.)
3. Repeat.

The idea in the above policy is to ensure that the time-averaged “density” of the UAV matches $\sqrt{\varphi}$. As $\sigma \rightarrow 0^+$, the system time using this patrolling strategy matches the lower bound and is hence optimal.

Interestingly, in the case in which σ is given, and $\varrho \rightarrow 1^-$, it turns out that the sensing-range limitation does not constrain the system's performance. In other words, in heavy-load conditions, the rate at which new tasks will be detected while servicing previously detected targets is high enough that sensing limitations do not make a difference, and the performance for the "standard" single-server DTRP is recovered.

85.4 Spatial Queueing Theory: The Multi-server Case

The previous section presented an algorithmic approach to spatial queueing theory for single-server problems; this section extends such an approach to the multi-server case. The focus is on *control decentralization*: in fact, a decentralized architecture can provide robustness to failures of single servers and can guarantee better time efficiency; also, it might reduce the total implementation and operation cost, increase reactivity and system reliability, and add flexibility and modularity with respect to the centralized counterpart.

The extension to the multi-server case coupled with the constraint of control decentralization adds significant challenges with respect to the single-server case. Fortunately, there are a number of cases where a simple, yet systematic approach allows to lift single-server routing policies to *decentralized* multi-server routing policies with provable performance guarantees. The idea is to have the servers partition the workspace into regions of dominance via a decentralized partitioning algorithm and then have each server follow a single-server policy within its own region. Specifically, one defines an *m-partition* of \mathcal{Q} as a collection of m closed subsets $\{Q_i\}_{i=1}^m$ with disjoint interiors and whose union is \mathcal{Q} . Given a single-server policy π and an *m-partition* of \mathcal{Q} , a *π -partitioning policy* is a multi-server policy such that (i) one server is assigned to each subregion (thus, there is a one-to-one correspondence between servers and subregions), and (ii) each server executes the single-server policy π to service demands that fall within its own subregion. Note that a partitioning policy is parametrized by the single-server policy π and by the *m-partition* of \mathcal{Q} , possibly computed with a decentralized partitioning algorithm. Which partitions should one consider, and to what extent this *decoupling* strategy affects optimality? These questions are discussed in detail in Pavone et al. (2009), where the authors illustrate a number of scenarios, partitioning schemes, and *decentralized* partitioning algorithms whereby one can retain optimality, or at least some degree of optimality, under this (systematic) decomposition.

In the following, paralleling the structure of the previous section, the multi-server dynamic routing problem will be studied for three problems: (1) the simplest case of teams of UAVs without motion constraints and with unlimited sensing, (2) the case of teams of UAVs with differential motion constraints and with unlimited sensing, and (3) the case of teams of UAVs without motion constraints but with

limited information about the environment. In all three cases, the aforementioned partitioning procedure will be pivotal for the design of provably efficient multi-UAV routing strategies.

85.4.1 Multi-UAV Routing with No Motion Constraints and Unlimited Sensing

The problem has the same definition of the DTRP problem, with the exception that m UAVs are available to provide service to the targets.

85.4.1.1 Lower Bounds

The lower bounds (and the techniques to derive them) are similar to the ones for the single-server case. Consider first the light-load case (i.e., $\varrho \rightarrow 0^+$). The m -median of \mathcal{Q} is defined as the set of m points that minimizes the expected distance between a random point sampled uniformly from \mathcal{Q} and the closest point in such set (in other words, the m -median of \mathcal{Q} is the global minimizer $P_m^* := \operatorname{argmin}_{(p_1, \dots, p_m) \in \mathcal{Q}^m} \mathbb{E}[\min_{k \in \{1, \dots, m\}} \|p_k - q\|]$). This distance can be written as $H_m^*(\mathcal{Q})\sqrt{A/m}$, where $H_m^*(\mathcal{Q})$ lies in the interval $[0.3761, c(\mathcal{Q})]$ where $c(\mathcal{Q})$ is a constant that depends only on the shape of \mathcal{Q} . The m -median of \mathcal{Q} induces a Voronoi partition that is called *median Voronoi tessellation*. Recall that the *Voronoi diagram* $\mathcal{V}(P_m^*) = (V_1, \dots, V_m)$ of \mathcal{Q} generated by points $P_m^* = (p_1, \dots, p_m)$ is defined by

$$V_i = \left\{ q \in \mathcal{Q} \mid \|q - p_i\| \leq \|q - p_j\|, \forall j \neq i, j \in \{1, \dots, m\} \right\}.$$

See Fig. 85.3 for an example of a Voronoi diagram. The expected system time in light load can then be lower bounded as

$$\bar{T} \geq \frac{H_m^*(\mathcal{Q})\sqrt{A}}{v\sqrt{m}} + \bar{s}, \quad (\text{as } \varrho \rightarrow 0^+).$$

Hence, in light load, the optimal system time scales with the square root of the number of UAVs. In the heavy-load case, one can show

$$\bar{T} \geq \frac{\beta_2^2 A}{2 v^2} \frac{\lambda}{m^2 (1 - \varrho/m)^2}, \quad (\text{as } \varrho/m \rightarrow 1^-).$$

A salient feature of the above lower bound is that it scales *quadratically* with the number of servers; note, however, that congestion effects are not included in this model.

Fig. 85.3 A Voronoi diagram with 25 generators

85.4.1.2 Routing for the Multi-server DTRP

The design of a partitioning policy relies on three basic steps, that is,

1. Characterization of an optimal (or constant-factor optimal) single-server routing policy
2. Characterization of efficient partitioning schemes
3. Design of (possibly decentralized) algorithms for workspace partitioning

Consider Step 2. Let π be an optimal (or constant-factor optimal) single-server policy for the DTRP. Assuming heavy-load conditions (when the problem resembles one of workload balance), one can show that a “ π -partitioning policy” that uses m -partitions whose subregions have *equal area* (i.e., *equitable* m -partitions) has the same optimality properties as π . This remarkable result extends to the case where the distribution of targets is not uniform, targets have priorities and targets have time windows and even to the case of non-holonomic UAVs, as illustrated in the next section. This result, however, only holds under the heavy-load assumption; when the load is only moderate, the shape of subregions can have a significant effect. In moderate load, a solution that turns out to be effective for the DTRP is to adopt equitable partitioning policies in which the subregions are “fat,” that is, with a small diameter for a given area, rather than long and thin. Finally, in light-load conditions, when the problem resembles one of geometric optimization, the relevant partitions are the *median Voronoi tessellations* defined in the previous lower bound section.

This discussion leads to the following (centralized) routing policy for the multi-server DTRP:

1. Compute an m median of \mathcal{Q} , and the corresponding Voronoi partition.
2. Assign one vehicle to each Voronoi region,
3. Each UAV executes the single-server DTRP policy in its own subregion.

Using the above routing policy, the average system time \bar{T} satisfies

$$\bar{T} = \frac{H_m^*(\mathcal{Q})\sqrt{A}}{\sqrt{mv}} + \bar{s}, \quad (\text{as } \varrho \rightarrow 0^+),$$

$$\bar{T} \leq \gamma \frac{A}{v^2} \frac{\lambda}{m^2 (1 - \varrho/m)^2}, \quad (\text{as } m \rightarrow +\infty \text{ and } \varrho/m \rightarrow 1^-).$$

where γ is the optimality factor of the single-server routing policy.

Note that the heavy-load result above relies on the fact that for large m , each Voronoi region in a median Voronoi tessellation has the same area (see Appendix A.1). For general m , this may not be the case; furthermore, one might wonder whether equitable partitions can be computed in a decentralized fashion (this corresponds to the third step in the aforementioned policy design procedure).

In the solution proposed in Pavone et al. (2011), power diagrams are the key geometric concept to obtain in a decentralized fashion, *equitable*, and *median Voronoi* partitions (or “good” approximations when they do not exist). Define

$$P_W := \left((p_1, w_1), \dots, (p_m, w_m) \right) \in (\mathcal{Q} \times \mathbb{R})^m.$$

The pair (p_i, w_i) is called a *power point*. The *power diagram* $\mathcal{V}(P_W) = (V_1, \dots, V_m)$ of \mathcal{Q} generated by power points P_W is defined by

$$V_i(P_W) = \left\{ q \in \mathcal{Q} \mid \|q - p_i\|^2 - w_i \leq \|q - p_j\|^2 - w_j, \forall j \neq i, j \in \{1, \dots, m\} \right\}.$$

The set P_W is the set of *power generators* of $\mathcal{V}(P_W)$, and V_i is the power cell of the i -th power generator. When all weights are the same, the power diagram coincides with the Voronoi diagram. One can show that given $m \geq 1$ distinct points (p_1, \dots, p_m) in \mathcal{Q} , there exist weights $w_i, i \in \{1, \dots, m\}$, such that the set of power points $\left((p_1, w_1), \dots, (p_m, w_m) \right)$ generates a power diagram that is equitable, that is, where all power regions have the same area. The basic idea, then, is to associate to each UAV i a *virtual* power generator (virtual generator for short) (p_i, w_i) ; then, the power cell V_i becomes the region of dominance for UAV i (see Fig. 85.4). A virtual generator (p_i, w_i) is simply an artificial (or logical) variable whose value is locally controlled by the i th UAV. In general, the position of an UAV and the position of its virtual generator are *distinct*, that is, the position of an UAV inside its own region of dominance V_i is independent from the position of its virtual generator (see Fig. 85.4). Note that an equitable power diagram can be obtained by just changing the values of the weights (while keeping the generators’s positions fixed). Thus, the degrees of freedom given by the positions

Fig. 85.4 Vehicles, virtual generators, tasks/demands, and regions of dominance. A positive weight w is represented by a yellow circle with radius \sqrt{w} ; a negative weight w is represented by a blue circle with radius $\sqrt{|w|}$. Note that the position of a UAV and the position of its virtual generator are, in general, distinct

of the generators can be used to “steer” the partition toward an equitable and *median* Voronoi partition. Specifically, the idea is to construct an energy function with the properties that (1) it depends on the weights and positions of the virtual generators, and (2) all its critical points correspond to vectors of weights and positions yielding an equitable power diagram. Then, each UAV updates its own virtual generator by updating the weight according to a *decentralized* gradient-descent law (with respect to the energy function) and by updating the virtual generator’s position so as to steer the partition toward a median Voronoi diagram, when this motion does not increase the disagreement between the areas of the neighboring regions (see Pavone et al. 2011 for details). Under this decentralized partitioning algorithm, an equitable partition is always achieved; hence the resulting partitioning policy is optimal in heavy load. Furthermore, if an m -median of \mathcal{Q} that induces a Voronoi partition that is equitable exists, this partitioning algorithm will locally converge to it; thus the resulting decentralized partitioning policy is locally optimal in light load.

85.4.2 Multi-UAV Routing with Motion Constraints and Unlimited Sensing

The definition of the problem is the same as the one for the single-server Dubins DTRP problem, but now there are m UAVs providing service. In the following, for brevity, this problem is referred to as the m -Dubins DTRP.

85.4.2.1 Lower Bounds

In contrast to the standard DTRP, the lower bound for the m -Dubins DTRP does not follow easily from the results for the single-server Dubins DTRP. Consider first the light-load case. In this case, the lower bound is a function of a non-dimensional parameter called *non-holonomic vehicle density*:

$$d_\rho := \frac{\rho^2 m}{A},$$

which is proportional to the ratio of the area of a disk whose radius is the turning radius and the area of \mathcal{Q} available per vehicle. Hence, d_ρ is representative of the significance of the turning radius with respect to the typical distance that an individual vehicle travels. One can give the following lower bounds for the m -Dubins DTRP:

$$\begin{aligned} \bar{T} &\geq \frac{H_m^*(\mathcal{Q})}{v} \left(\frac{A}{m} \right)^{1/2}, & (\text{as } \lambda \rightarrow 0^+ \text{ and } d_\rho \rightarrow 0^+), \\ \bar{T} &\geq \frac{3\sqrt[3]{3}}{4v} \left(\frac{\rho A}{m} \right)^{1/3}, & (\text{as } \lambda \rightarrow 0^+ \text{ and } d_\rho \rightarrow +\infty). \end{aligned}$$

The first bound is obtained by approximating the Dubins distance (i.e., the length of the shortest feasible path for a Dubins vehicle) with the Euclidean distance. The second lower bound is obtained by explicitly taking into account the Dubins turning cost. Note that when the motion constraint becomes “active” as $d_\rho \rightarrow +\infty$, the lower bound scales with $m^{-1/3}$.

Reachability arguments show that when λ is large (i.e., in heavy load), a lower bound for the heavy-load case is as follows:

$$\bar{T} \geq \frac{81}{64} \frac{\rho A}{v^3} \frac{\lambda^2}{m^3}, \quad (\text{as } \lambda/m \rightarrow +\infty).$$

Hence, for the m -Dubins DTRP, the lower bound scales with the inverse of the *cube* of the number of UAVs (in contrast to the standard DTRP where the scaling is inverse of the square); note, again, that the model does not include congestion effects.

85.4.2.2 Routing Policies for the m -Dubins DTRP

Consider, first, the case when λ is small (i.e., light load) and the non-holonomic density is low; in this case, the problem resembles the standard multi-server DTRP problem. Accordingly, the relevant partition scheme is a median Voronoi tessellation, and the following partitioning policy is efficient in this case.

1. Compute a m -median of \mathcal{Q} ,
2. Assign one UAV to each Voronoi region,

Fig. 85.5 Illustration of the light-load policy for low values of non-holonomic density. The squares represent elements of $P_m^*(Q)$, the m -median of Q . Each vehicle loiters about its respective generator at a radius ρ . The regions of dominance are the Voronoi partition generated by $P_m^*(Q)$. In this figure, a task has appeared in the subregion roughly in the upper-right quarter of the domain. The vehicle responsible for this subregion has left its loitering orbit and is en route to service the demand

- Each UAV visits the demands in the Voronoi region in the order in which they arrive. When no demands are available, the UAV returns to the median and loiters on a circular trajectory of radius ρ centered at the median of the subregion.

This policy is illustrated in Fig. 85.5. The performance of this policy is given by

$$\bar{T} \leq \frac{H_m^*(Q)}{v} \left(\frac{A}{m} \right)^{1/2}, \quad (\text{as } \lambda \rightarrow 0^+ \text{ and } d_\rho \rightarrow 0^+),$$

that is, this policy is optimal. Hence, in this asymptotic regime, the system time scales as $1/(v\sqrt{m})$.

In light load, when the non-holonomic density is large, one should instead consider *dynamic* partitions; in particular, an effective policy is as follows:

- Bound the environment Q with a rectangle of minimum *height*, where height denotes the smaller of the two side lengths of a rectangle. Let W and H be the *width* and *height* of this bounding rectangle, respectively. Divide Q into strips of width w , where

$$w = \min \left\{ \left(\frac{4}{3\sqrt{\rho}} \frac{WH + 10.38\rho H}{m} \right)^{2/3}, 2\rho \right\}.$$

- Orient the strips along the side of length W .
- Construct a closed Dubins path which runs along the longitudinal bisector of each strip, visiting all strips in top-to-bottom sequence, making U-turns between

Fig. 85.6 Illustration of the light-load policy for large non-holonomic densities. The segment providing closure of the loitering path (returning the UAVs from the end of the last strip to the beginning of the first strip) is not shown here for clarity of the drawing

strips at the edges of Q , and finally returning to the initial configuration. The m UAVs loiter on this path, equally spaced, in terms of path length.

A depiction of this policy is shown in Fig. 85.6. At the instant a target arrives, one constructs a circle of radius ρ which is tangent to the loitering path and intersects the target. The UAV responsible for visiting the target is the one closest in terms of loitering path length to the point of departure, at the time of target arrival. After a UAV has serviced a target, it must return to its place in the loitering pattern.

Note that the dynamic partition associated with a particular UAV is in fact fixed in the reference frame of that UAV and that in the global frame, these partitions could be regarded as a *dynamic version of an equitable partition* of Q , modulo the boundary effects. The reason for using dynamic equitable partitions is as follows. For large values of non-holonomic density, the area per vehicle is small in comparison to the disk of radius ρ , and hence the efficient regions of responsibility for the UAVs in such a regime coincide with their *small-time* reachable sets. Since the UAVs modeled as a Dubins vehicle cannot stall, a simple way to ensure that the regions of responsibility are contained inside the small-time reachable sets all the time is to have the regions of responsibility fixed in the reference frame of the UAVs.

The system time of the above policy that uses dynamic partitions satisfies

$$\bar{T} \leq \begin{cases} \frac{1.238}{v} \left(\frac{\rho WH + 10.38 \rho^2 H}{m} \right)^{1/3} + \frac{W + H + 6.19\rho}{mv} & \text{for } m \geq 0.471 \left(\frac{WH}{\rho^2} + \frac{10.38H}{\rho} \right), \\ \frac{WH + 10.38\rho H}{4\rho mv} + \frac{W + H + 6.19\rho}{mv} + \frac{1.06\rho}{v} & \text{otherwise.} \end{cases}$$

Hence this policy is within a constant factor of the optimal in the asymptotic regime where $\lambda/m \rightarrow 0^+$ and $d_\rho \rightarrow +\infty$. Moreover, in such asymptotic regime, the optimal system time scales as $1/(v\sqrt[3]{m})$.

Finally, for the heavy load, the relevant partitions are *additively weighted equitable* partitions, as follows:

1. Divide the environment into regions of dominance with lines parallel to the bead rows. Let the area and height of the i th vehicle's region be denoted with A_i and H_i . Place the subregion dividers in such a way that

$$A_i + \frac{7}{3}\pi\rho H_i = \frac{1}{m} \left(A + \frac{7}{3}\pi\rho H \right), \quad \text{for all } i \in \{1, \dots, m\}.$$

2. Allocate one subregion to every vehicle.
3. Each vehicle executes the single vehicle policy in its own region, where the size of bead in region i is chosen to be $\ell_i = \min\{C_{BT,i}v/\lambda_i, 4\rho\}$, with $\lambda_i = \lambda A_i/A$ being the arrival rate in region i , and $C_{BT,i} = \frac{7-\sqrt{17}}{4} \left(1 + \frac{7\pi\rho H_i}{3A_i}\right)^{-1}$.

The system time for this policy satisfies

$$\bar{T} \leq 71 \frac{\rho A}{v^3} \left(1 + \frac{7\pi\rho H}{3A}\right)^3 \frac{\lambda^2}{m^3}, \quad (\text{as } \lambda/m \rightarrow +\infty).$$

Hence, this policy is within a constant factor of the optimal in heavy load and the optimal system time in this case scales as $\lambda^2/(mv)^3$.

Note that all the above three policies are partitioning policies; the partitions used are, however, quite different, ranging from median Voronoi tessellations, to dynamic partitions, to additively weighted equitable partitions. Median Voronoi tessellations and additively weighted equitable partitions can be computed in a *decentralized* fashion with the partitioning algorithm discussed for the multi-DTRP problem (indeed, a median Voronoi tessellation can be computed even without interagent communication). No decentralized algorithms have been developed so far for dynamic partitions.

It is instructive to compare the scaling of the optimal system time with respect to λ , m , and v for the m -DTRP and for the m -Dubins DTRP. Such comparison is shown in Table 85.1. One can observe that in heavy load, the optimal system time for the m -Dubins DTRP is of the order $\lambda^2/(mv)^3$, whereas for the m -DTRP, it is of the order $\lambda/(mv)^2$. This analysis rigorously establishes the following intuitive fact: bounded-curvature constraints make the optimal system much more sensitive to increases in the demand generation rate. Perhaps less intuitive is the fact that the optimal system time is also more sensitive with respect to the number of vehicles and the vehicle speed in the m -Dubins DTRP as compared to the m -DTRP. In the light load, the optimal system time for the m -DTRP is of the order $1/(v\sqrt{m})$, which is the same for the m -DTRP but only when the non-holonomic density is small. When the non-holonomic density is high, the optimal system time is of the order $1/(v\sqrt[3]{m})$, that is, it is more sensitive to the number of vehicles than in the low non-holonomic density case. This suggests the existence of a critical value of d_ρ below which the partitioning policy using median Voronoi partitions is efficient and

Table 85.1 A comparison between the scaling of the optimal system time for the multi-server DTRP and for the m -Dubins DTRP

| | $\bar{T}^*, m\text{-DTRP}$ | $\bar{T}^*, m\text{-Dubins DTRP}$ |
|--|--|--|
| Heavy load ($\lambda/m \rightarrow +\infty$) | $\Theta\left(\frac{\lambda}{m^2 v^2}\right)$ | $\Theta\left(\frac{\lambda^2}{m^3 v^3}\right)$ |
| Light load ($\lambda/m \rightarrow 0^+$) | $\Theta\left(\frac{1}{v\sqrt{m}}\right)$ | $\Theta\left(\frac{1}{v\sqrt{m}}\right)$ if $d_\rho \rightarrow 0^+$ |
| | | $\Theta\left(\frac{1}{v^3\sqrt{m}}\right)$ if $d_\rho \rightarrow +\infty$ |

above which the dynamic partitioning policy is efficient. The details of such phase transitions can be found in Enright et al. (2009).

85.4.3 Multi-UAV Routing with Limited Sensing Capabilities

The definition of the problem is the same as in the single-server persistent patrolling problem, with the only difference being the number of UAVs providing service.

85.4.3.1 Lower Bounds

As in the single-server case, the discussion will focus on the case in which $\sigma \rightarrow 0^+$. In this case, the system time is bounded by

$$\bar{T} \geq \frac{1}{4mv\sigma} \left(\int_{\mathcal{Q}} \sqrt{\varphi(q)} dq \right)^2 + \bar{s}.$$

85.4.3.2 Routing Policies for the m -Server PPP

Optimal static partitioning policies can be designed using partitions that are simultaneously equitable with respect to φ and $\sqrt{\varphi}$. (Such partitions can always be found.) However, a simpler strategy is based on a “dynamic” partition, as follows:

1. If any outstanding tasks have been revealed, use the multi-server DTRP routing policy to complete these tasks.
2. Otherwise, move to the “next” tile in the “next” subregion, and sweep this tile using a lawnmower pattern. (The initial tile and subregion for each vehicle are chosen in such a way that vehicles are uniformly spaced along the subregion/tile cycle.)
3. Repeat.

The above policy matches the lower bound and is hence optimal as $\sigma \rightarrow 0^+$. In the case in which σ is finite, and $\varrho \rightarrow 1^-$, the sensing-range limitation does not

constrain the system's performance, and the performance for the "standard" multi-server DTRP is recovered. As discussed above, no decentralized algorithms have been developed so far for dynamic partitions.

85.5 Conclusions

In this chapter, we presented a dynamic vehicle routing framework for coordination of UAVs performing spatially distributed tasks in uncertain and dynamic environments. The technical approach relies on using algorithmic spatial queueing theory for designing efficient algorithms for single vehicles, and then augmenting it with spatial partitioning policies to extend it to multiple vehicles. To illustrate this approach, a variety of problems were considered, ranging from the simplest case with no motion or sensing constraints to the cases with motion differential constraints and with limited sensing constraints. Additionally, multi-UAV versions for each of these cases were considered. For each scenario, UAV routing policies have been provided, which are provably optimal or approximately optimal in the asymptotic regimes of light and heavy load. The dependence of the performance of these algorithms on mission parameters such as the number, speed, sensor footprint and turning radius of the UAVs, and the dimension of the workspace was discussed. A system designer could interpolate between such scaling laws for the extreme cases as established in this chapter to choose a policy that best fits given problem specifications. Moreover, the algorithms and their underlying principles presented in this chapter for canonical scenarios could also provide guidelines to design algorithms for other scenarios not explicitly considered in this chapter.

Appendix A

A.1 The Continuous Multi-median Problem

Given a set $\mathcal{Q} \subset \mathbb{R}^d$ and a vector $P = (p_1, \dots, p_m)$ of m distinct points in \mathcal{Q} , the expected distance between a random point q , generated according to a probability density function φ , and the closest point in P is given by

$$\begin{aligned} H_m(P, \mathcal{Q}) &:= \mathbb{E} \left[\min_{i \in \{1, \dots, m\}} \|p_i - q\| \right] \\ &= \sum_{i=1}^m \int_{\mathcal{V}_i(P, \mathcal{Q})} \|p_i - q\| \varphi(q) dq, \end{aligned}$$

where $\mathcal{V}(P, \mathcal{Q}) = (\mathcal{V}_1(P, \mathcal{Q}), \dots, \mathcal{V}_m(P, \mathcal{Q}))$ is the Voronoi partition of the set \mathcal{Q} generated by the points P . In other words, $q \in \mathcal{V}_i(P, \mathcal{Q})$ if $\|q - p_i\| \leq \|q - p_k\|$, for all $k \in \{1, \dots, m\}$. The set \mathcal{V}_i is referred to as the Voronoi cell of the generator p_i .

The function H_m is known in the locational optimization literature as the continuous Weber function or the continuous multi-median function; see (Agarwal and Sharir 1998; Drezner 1995) and references therein.

The m -median of the set \mathcal{Q} , with respect to the measure induced by φ , is the global minimizer

$$P_m^*(\mathcal{Q}) = \operatorname{argmin}_{P \in \mathcal{Q}^m} H_m(P, \mathcal{Q}).$$

Let $H_m^*(\mathcal{Q}) = H_m(P_m^*(\mathcal{Q}), \mathcal{Q})$ be the global minimum of H_m . It is straightforward to show that the map $P \mapsto H_1(P, \mathcal{Q})$ is differentiable and strictly convex on \mathcal{Q} . Therefore, it is a simple computational task to compute $P_1^*(\mathcal{Q})$. It is convenient to refer to $P_1^*(\mathcal{Q})$ as the median of \mathcal{Q} . On the other hand, the map $P \mapsto H_m(P, \mathcal{Q})$ is differentiable (whenever (p_1, \dots, p_m) are distinct) but not convex, thus making the solution of the continuous m -median problem hard in the general case. It is known (Agarwal and Sharir 1998; Megiddo and Supowit 1984) that the discrete version of the m -median problem is NP-hard for $d \geq 2$. Gradient algorithms for the continuous m -median problems can be designed by means of the equality

$$\frac{\partial H_m(P, \mathcal{Q})}{\partial p_i} = \int_{\mathcal{V}_i(P, \mathcal{Q})} \frac{p_i - q}{\|p_i - q\|} \varphi(q) dq.$$

The set of critical points of H_m contains all configurations (p_1, \dots, p_m) with the property that each p_i is the generator of the Voronoi cell $\mathcal{V}_i(P, \mathcal{Q})$ as well as the median of $\mathcal{V}_i(P, \mathcal{Q})$. We refer to such Voronoi diagrams as *median Voronoi diagrams*. It is possible to show that a median Voronoi diagram always exists for any bounded convex domain \mathcal{Q} and density φ .

The dependence of $H_m^*(\mathcal{Q})$ on m plays a crucial role in the design and analysis of algorithms relying on geometric optimization. However, finding the exact relationship for the general case is difficult; hence, it is of great interest to provide bounds on $H_m^*(\mathcal{Q})$. This problem is studied thoroughly in Papadimitriou (1981) for square regions and in Zemel (1984) for more general compact regions. It is known that, in the asymptotic case ($m \rightarrow +\infty$), $H_m^*(\mathcal{Q}) = c_{\text{hex}} \sqrt{A/m}$ almost surely, where $c_{\text{hex}} \approx 0.377$ is the first moment of a hexagon of unit area about its center. This optimal asymptotic value is achieved by placing the m points at the centers of the hexagons in a regular hexagonal lattice within \mathcal{Q} (the honeycomb heuristic). Working towards the above result, it is also known that for any $m \in \mathbb{N}$,

$$\frac{2}{3} \sqrt{\frac{A}{\pi m}} \leq H_m^*(\mathcal{Q}) \leq c(\mathcal{Q}) \sqrt{\frac{A}{m}},$$

where $c(\mathcal{Q})$ is a constant depending on the shape of \mathcal{Q} .

Appendix B

B.1 The Euclidean Traveling Salesman Problem

The Euclidean TSP is formulated as follows: given a finite set D of n points in \mathbb{R}^d , find the minimum-length closed curve through all points in D . In graph theoretical language, a tour of the point set D is a spanning cycle of the complete graph with vertex set D ; the length of a tour is the sum of all Euclidean distances between points in the tour.

The asymptotic behavior of stochastic TSP problems for large n exhibits the following interesting property. Let $\text{ETSP}(n)$ be a random variable returning the length of the Euclidean TSP tour through n points, independently and uniformly sampled from a compact set \mathcal{Q} of unit area; in Beardwood et al. (1959), it is shown that there exists a constant β_2 such that, almost surely,

$$\lim_{n \rightarrow +\infty} \frac{\text{ETSP}(n)}{\sqrt{n}} = \beta_2.$$

In other words, the optimal cost of stochastic TSP tours approaches a deterministic limit and grows as the square root of the number of points to be visited; the current best estimate of the constant appearing in the limit is $\beta_2 = 0.7120 \pm 0.0002$; see Percus and Martin (1996) and Johnson et al. (1996). Similar results hold in higher dimensions, and for nonuniform point distributions from Steele (1990), the above limit takes the general form

$$\lim_{n \rightarrow +\infty} \frac{\text{ETSP}(n)}{n^{1-1/d}} = \beta_d \int_{\mathcal{Q}} \bar{\varphi}(q)^{1-1/d} dq \quad \text{almost surely,}$$

where $\bar{\varphi}$ is the density of the absolutely continuous part of the distribution φ from which the n points are independently sampled. Notice that the bound holds for all compact sets: the shape of the set only affects the convergence rate to the limit. According to Larson and Odoni (1981), if \mathcal{Q} is a “fairly compact and fairly convex” set in the plane, the estimate $\text{ETSP}(n) \approx \beta_2 \sqrt{n}$ for values of n as low as 15. Remarkably, the asymptotic cost of the stochastic TSP for uniform point distributions is an upper bound on the asymptotic cost for general point distributions, that is,

$$\lim_{n \rightarrow +\infty} \frac{\text{ETSP}(n)}{n^{1-1/d}} \leq \beta_d.$$

This follows directly from an application of Jensen’s inequality, that is,

$$\int_{\mathcal{Q}} \bar{\varphi}(q)^{1-\frac{1}{d}} dq \leq \left(\int_{\mathcal{Q}} \bar{\varphi}(q) dq \right)^{1-\frac{1}{d}} \leq \varphi(\mathcal{Q})^{1-\frac{1}{d}} = 1.$$

The TSP is known to be NP-hard, which suggests that there is no general algorithm capable of finding the optimum tour in an amount of time polynomial in the size of the input. Even though the exact optimal solutions of a large TSP can be very hard to compute, several exact and heuristic algorithms and software tools are available for the numerical solution of Euclidean TSPs.

The most advanced TSP solver to date is arguably *concorde* (Applegate et al. 1998). Heuristic polynomial-time algorithms are available for constant-factor approximations of TSP solutions, such as Christofides' algorithm, providing a $3/2$ approximation factor (Christofides 1972). On a more theoretical side, Arora (1997) proved the existence of polynomial-time approximation schemes, providing a $(1 + \varepsilon)$ constant-factor approximation for any $\varepsilon > 0$.

A modified version of the Lin-Kernighan heuristic (Lin and Kernighan 1973) is implemented in *linkern*; this powerful solver yields approximations in the order of 5 % of the optimal tour cost very quickly for many instances. For example, in numerical experiments on a 2.4 GHz Pentium machine, approximations of random TSPs with 1,000 points typically required about 2 s of CPU time. Both *concorde* and *linkern* are written in ANSI C and, at the time of writing, are freely available for academic research use at <http://www.tsp.gatech.edu/concorde/index.html>.

In this chapter, several routing policies were presented requiring on-line solutions of large TSPs. Practical implementations of the algorithms will rely on heuristics, such as Lin-Kernighan's or Christofides'. If a constant-factor approximation algorithm is used, the effect on the asymptotic performance guarantees of our algorithms can be simply modeled as a scaling of the constant β_d .

Section XVI

UAV Integration into the National Airspace

*Konstantinos Dalamagkidis and
Richard S. Stansbury*

Kimon P. Valavanis and George J. Vachtsevanos

UAV Integration into the National Airspace reviews and presents policies, procedures, and requirements for manned aviation and relates them to existing and under development equivalent policies and requirements for unmanned aviation. Integration of unmanned aviation into the (any) national airspace requires, again, that “UAVs function as if there were a human pilot onboard.” This requirement and restriction dictates that equivalent levels of safety (ELOS) must be derived for unmanned aviation (depending on the UAV classification), in addition to reliability and fault tolerance requirements. The major deviation from manned aviation requirements is that a controlled crash may be allowed for UAVs provided that human lives are not endangered and that collateral damage is minimized.

► [Aviation Regulation](#) by Dalamagkidis presents a brief introduction to aviation regulation. Key terms are defined and an overview of current manned aviation regulations is provided using the U.S. Federal Aviation Regulation as an example. This includes airworthiness certification, operation rules, and airspace classes.

► [Human Factors of Unmanned Aircraft System Integration in the National Airspace System](#) by Kaliardos and Lyall focuses on identifying human factor challenges to integrating UAS in the National Airspace System (NAS) for both pilots and air traffic controllers. The method for identifying these challenges is primarily based on the differences or “gaps” between manned aircraft in the NAS today and the unique aspects of UAS. The goal is not to generate a comprehensive

G.J. Vachtsevanos

Professor Emeritus, School of Electrical and Computer Engineering, The Georgia Institute of Technology, Atlanta, GA, USA

e-mail: gjv@ece.gatech.edu

list of human factor issues, but to focus on those that are traceable to fundamental characteristics of UAS and that are also considered challenging with respect to the current NAS and its regulatory framework. It is assumed that for integration into the NAS, future UAS will be much more standardized in many respects than in the past – closer to that of today’s civil manned aircraft, which are subject to rigorous design, operational, manufacturing, and training approvals by the FAA. Under such assumptions, human factors are not only central to the very definition of UAS but are also central to some of the most important challenges facing the integration of UAS in the NAS.

► **Methodologies for Regulatory Compliance and Harmonization** by Marshall proposes a methodology for analysis of current regulations for applicability to UAS activities. Where the rules are in development, or merely being contemplated, a structure for harmonization with international standards is proposed. The focus is on the USA as the nation that has the most comprehensive aviation regulations, while also supporting major efforts to promulgate regulations and standards to supplement those regulations with UAS specific requirements and criteria. To provide global context, the International Civil Aviation Organization’s (ICAO’s) structure and procedures are reviewed in detail and contrasted with state-sponsored regulatory processes, with an analysis of the applicability of ICAO’s standards to UAS operations.

► **A Certification Strategy for Small Unmanned Aircraft Performing Nomadic Missions in the U.S. National Airspace System** by Stachura, Elston, Argrow, Frew, and Dixon discusses the specifics of the Certificates of Authorization (COA) obtained for the second Verification of the Origin of Rotation in Tornadoes Experiment (VORTEX2) project and how the operations are conducted to satisfy the COA requirements. A strategy is outlined for operating these nomadic missions with small UAS within the confines of FAA regulations. This includes information on getting FAA COAs for a large area, specifically focusing on area selection, airworthiness, and emergency procedures, which are the keys to these applications.

► **Hazard and Safety Risk Modeling** by Dalamagkidis presents aspects of risk modeling with a focus on UAS. It provides an overview of the current level of safety of manned aviation in terms of accident statistics. These are then mapped as target levels for UAS under the “Equivalent Level of Safety” principle to provide a glimpse at what that may entail for UAS regulations. Different methodologies are presented for estimating the risk of ground impact and midair collision accidents and how these estimates can be translated to system requirements. Guidelines are provided on the use of different risk models followed by applying a selection of them to five different UAS in two distinct scenarios, to compare the results of different choices.

► **Safety Risk Management of Unmanned Aircraft Systems** by Clothier and Walker provides existing risk practitioners with a high-level introduction to some of the unique issues and challenges in the application of the safety risk management process to UAS. The scope is limited to safety risks associated with the operation of unmanned aircraft in the civil airspace system and over inhabited areas. This chapter notes the unique aspects associated with the application of the safety risk management process to UAS compared to that of conventionally piloted aircraft.

Key challenges discussed include the specification of high-level safety criteria; the identification, analysis, and evaluation of the risks; and the effectiveness of available technical and operational mitigation strategies. Some solutions to these challenges are examined including those currently in practice and those still under research and development.

► **Certification of Small UAS** by Leijgraaf describes certification procedures for (small) UAS. It focuses on the certification process, the requirements for the safe design of a UAS, and the organizational requirements for the company designing the UAS.

► **Technology Surveys and Regulatory Gap Analyses of UAS Subsystems Toward Access to the NAS** by Stansbury and Wilson provides the necessary details on how to conduct a technology survey and regulatory gap analysis of UAS technology subsystems. Four past studies performed by Embry-Riddle Aeronautical University for the FAA's William J. Hughes Technology Center are discussed. These studies address UAS propulsion systems, sense and avoid technologies and procedures, command control and communication, and emergency recovery and flight termination systems. A recommended process for future studies is provided.

► **Concept of Operations of Small Unmanned Aerial Systems: Basis for Airworthiness Towards Personal Remote Sensing** by Stark, Coopmans, and Chen discusses the challenges of UAS integration into the NAS for a class of small UAS for personal remote sensing (PRS). This approach is centered on the three-pillared foundations for NAS integration presented by the U.S. DoD Unmanned Aircraft System Airspace Integration Plan and focuses on the specific challenges that are unique to the PRS UAS platform. This chapter presents a concept of operations for these unmanned aircraft along with an application scenario example and concludes with a discussion of the future use of UAS in the NAS and how it is achievable through adequate regulations and standards.

► **Standards and Certification of a UAS Sense and Avoid Capability** by Zeitlin centers on "certifiable" and "standardized" UAV sense and avoid (SAA) capabilities that are needed to mitigate for the lack of a remote pilot's ability to "see and avoid" other aircraft, which is an operational requirement. Regulators certify the airworthiness of aircraft, assuring their compliance with applicable regulations. Approvals of SAA implementations constitute part of that process. Each applicant needs to develop a Project Specific Certification Plan in close coordination with the regulator. Various tools for safety analysis and configuration control support this effort. Specification of the certification basis for SAA needs close attention, since the system addresses functions traditionally allocated to an onboard pilot. Algorithms and software will receive scrutiny due to their safety roles. Standards are developed to capture common requirements in support of systems that may use some degree of unique design innovation. A standard should suggest means of demonstrating compliance to its requirements, and so doing will greatly simplify the burden for both applicant and regulator. The closest existing standard to SAA is that for the Traffic Alert and Collision Avoidance System II (TCAS II), but SAA includes the additional function of self-separation. SAA can be implemented with various technologies in a variety of architectures. SAA should provide two

basic functions, each performing prescribed subfunctions. Considerable modeling and simulation will be required to validate system performance and support the safety case. The regulator may offer guidance to applicants through publication of an Advisory Circular.

Collectively, this section provides nothing but a “glimpse” of challenges and issues that need to be addressed and solved before unmanned aircraft fly in unison with manned aircraft. Regardless, the information provided in this section is, to some degree, complete and comprehensive allowing for the reader to understand airspace regulation, certification procedures, airworthiness, UAV safety, and reliability.

87.1 Introduction

The need to regulate civil aviation ensuring safety and healthy competition dates back to the 1920s, with several relevant conventions addressing such issues and concerns. The most significant such convention took place in Chicago in 1944, right after the end of the Second World War with more than 50 States attending. The accomplishments of that conference set the groundwork for aviation safety and international cooperation on regulations, standards, and procedures development, all relevant even to this day. Attending States also founded the International Civil Aviation Organization (ICAO) as a means to secure progress accomplished during the conference, as well as to facilitate future cooperation.

Although UAV operations were very limited before the 1944 Chicago Convention, Article 8 refers specifically to pilotless aircraft, and provisions within still apply to current systems. Some of those provisions are that a UAV cannot fly over another State without special authorization by that State (Article 8), UAVs are required to bear registration marks (Article 20), and they must have a certificate of airworthiness (Article 31). It should be noted that the Chicago Convention applies to civil aircraft, and as a result, aircraft used in military or law enforcement services may have different restrictions.

In the United States, aviation regulations are collected and codified in the Code of Federal Regulations (CFR), Title 14, Chap. I, also known as Federal Aviation Regulation (FAR). Similarly, in Europe the Joint Aviation Authorities (JAA) has issued the Joint Aviation Requirements (JAR), while other countries/regions may have other similar regulatory documents. Due to an ongoing effort for harmonization between the aviation regulations, part and section numbers between the JAR and the Title 14 CFR are largely the same.

This chapter presents an overview of key parts of current manned aviation regulations as defined in the Title 14 CFR, with the understanding that the provisions of other aviation regulations of other countries will be similar, if not the same. It should be noted that these regulations are currently applicable to manned aircraft but are more than likely to influence UAV regulations. Where appropriate, the relative section in the Title 14 CFR will be given. The aim of this chapter is to familiarize the reader with the general regulatory framework and with terms and concepts that are used throughout the handbook. For the latest and most accurate information, one is advised to consult with the civil aviation authority of his/her country and the current version of the respective regulations. For example, the Title 14 CFR is publicly available both online and in print from the Government Printing Office.

The main focus of aviation regulation is to ensure that the aviation industry operates in a safe manner. For example, the U.S. Federal Law gives the Secretary of Transportation and the Administrator of the Federal Aviation Administration (FAA) the authority to *conduct investigations, prescribe regulations, standards, and procedures, and issue orders* [49 USC §40113(a)]. The paragraph on safety considerations in public interest [49 USC §40101(d)] reads:

...the Administrator shall consider the following matters, among others, as being in the public interest:

1. assigning, maintaining, and enhancing safety and security as the highest priorities in air commerce.
2. regulating air commerce in a way that best promotes safety and fulfills national defense requirements.
3. encouraging and developing civil aeronautics, including new aviation technology.
4. controlling the use of the navigable airspace and regulating civil and military operations in that airspace in the interest of the safety and efficiency of both of those operations.
5. consolidating research and development for air navigation facilities and the installation and operation of those facilities.
6. developing and operating a common system of air traffic control and navigation for military and civil aircraft.
7. providing assistance to law enforcement agencies in the enforcement of laws related to regulation of controlled substances, to the extent consistent with aviation safety.

The statutory mandate of the FAA also includes regarding safety:

...before authorizing new air transportation services, evaluating the safety implications of those services; and preventing deterioration in established safety procedures, recognizing the clear intent, encouragement, and dedication of Congress to further the highest degree of safety in air transportation and air commerce, and to maintain the safety vigilance that has evolved in air transportation and air commerce and has come to be expected by the traveling and shipping public. [49 USC §40101(a)]

The Title 14 CFR comprises of several subchapters as follows:

- A Definitions (Parts 1–3)
- B Procedural rules (Parts 11–17)
- C Aircraft (Parts 21–50). Includes airworthiness certification (21–39), maintenance (43), as well as aircraft registration and marking (45–49)
- D Airmen (Parts 60–67)
- E Airspace (Parts 71–77)
- F Air Traffic and General Operating Rules (Parts 91–106) which includes operating rules (91–99) and special classes of vehicles (101–105)
- G Air Carriers and Operators for Compensation or Hire: Certification and Operations (Parts 110–139)
- H Schools and Other Certified Agencies (Parts 140–147)
- I Airports (Parts 150–169)
- J Navigational Facilities (Parts 170–171)
- K Administrative Regulations (Parts 183–193)
- N War Risk Insurance (Parts 198–199)

The provisions of the Title 14 CFR notwithstanding, the FAA issues supplementary nonregulatory material like handbooks, orders, Advisory Circulars (AC), and Technical Standard Orders (TSO) that clearly define appropriate procedures, standards, and practices that may be followed to ensure compliance with current regulations. This material helps ensure that aircraft manufacturers and operators are able to establish the minimum level of safety and reliability required for civil operations ASTM International (2004). Nevertheless, the following sections will draw material only from the CFR since the focus of this chapter is on regulatory requirements.

With respect to the ACs, of particular interest are AC 00-2 and AC 00-44. The first provides a checklist of all ACs, as well as the status of other FAA publications, while the second contains a list of any changes made by the FAA to the CFR. The FAA also publishes the Aeronautical Information Manual (AIM), a regularly updated document, mainly aimed at pilots. The AIM contains the basic flight information and procedures when flying in the U.S. National Airspace System (NAS). It consists of the following chapters:

1. Air Navigation
2. Aeronautical Lighting and Other Airport Visual Aids
3. Airspace
4. Air Traffic Control
5. Air Traffic Procedures
6. Emergency Procedures
7. Safety of Flight
8. Medical Facts for Pilots
9. Aeronautical Charts and Related Publications
10. Helicopter Operations

The AIM is supplemented by the International Flight Information Manual (IFIM) which provides information for planning international flights. Other handbooks published by the FAA that might be of interest include the “Airplane Flying Handbook,” the “Helicopter Flying Handbook,” and the “Pilot’s Handbook of Aeronautical Knowledge,” all aimed at pilots, as well as the “Aviation Maintenance Technician Handbook” and the “Aviation Instructor’s Handbook” for technicians and instructors, respectively. These and a number of other documents are available for download from the FAA website free of charge.

Several of the aforementioned documents adopt established standards prepared by government agencies like the U.S. Department of Defense, standards development organizations, as well as other organizations, national or international. A non-exhaustive list of organizations that have been involved with the development of aerospace-related standards is provided below:

- Aeronautical Radio, Incorporated (ARINC)
- American Institute of Aeronautics and Astronautics (AIAA)
- American National Standards Institute (ANSI)
- American Society of Testing & Materials (ASTM)
- American Welding Society (AWS)
- Electronic Industries Alliance (EIA)
- Electrostatic Discharge Association (ESDA)
- European Organization for Civil Aviation Equipment (EUROCAE)
- Institute of Electrical and Electronics Engineers (IEEE)
- Institute of Environmental Sciences and Technology (IEST)
- International Civil Aviation Organization (ICAO)
- International Electrotechnical Commission (IEC)
- International Organization for Standardization (ISO)
- National Aeronautics and Space Administration (NASA)
- National Institute of Standards and Technology (NIST)

- The North Atlantic Treaty Organization Standards Agency (NSA)
- Occupational Safety and Health Administration (OSHA)
- Radio Technical Commission for Aeronautics (RTCA)
- Society of Automotive Engineers (SAE)

87.2 Important Definitions

In this section, some definitions will be provided that are important from a regulatory viewpoint. The first concerns the definition of the term *aircraft*, which according to the ICAO is “... *any machine that can derive support in the atmosphere from the reactions of the air other than the reactions of the air against the earth’s surface*” [ICAO Annex 1, Annex 6 Part I]. The FAA defines an aircraft as “... *a device that is used or intended to be used for flight in the air*” [Title 14 CFR §1.1]. As such, among many other things, UAVs also fall within that definition.

An aircraft can be classified as *public* or *civil*. A public aircraft is defined by the FAA as either “... *an aircraft used only for the United States Government, ... [or] owned and operated by the government of a State, the District of Columbia, or a territory or possession of the United States or a political subdivision of one of these governments*” or “... *an aircraft owned or operated by the armed forces or chartered to provide transportation to the armed forces. ...*,” provided some conditions are met. Civil aircraft are all aircraft that are not public [Title 14 CFR §1.1]. To *operate* an aircraft means “*use, cause to use or authorize to use aircraft, for the purpose of air navigation including the piloting of aircraft, with or without the right of legal control (as owner, lessee, or otherwise)*” [Title 14 CFR §1.1].

Aircraft often operate within *controlled airspace*, that is, “*an airspace of defined dimensions within which air traffic control service is provided to IFR flights and to VFR flights in accordance with the airspace classification*” [Title 14 CFR §1.1]. The *air traffic control service (ATS)* is a “*a service operated by appropriate authority to promote the safe, orderly, and expeditious flow of air traffic*” [Title 14 CFR §1.1]. Another relevant term is *air traffic management (ATM)* which refers to “*the dynamic, integrated management of air traffic and airspace – safely, economically and efficiently – through the provision of facilities and seamless services in collaboration with all involved parties*” (Air Transport Association (ATA) 2008).

The terms *accident*, *incident*, *damage*, and *hazard* are of particular importance when specifying safety requirements. One can find varying definitions for the term *accident*. One of the most succinct used by the FAA is “*An unplanned event or series of events that results in damages.*” (Federal Aviation Administration 2000). The ICAO defines the same term as “*An occurrence associated with the operation of an aircraft which takes place between the time any person boards the aircraft with the intention of flight until such time as all such persons have disembarked, in which (a) a person is fatally or seriously injured as a result of: being in the aircraft; or direct contact with any part of the aircraft, including parts which have become detached from the aircraft; or direct exposure to jet blast (except when the injuries are from natural causes, self inflicted or inflicted by other persons, or when*

the injuries are to stowaways hiding outside the areas normally available to the passengers or crew); or (b) the aircraft sustains damage or structural failure which: adversely affects the structural strength, performance or flight characteristics of the aircraft and would normally require major repair or replacement of the affected component (except for engine failure or damage, when the damage is limited to the engine, its cowlings or accessories; or for damage limited to propellers, wing tips, antennas, tires, brakes, fairings, small dents or puncture holes in the aircraft skin); or (c) the aircraft is missing or is completely inaccessible” [ICAO Annex 13]. On the other hand, incident is defined as “An occurrence, other than an accident, associated with the operation of an aircraft which affects or could affect the safety of operation” [ICAO Annex 13].

The definition of accidents makes use of the term *damage*, which in turn is defined as “... *the severity of injury, and/or the physical, and/or functional, and/or monetary loss that could result if hazard control is less than adequate*” (Federal Aviation Administration 2000).

The term *hazard* refers to conditions that may lead to accidents, regardless of their probability or the severity of the outcome. The FAA differentiates between primary hazards and contributory hazards: “A *primary hazard is one that can directly and immediately results in: loss, consequence, adverse outcome, damage, fatality, system loss, degradation, loss of function, injury, etc. The primary hazard is also referred to as: catastrophe, catastrophic event, critical event, marginal event, and negligible event*” (Federal Aviation Administration 2000). Initiating hazards include events and conditions that start an adverse chain of events that can lead to an accident. Primary hazards are events that directly and immediately cause an accident. Contributory hazards are any kind of conditions that can lead to an accident, including primary hazards.

87.3 Airworthiness Certification

In order for any aircraft to fly legally in the United States, it must carry an airworthiness certificate issued by the FAA [Title 14 CFR §91.203]. Airworthiness certification covers a wide spectrum of areas related to aspects of the aircraft design, construction, and operation. Presented below are some of these areas along with a selection of the various aspects investigated during certification:

Flight: Performance, flight characteristics, controllability, maneuverability, and stability

Structure: Loads, control surfaces, stabilizing and balancing surfaces, and fatigue evaluation

Design and construction: Wings, control surfaces, control systems, landing gear, and pressurization

Powerplant: Fuel system, oil system, cooling system, induction system, exhaust, and control

Equipment: Instruments' installation, electrical systems, lights, and safety equipment

In addition to aircraft, Airworthiness Directives (AD) exist for aircraft engines and propellers.

According to FAA Order 8130.2F, there are two conditions that need be met in order for an aircraft to be considered airworthy; it must conform to its type certificate including any supplemental certificates, and it must be in a condition that ensures safe operation Federal Aviation Administration (2004). For aircraft that are not type certified, compliance with the second condition is adequate. Besides standard certification, Special Airworthiness Certificates (SAC) are also available, usually for experimental or special purpose aircraft.

It should be noted that the Title 14 CFR allows the FAA administrator to prescribe additional requirements and special conditions for aircraft, aircraft engines, or propellers when due to a novel or unusual feature, current airworthiness regulations are inadequate or inappropriate [Title 14 CFR §21.16].

87.3.1 Type Certificate

A type certificate is a collection of documents, drawings, specifications, datasheets and any related information needed to demonstrate compliance with the applicable paragraphs of the Title 14 CFR [Title 14 CFR §21.41]. These may also include inspection and preventive maintenance programs and instructions for continued airworthiness [Title 14 CFR §21.31]. During the application for type certificate, the FAA administrator may require an inspection and test of the aircraft [Title 14 CFR §21.33], which may also include flight tests [Title 14 CFR §21.35].

Once a type certificate has been issued, it is in effect until surrendered, suspended, or revoked [Title 14 CFR §21.51]. Nevertheless, after modifications to an aircraft, a new certificate may be required. When the extend of the changes is not significant, the type certificate can be amended [Title 14 CFR §21.91] or a supplemental certificate will be issued [Title 14 CFR §21.113].

87.3.2 Standard Certificates

Standard airworthiness certificates are given to aircraft that are type certified in any of the categories defined in [Title 14 CFR §21.175], including:

- Normal, utility, acrobatic, and commuter aircraft (Title 14 CFR Part 23)
- Transport aircraft (Title 14 CFR Part 25)
- Normal rotorcraft (Title 14 CFR Part 27)
- Transport rotorcraft (Title 14 CFR Part 29)
- Manned free balloons (Title 14 CFR Part 31)

In addition to the above categories, type certification is available for primary [Title 14 CFR §21.24], restricted [Title 14 CFR §21.25], U.S. Army surplus [Title 14 CFR §21.27] and imported [Title 14 CFR §21.29] aircraft, as well. An overview of the applicability requirements for each of the aforementioned categories is given in Table 87.1.

Table 87.1 Aircraft types with standard airworthiness certificates along with occupancy, weight, and other restrictions (compiled from information in the Title 14 CFR)

| Category | Max. seats | MTOW (kg) | Notes |
|-----------------------------------|------------------|-----------|---|
| Normal | ≤9 ^a | ≤5,670 | Non-acrobatic operations |
| Utility | ≤9 ^a | ≤5,670 | Limited acrobatic operations |
| Acrobatic | ≤9 ^a | ≤5,670 | No restrictions |
| Commuter | ≤19 ^a | ≤8,600 | Non-acrobatic operations |
| Transport | N/A | N/A | |
| Primary | ≤4 ^b | ≤1,225 | Limited power/unpressurized cabin |
| Restricted | N/A | N/A | Special purpose operations ^c |
| Normal rotorcraft | ≤9 ^a | ≤3,175 | |
| Transport rotorcraft ^d | ≤9 ^a | ≤9,070 | |
| Manned free balloons | N/A | N/A | |

^aExcluding pilot seats^bIncludes the pilot^cIncludes agricultural, forest and wildlife conservation, aerial surveying, patrolling, weather control, and aerial advertising operations^dTransport rotorcraft are type certificated in two categories (A and B). Rotorcraft that meet the above restriction may be certificated in the B category, while those with higher seating capacity must be certificated in the A category

87.3.3 Special Certificates

In FAA Order 8130.2F and for aircraft that do not meet requirements for a standard certificate but are still capable of safe flight, SAC are available. More specifically special certificates can be given in the primary [Title 14 CFR §21.184], restricted [Title 14 CFR §21.185] and limited [Title 14 CFR §21.189] categories, for aircraft type certificated under these categories. In addition to that, SACs are available for aircraft belonging to the light-sport category and for experimental aircraft. Finally special flight permits are also available.

87.3.3.1 Light-Sport

FAA Order 8130.2F also provides rules for certification of light-sport Aircraft (LSA). This category is for aircraft other than helicopters that do not exceed 600–650 kg, having a maximum speed of not more than 120 knots and a capacity of not more than two persons. Additional requirements are made based on the presence of certain equipment.

A SAC is issued for aircraft of this type after successful inspection of the aircraft and its documentation. The latter includes operating instructions and maintenance procedures and a statement from the manufacturer that the aircraft complies with the provisions of the appropriate consensus standards [Title 14 CFR §21.190]. Upon successful completion of the inspection, the FAA may amend the certificate with operational restrictions, if deemed necessary.

87.3.3.2 Experimental

Experimental certificates are given for a variety of purposes [Title 14 CFR §21.191]:

- Research and development of equipment, operating techniques, or new aircraft designs.
- Showing aircraft compliance with a type certificate or a supplemental certificate after major changes.
- Crew training.
- Exhibitions at air shows or movies. This includes required pilot training and flight from and to the exhibition area.
- Air racing, including practicing and flight from/to the area.
- Market surveys, sales training and customer flight crew training.
- Operating of amateur-built aircraft.
- Operating of primary kit-built aircraft that have not been assembled under the supervision and control of a production certificated entity.
- Operation of certain types of light-sport aircraft.

Before a special certificate in this category is issued, the applicant must submit appropriate documentation. In the case of aircraft used for research and development purposes, this documentation includes the purpose of the experiment along with the number of flights, the location, and drawings/photographs of the aircraft [Title 14 CFR §21.193]. FAA Order 8130.2F makes provisions for several operational restrictions for experimental aircraft depending on their characteristics. The duration of experimental certificates is 1 year or less except for kit-built aircraft that typically do not expire [Title 14 CFR 21.181].

87.3.3.3 Special Flight Permits

These permits are given to aircraft that would not qualify for other airworthiness certificates but are capable of safe flight [Title 14 CFR §21.197]. The purpose of these permits is to allow the aircraft to fly to a different location for storage, repairs, and maintenance or to avoid areas of impending danger. The permit is issued after an application where the purpose and characteristics of the flight are detailed, and it may include limitations or special instructions from the FAA [Title 14 CFR §21.199].

Special flight permits may also be given for airworthy aircraft, to allow them to fly with excess fuel weight, beyond their certificated capacity or when flying over areas where refueling is not possible [Title 14 CFR §21.197].

87.4 Special Aircraft Categories

Although normally all aircraft need either a standard or a SAC to fly, there is a category of aircraft (classified as vehicles in the Title 14 CFR) for which this requirement is waived. The other special category concerns remote-controlled (R/C) model aircraft that also operates under few restrictions. Although not mentioned in the

Title 14 CFR, R/C aircraft are of interest since they present the basis of many UAS designs. It should be stressed however that R/C models are allowed to operate only for recreational purposes and that in the Federal Aviation Administration (2007) it was made clear that UAS operations cannot be based on R/C model procedures.

87.4.1 Vehicles

This category of aircraft includes moored balloons, unmanned balloons, unmanned rockets defined in Title 14 CFR Part 101, and ultralights defined in Title 14 CFR Part 103. Ultralights are single-occupant, manned aircraft used for recreation or sport purposes only, with a maximum empty weight of 70 kg for unpowered and 115 kg for powered vehicles [Title 14 CFR §103.1].

Many of the requirements regarding pilot certification, operating and flight rules, vehicle registration and marking, and maintenance certification, including the requirement to carry an airworthiness certificate that are normally applicable to aircraft, are waived for this category. Nevertheless, operational restrictions may be in place.

For example, the following pertain to the operation of ultralight vehicles:

- Daylight operations only [Title 14 CFR §103.11].
- Yield the right-of-way to all aircraft [Title 14 CFR §103.13].
- No operations allowed over congested areas [Title 14 CFR §103.15].
- No operations allowed in Class A, B, C, and D airspace. For operations in Class E near airports, ATC authorization is required first [Title 14 CFR §103.17].
- Pilot must operate by visual reference with the surface [Title 14 CFR §103.21].

87.4.2 R/C Models

Model airplanes are regulated on a voluntary basis, based on AC91-57 with few operational restrictions. In addition to that an independent organization, the Academy of Model Aeronautics (AMA) issues normal or restricted flight permits after inspection of the model, provides insurance for its members, and organizes areas to safely practice aeromodeling. It is noteworthy that in Academy of Model Aeronautics (2007), restrictions additional to the ones in FAA AC91-57 are imposed, both in design (e.g., the weight of the models and their propulsion methods) as well as in operation.

87.5 Pilot Certification

Title 14 CFR Part 61 is involved with the requirements for issuing pilot, flight instructor, and ground instructor certificates, ratings, and authorizations [Title 14 CFR §61.1]. An appropriate pilot certificate is required for a person to assume the role of pilot in command or of required crew member [Title 14 CFR §61.3]. Some

Table 87.2 Pilot certificates summarized from [Title 14 CFR §61.5]

| Category | Class |
|-------------------------------|------------------------------------|
| Airplane | Single-engine land |
| | Multiengine land |
| | Single-engine sea |
| | Multiengine sea |
| Rotorcraft | Helicopter |
| | Gyroplane |
| Lighter-than-air | Airship |
| | Balloon |
| Weight-shift-control aircraft | Weight-shift-control aircraft land |
| | Weight-shift-control aircraft sea |
| Powered lift | N/A |
| Powered parachute | Powered parachute land |
| | Powered parachute sea |

operators are also required to possess a current medical certificate issued based on procedures described in Title 14 CFR Part 67.

There are several types of pilot certificates with different training and certification requirements and with different privileges for their holders [Title 14 CFR §61.5]:

- 1. Student pilot
- 2. Sport pilot
- 3. Recreational pilot
- 4. Private pilot
- 5. Commercial pilot
- 6. Airline transport pilot certificate

Each pilot certificate (with the exception of a student certificate) comes with ratings for aircraft categories, classes, and types the holder may operate as well as the instrument rating for private and commercial pilots. Table 87.2 summarizes the aircraft category and class ratings. There are also instrument ratings for airplanes, helicopters, and powered lifts [Title 14 CFR §61.5].

Similar ratings are placed on flight instructor and ground instructor certificates when all the training and certification requirements are met.

Title 14 CFR Part 61 also includes the level of knowledge, training, operations proficiency, and experience a pilot must possess before being issued a certificate. This includes training and testing procedures. Title 14 CFR Part 63 is involved with certification of crew members other than pilots and Title 14 CFR Part 65 with airmen certification.

87.6 Operation Rules

Operational rules for manned aircraft operating in the U.S. NAS are prescribed in Title 14 CFR Part 91, which applies to all aircraft with the exception of moored balloons, kites, unmanned rockets, unmanned free balloons, and ultralights

[Title 14 CFR §91.1]. Part 91 also establishes the responsibility for aircraft operators to support the continued airworthiness of each airplane [Title 14 CFR §91.1].

The person ultimately responsible for the operation of the aircraft is the pilot in command [Title 14 CFR §91.3]. The pilot is also responsible for evaluating the airworthiness of the aircraft and determining if it is in a condition safe to fly [Title 14 CFR §91.7]. After the aircraft has been deemed safe to fly and before takeoff, the pilot needs to be familiar with any information concerning the flight, such as weather reports, fuel requirements, airport characteristics, and aircraft performance characteristics [Title 14 CFR §91.103].

To minimize the risk of collisions, no person is allowed to operate an aircraft in close proximity to another [Title 14 CFR §91.111], and when the weather conditions permit, the pilot should be alert in order to *see and avoid* other aircraft [Title 14 CFR §91.113]. Additionally right-of-way rules are established [Title 14 CFR §91.113]. With the exception of water operations, typically the aircraft with less maneuverability has the right-of-way. This rule is superseded when an aircraft is in distress, at which time it has the right-of-way with respect to all other air traffic. In general during emergencies pilots are allowed to deviate from the requirements of Part 91, even contrary to ATC instruction, provided that Air traffic control (ATC) is notified of this deviation as soon as possible [Title 14 CFR §91.3, §91.123]. In any other situation, no one is allowed to deviate from ATC clearance and instructions [Title 14 CFR §91.123].

Additional safety regulations do not permit pilots to fly below 10,000 ft or in proximity of Class B, C, and D airspace at speeds exceeding 250 and 200 knots, respectively [Title 14 CFR §91.117]. Similarly, minimum safe altitudes are established so that upon catastrophic failures, an emergency landing can take place without undue risk to people or property [Title 14 CFR §91.119].

87.6.1 Flight Rules

Title 14 CFR Part 91 defines two types of flight rules: visual flight rules (VFR) and instrument flight rules (IFR). In addition to the normal operations, Title 14 CFR Part 91 includes guidelines for emergencies as well as special operations like aerobatics, towing, and parachuting.

87.6.1.1 Visual Flight Rules

Under VFR the pilot is expected to control the aircraft's trajectory and avoid other aircraft based on visual cues, although separation instruction may be provided by ATC when flying in certain classes of controlled airspace.

A prerequisite to flying under VFR is the presence of enough fuel onboard, so that the aircraft can reach its first landing destination and fly for 30 min or 45 min after that during the day or night, respectively [Title 14 CFR §91.151]. Similar requirements exist on the flight altitude and weather conditions [Title 14 CFR §91.155]. The minimum weather conditions for VFR operations are summarized in Table 87.3.

Table 87.3 Weather minimums for VFR operations (Source: [Title 14 CFR §91.155])

| Airspace | Visibility (statute miles) | Distance from clouds | | |
|---|-------------------------------|----------------------|----------|--------------|
| | | Above | Below | Horizontal |
| Class A | N/A | N/A | | |
| Class B | 3 | Clear of clouds | | |
| Class C | 3 | 1,000 ft | 500 ft | 2,000 ft |
| Class D | 3 | 1,000 ft | 500 ft | 2,000 ft |
| Class E (<10,000 ft) | 3 | 1,000 ft | 500 ft | 2,000 ft |
| Class E (≥10,000 ft) | 5 | 1,000 ft | 1,000 ft | 1 stat. mile |
| Class G (day, ≤1,200 ft) | 1 | Clear of clouds | | |
| Class G (day, >1,200 ft and <10,000 ft) | 1 | 1,000 ft | 500 ft | 2,000 ft |
| Class G (night, <10,000 ft) | 3 | 1,000 ft | 500 ft | 2,000 ft |
| Class G (≥10,000 ft) | 5 | 1,000 ft | 1,000 ft | 1 stat. mile |

The information required when filing a VFR flight plan includes, besides the aircraft and pilot identification data, the point and time of departure, the route, altitude and airspeed, the amount of fuel onboard, and the point and time of arrival [Title 14 CFR §91.153].

87.6.1.2 Instrument Flight Rules

Flight under IFR is subject to similar restrictions in terms of fuel availability [Title 14 CFR §91.167], but in addition to that the presence of an operational and properly maintained VHF omnidirectional range (VOR) radio navigation system is also required [Title 14 CFR §91.171].

In order to operate IFR in controlled airspace, the pilot must first submit an IFR flight plan and receive appropriate ATC clearance [Title 14 CFR §91.173]. Once in controlled airspace, the pilot is required to monitor the appropriate communication frequency and report to ATC when she/he reaches predetermined points, encounters unforecast weather conditions, or other problems that may affect flight safety [Title 14 CFR §91.183].

87.6.2 Emergency Rules

In the case of disasters, the FAA administrator can issue a Notice to Airmen (NOTAM) designating an area within which temporary flight restrictions apply [Title 14 CFR §91.137]. In this case, no aircraft can enter the designated area except for aircraft participating in hazard relief, carrying law enforcement officials or any other category specified in [Title 14 CFR §91.137].

The FAA can also use the NOTAM system to issue new emergency traffic rules or regulations, whenever conditions for safe operations under normal rules are or will not be sufficient [Title 14 CFR §91.139].

87.6.3 Maintenance Requirements

The person responsible for the maintenance of the aircraft is either the owner or the operator who may not operate the aircraft unless the inspection and replacement intervals as well as any other prescribed maintenance procedures have been complied with [Title 14 CFR §91.403]. More specifically an annual inspection is required along with an inspection for the issuance of an airworthiness certificate [Title 14 CFR §91.409]. Additional inspections may be required for other types of aircraft.

After any maintenance procedure, the aircraft must be approved to return to service by an authorized person and the maintenance record has been updated [Title 14 CFR §91.407]. In some cases, an operational inspection by a pilot with adequate rating may be required [Title 14 CFR §91.407].

In addition to that, Title 14 CFR Part 91 requires operators to “support the continued airworthiness” of each airplane, by revising the inspection schedule, incorporating any design changes and revisions to the instructions for continued airworthiness [Title 14 CFR §91.1501].

87.7 Airspace Classes

Depending on the altitude and proximity to airports, the NAS is segregated into several classes as shown in Fig. 87.1. For each airspace class, different operating rules may be in effect, based on the stipulations of Title 14 CFR Part 91.

Classes A through E, ordered from most restrictive to less restrictive, correspond to controlled airspace. Wherever different airspace classes overlap, the most restrictive designation applies [Title 14 CFR §71.9].

Airspace between 18,000 ft above mean sea level (MSL) to about 60,000 ft belongs to the Class A airspace [Title 14 CFR §71.33]. Class A airspace is reserved for IFR traffic and an aircraft needs to receive ATC clearance before entering [Title 14 CFR §91.133]. There are also requirements for communication and transponder equipment.

Classes B [Title 14 CFR §71.51] and D [Title 14 CFR §71.61] include the airspace above and around airports of different sizes. They are designed to include traffic from/to the airport and ensure appropriate separation. In order to operate an aircraft in Class B airspace, ATC clearance is required from the facility controlling that area, and the pilot must possess at least a private pilot certificate although exceptions exist for other pilot certificates when specific requirements are met [Title 14 CFR §91.131]. In addition to the above, the aircraft needs to be equipped with appropriate communications and navigation equipment as well as an operating transponder [Title 14 CFR §91.131].

Requirements for operations in Class C and D airspace are similar, although more relaxed. In general, an aircraft entering these classes of airspace must establish

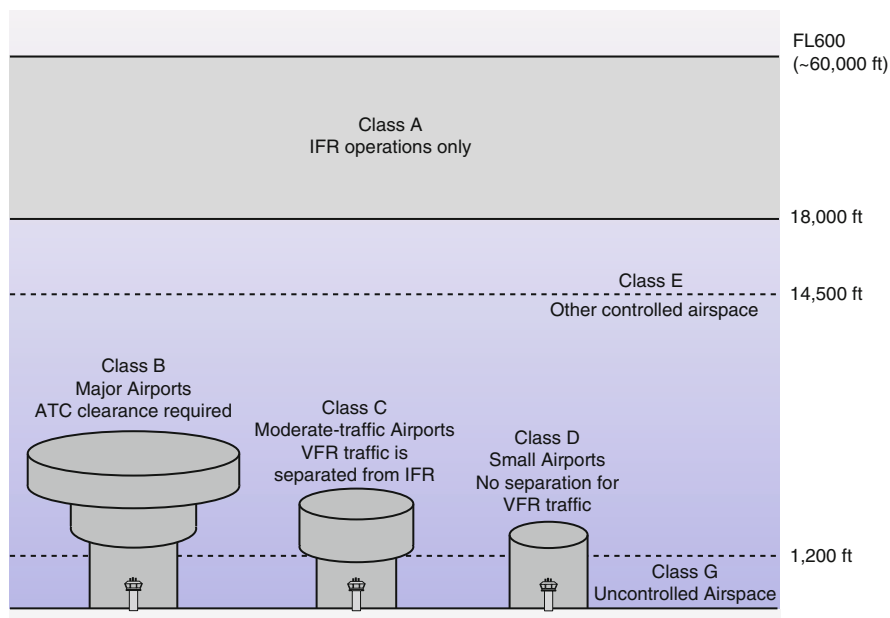

Fig. 87.1 Overview of the NAS classes. This figure depicts only a general view of the airspace classes. For the accurate extends of each airspace class, the reader is referred to the latest FAA Order 7400.9

and maintain communications with ATC while within that airspace, regardless of whether it is arriving or being only through traffic [Title 14 CFR §91.129, §91.130].

Finally, Class E corresponds to the rest of the controlled airspace. It includes the airspace from 14,500 ft up to the Class A boundary, as well as the airspace above 60,000 ft [Title 14 CFR §71.71]. In the vicinity of airports, class E airspace may extend down to the surface. Similarly in the proximity of federal airways, Class E airspace extends upwards from 700 or 1,200 ft above ground level. In the vicinity of an airport in Class E airspace, the pilot must establish two-way radio communication with ATC, although in the case of radio failure landing is still allowed, provided that VFR conditions exist, visual contact with the tower is maintained, and a clearance to land has been received [Title 14 CFR §91.127].

The last class is Class G airspace, which normally includes the space up to 1,200 ft above the ground but can be up to 14,500 ft. Although Class G airspace is also known as uncontrolled airspace, operating rules do apply. Helicopters and aircraft flying below 1,200 ft should typically operate clear of clouds and at speeds that allow the pilot to see and avoid other traffic as well as any obstructions on the ground [Title 14 CFR §91.155]. In the vicinity of airports, two-way radio communication with ATC must be established, and in addition to that, all turns must be made to the left, unless the airport indicates the opposite [Title 14 CFR §91.126].

Other restrictions may also be in effect depending on the type of the aircraft, such as avoiding crowded areas and noise limits.

Every year the FAA publishes a revised Order 7400.9, which includes the current airspace designations for the U.S. NAS.

87.8 Regulation Development Models

The traditional model of regulation development has been based on sufficiently mature technologies for which standards had been developed and possibly implemented. The regulatory body, in this case the FAA, undertakes the task of assessing the technology and standards available and develops appropriate regulations. Because of the aforementioned requirements, this process is slow, costly, and in some cases counterproductive since developed technology and standards are not necessarily adopted.

In March of 1996, the U.S. Congress recognizing the need to advance cooperation between industry and the Federal Government, signed Public Law 104–113, also known as the National Technology Transfer and Advancement Act of 1995. Section 12(d)(1) reads:

Except as provided in paragraph (3) of this subsection, all Federal agencies and departments shall use technical standards that are developed or adopted by voluntary consensus standards bodies, using such technical standards as a means to carry out policy objectives or activities determined by the agencies and departments.

This “industry consensus” model was recently used for the regulation of the LSA category. In this case, the FAA participated actively in the development of standards, and as a result, these standards were immediately incorporated into the regulatory framework upon publication. This approach is faster and more cost-effective, since the burden of drafting the standards is mostly with the industry. In addition to that, conformance with the standard is self-regulated and FAA involvement is limited to oversight and penalizing nonconformance, thus further reducing the cost to the Federal Government. More information about this model can be found in Anand (2007).

Regardless of the regulation model, another key characteristic of regulation development is the basis of the airworthiness certification. As discussed by Haddon and Whittaker (2002), military systems have been traditionally evaluated under a safety target approach. In this case, the aircraft is designed and operated with a particular role and operating environment in mind, and the airworthiness certification includes appropriate operational restrictions to ensure that an adequate level of safety is achieved.

According to manned aviation regulations, airworthiness is based on compliance with a code of requirements. This approach has the advantage of no interlinking between airworthiness and operation, facilitating a variety of applications as well as interoperability. Nevertheless, special safety targets are also included to evaluate new technologies or designs, not covered by existing code. These can be found in

paragraph 1309 of current Certification Specifications (CS) or the corresponding Acceptable Means of Compliance (AMC) sections.

Abstract

The purpose of this chapter is to identify human factors challenges to integrating Unmanned Aircraft Systems (UASs) in the National Airspace System (NAS), for both pilots and air traffic controllers. The method for identifying these challenges

B. Kaliardos (✉)
Federal Aviation Administration, Washington, DC, USA

was primarily based on the differences or “gaps” between manned aircraft in the NAS today and the unique aspects of UASs. The goal is not to generate a comprehensive list of human factors issues, but to focus on those that are traceable to fundamental characteristics of UASs (primarily due to the UAS pilot being physically remote from the aircraft) and that are also considered challenging with respect to the current NAS and its regulatory framework.

Current UAS designs do not generally emphasize NAS integration considerations, and approvals for airworthiness and operations are based on special operational limitations determined on a case-by-case basis. This chapter assumes that, for integration into the NAS, future UASs will be much more standardized in many respects than in the past – closer to that of today’s civil manned aircraft, which are subject to rigorous design, operational, manufacturing, and training approvals by the Federal Aviation Administration (FAA). Under such assumptions, human factors is not only central to the very definition of UAS but is also central to some of the most important challenges facing the integration of UAS in the NAS.

The human factors gaps are discussed in two parts. The chapter first addresses human factors for pilot operations at the control station covering the loss of natural sensing, control loop degradation, link monitoring, automation, and information formats. The chapter then addresses human factors for air traffic controllers, which covers aircraft performance and missions, visual instructions, lost-link predictability and procedures, communications, workstation information, and detection of small-size aircraft.

88.1 Introduction

Human factors (HF) entails a multidisciplinary effort to generate and compile information about human capabilities and limitations and apply that information to equipment, system facilities, procedures, jobs, environments, training, staffing, and personnel management for safe, comfortable and effective human performance (Federal Aviation Administration, Order 9550.8). When the human is a functional element within a larger system such as the National Airspace System (NAS), human factors is important in overall system performance such as safety and efficiency of aircraft operations. In this chapter, “human-system integration” (HSI) is used interchangeably with “human factors,” but the discussion here is primarily limited to equipment and procedures.

For Unmanned Aircraft Systems (UASs), the question often arises: “How can there be human factors for an aircraft that does not have a human onboard?” While it is true that the human is not physically integrated with the aircraft, the human is functionally integrated with the aircraft and, in fact, physically integrated with the unmanned aircraft *system*. That system typically comprises of the unmanned aircraft (UA), control station, and control/communication (C2) links. Therefore,

human factors is an important part of UAS design and operation, particularly when considering integration with the NAS.

In this chapter, “integration” in human-system integration applies to two conditions of humans (H) and systems (S):

- When the S in HSI refers to UAS and the H refers to the pilots
- When the S in HSI refers to NAS and the H refers primarily to the pilots and/or air traffic controllers (ATC)

UAS in the NAS can therefore be considered as a system of systems, in which multiple humans are functional elements.

The perspective presented here focuses on civil UAS with minimum operational restrictions, unlike the current environment. Today, public operators (such as the military services) versus civil operators dominate UAS operations in the NAS with an emphasis on mission effectiveness in segregated airspace. Furthermore, much of the near-term growth of civil UAS is expected for UAs that are smaller than manned aircraft and with strict operational limits such as line-of-sight control. However, it is assumed here that the true integration of UASs in the NAS will be based on nonsegregated airspace with minimum operational restrictions. This would present unique human factors challenges that are driven primarily by safety of the flying and nonflying public and workload for air traffic controllers, but constrained by manned aircraft operations, air traffic services, certification services, etc. FAA policy (e.g., Notices 8900.227, 7210.846), Civil UAS Integration Roadmap, and Concept of Operations (draft) describe similar assumptions, scope, and other relevant background information in more detail.

The “lessons learned” from UAS so far (e.g., accident statistics, air traffic control experience) are relevant, but need to be carefully treated because they do not necessarily represent tomorrow’s UAS. It is expected that future UAS integration into the NAS will be accomplished not on a case-by-case basis (such as with today’s Certificate of Authorizations or Special Airworthiness Certificate – Experimental Category), but likely through the development and application of standardization. That is, future UASs are expected to be much more standardized in many respects than in the past – closer to that of today’s civil manned aircraft, which are subject to rigorous design, operational, manufacturing, and training approvals by the FAA and based upon a combination of federal regulations, policy, guidance material, and industry standards.

Nevertheless, UAS approvals will still be different in many respects than manned aircraft due to fundamentally unique characteristics of UAS design and architecture. The fundamental differences – the “gaps” – between UAS and manned aircraft provide a basis for understanding the human factors challenges for UAS integration in the NAS.

There is much to understand to effectively integrate UASs into the NAS, and a good starting point is to describe the potential gaps between what is known about manned aircraft and operations and what is expected for UASs. While similar UAS human factors analyses have been done in the past (e.g., McCarley and Wickens 2005), the gaps presented here are primarily from the FAA regulatory guidance, and

policy perspective. The remainder of this chapter is organized around these gaps and presented in two parts: pilot operations at the control station and air traffic control.

88.2 Pilot Operations at the Control Station

The first category of UAS human factors considerations pertains to pilot operations at the control station. For current approvals, FAA policy (e.g., Interim Operational Approval Guidance 2008, Notices 8900.227 and 7210.846) specifies a “pilot” or “pilot in command” that is responsible for the UAS flight operation, which is referred to here for brevity as the UAS “pilot.” The control station provides the interface between the pilot and aircraft, as well as between the pilot and other UAS and NAS elements.

88.2.1 Gap: Loss of Natural Sensing

Pilots of unmanned aircraft possess an awareness of the aircraft and operation that is qualitatively different from manned aircraft, and a key reason for this is because pilots are not colocated with the UA and therefore not able to naturally sense the aircraft and its local environment. To naturally sense means to use physiological senses (visual, aural, tactile, proprioceptive, vestibular, etc.) to perceive information directly, without the aid of technology such as artificial sensors and displays. Information is sensed “locally” in that pilots unaided by technology only see and hear, for example, within a limited volume around them. For manned aircraft pilots, examples of naturally sensed information include aircraft orientation and turbulence through “seat of the pants” flying, engine power through aural and tactile sensing, and traffic and terrain through viewing out the windshield. For unmanned aircraft pilots, locally sensed information (near the control station) is of limited value, even with direct line-of-sight of the UA. Although technology can mitigate and sometimes enhance certain information, the fact remains that unmanned aircraft pilots simply do not use their natural senses in the same way as manned aircraft pilots.

88.2.1.1 Loss of Natural Vision

Natural vision may be the most critical difference between manned and unmanned aircraft pilots. For example, for manned aircraft, the aircraft windshield is critical for natural vision. Title 14 of the Code of Federal Regulations (14 CFR) 25.773 states, “Each pilot compartment must be arranged to give the pilots a sufficiently extensive, clear, and undistorted view, to enable them to safely perform any maneuvers within the operating limitations of the airplane, including taxiing takeoff, approach, and landing” (see also 14 CFR 23.773). Natural vision can be used in a variety of important pilot tasks, such as to detect and assess environment states (e.g., traffic, terrain and obstacles, foreign objects, weather) and aircraft states (e.g., orientation,

speed, icing, engine flameouts). Guidance on windshield criteria for visibility such as field of view and optical properties are provided in FAA Advisory Circular (AC) 25-773-1, for example. UAS compensatory strategies such as aircraft cameras (visible spectrum) might provide some level of equivalency to meet the applicable equipment and operational pilot visibility requirements, but so far such equivalency, means of compliance, or new regulations remain to be determined. The problem is complicated by data link bandwidth limits, which can constrain field of view (instantaneous and overall), resolution, latency, frame rate, etc. In short, in the absence of natural vision of an onboard pilot, UAS currently cannot comply with Visual Flight Rules (VFR) or comply with any clearance that includes a visual component.

Even in instrument flight rules (IFR) there are many visual operations. Manned aircraft pilots are required to see certain features when operating on or near the surface. For example, 14 CFR 91.175 is an operational regulation, which includes requiring that visual references such as the approach light system, runway, and threshold are distinctly visible and identifiable to the pilot when operating below specified altitudes. Pilots of UAs obviously cannot look directly through the windshield for visual identification, but technologies may be able to provide compensatory alternatives for safe operation in which pilots rely solely on artificial sensing and displays. In fact, manned aircraft today make use of enhanced flight vision systems (EFVS) to provide supplemental information to receive operational approvals for landing in lower visibility conditions, but only with displays such as HUDs that *complement* natural vision with the pilot seated in a normal position and line of vision and looking forward along the flight path. (Under 14 CFR 91.175(l), a pilot may use an approved EFVS to descend below decision altitude (DA) or minimum descent altitude (MDA) to 100 feet above the touchdown zone (TDZ) elevation (TDZE) from a straight-in instrument approach procedure (IAP) other than category II (CAT II) or category III (CAT III).) An EFVS uses imaging sensing technologies, such as in the long-wavelength spectrum (e.g., infrared, microwave) to provide a real-time enhanced image of the external scene topography to the pilot. For manned aircraft, EFVS operations are proof that electronic imaging can be used beyond “situation awareness” (which is what would be needed for UAS), but only in the context of clearly defined procedures that are based on natural vision.

Similarly, some manned aircraft also have installed synthetic vision systems (SVS), which utilize a terrain and obstacle database that is accessed and displayed according to real-time aircraft position and attitude data. Although SVS has not yet enabled operational credit, such concepts continue to be discussed. As with EFVS, critical to these discussions is also how SVS is used by pilots that can also view the external scene through a windshield.

Both EFVS and SVS are relatively new technologies for manned aircraft, and they may offer lessons for compensatory information for UA operation. However, the use of real or synthetic images as a replacement versus a complement to natural vision presents many challenges for integrating UAS in the NAS. Many other related NAS integration challenges will likely be encountered, such as those mentioned for standard non-enhanced visible spectrum imaging (e.g., field of view, camera and

display resolution, image latency), as well as database integrity, and procedures for normal and non-normal conditions. For more information on EFVS and SVS, see AC 90-106 and AC 20-167.

88.2.1.2 Loss of Nonvisual Sensing

Another consequence of the UA pilot's inability to use natural senses involves the nonvisual senses. While visual modalities often involve focused attention, such as in a pilot's sequential instrument scan, other senses offer the advantage of acquiring information without such directed attention. For example, in manned aircraft, engines create background noise that is often simple to detect when it changes, as in a loss of power. Likewise, turbulence moves and orients the (aircraft and) pilot, with naturally salient cues to their vestibular, haptic, and proprioceptive senses to detect orientation, force, and position. Vibration and buffeting can adversely affect pilot fatigue and control but can also provide valuable flight envelope cues (e.g., as described in 14 CFR 23.251). These examples illustrate how natural sensing can be effective for easily detecting certain manned aircraft conditions, which, for UAs, is practically impossible without artificial means. Compensatory technologies include the reproduction of, say, aural cues, motion/vibration, and control force feedback at the control station. The same information can also be represented visually on a display, but such displays can add to visual overload, and the effectiveness of reproducing non-visual aircraft cues visually at the control station remains to be determined. These issues need further investigation to determine the nature and quality of information required at the UA control station.

The consequences of UA pilots not being able to directly sense the aircraft and its environment depend on the type of operations and the compensatory technologies used at the control station and the aircraft (Williams 2008). Flying manned aircraft in the NAS currently is based on regulations, guidance, and standards that were developed with the assumption that pilots are able to obtain important information, visual and otherwise, through natural sensing of the aircraft and its local environment. A challenge for integrating UAS in the NAS is to develop a new or modified basis to account for the loss of this naturally sensed information.

88.2.2 Gap: Control Loop Degradation: Data Dropouts

In the feedback control of aircraft, pilots provide a variety of system inputs and receive feedback on their effects. The focus in this section is on flight control. However, the human factors effects of control loop degradation apply to other systems as well.

The UAS control function through the wireless data link is inherently less reliable than the direct hardwired links used in manned aircraft. Link degradation can occur in both paths of the feedback control loop: (a) downlinked "feedback" information to the control station displays and (b) uplinked "control" information to the aircraft. While both information components often degrade simultaneously, each may also degrade separately. Furthermore, degradation is often in the form of relatively short

intermittent periods or “dropouts,” which is the focus of this section. Link failures of relatively long duration, in which the aircraft is in autonomous “lost-link” mode, are discussed in other sections of this chapter, such as Sects. 88.2.5 and 88.3.3.

88.2.2.1 Feedback, Downlinked Portion

The extent of control loop degradation is a unique issue with UAS. For comparison, it is worth mentioning that degradation does occur to some degree in the manned aircraft equivalent. In particular, for the feedback “information” portion of the control loop, even hardwired display systems can potentially suffer from data dropouts, whether due to the sensor, data bus, processing, or display systems.

However, *wireless* feedback control loops introduce UAS flight control issues never before experienced with manned aircraft. Consider the downlinked or telemetry portion, in which sensor and other data collected at the UA are transmitted to the control station, for processing by computers or humans. In today’s UAS, it is common for short dropouts to occur (Williams 2008). To address this, current UAS architectures and operations reduce the likelihood of intermittent dropouts to noncritical flight phases, such that the highest reliability is achieved during critical phases such as takeoff and landing. However, operation-specific system behavior such as primary flight displays that depend on the phase of flight might be unacceptable, based on, for example, 14 CFR 23.1301 and 23.1309. It remains to be determined what will be acceptable for UAS.

Existing guidance that could possibly apply to UAS data dropouts in the feedback portion of the control loop include AC 25-11A, which provides display-related system safety guidelines:

There should be a means to detect the loss or erroneous primary flight information, either as a result of a display system failure or the failure of an associated sensor. When loss or malfunction of primary flight information is detected, the means used to indicate the lost or erroneous information should ensure that the erroneous information will not be used by the flight crew (for example, removal of the information from the display or placement of an ‘X’ through the failed display).

The above guidance was likely written under the assumptions of infrequent occurrence of data dropouts and with backup standby displays and complementary views out the window. For UAS, the occurrence of dropouts, their indication, and the procedures to accommodate them will need to be developed, factoring in the likely reduced availability of backup or secondary sources to provide similar information (which might use the same link). Additionally, transitions between good data and stale data at the control station (e.g., “freezing and unfreezing” the displays) will add more challenges to the effects of degradation of the feedback portion of the control loop.

88.2.2.2 Control, Uplinked Portion

For the uplinked portion of the control loop, manned aircraft operation does not provide a useful analogy from direct control links, whether mechanical, hydraulic, or fly-by-wire. All manned aircraft applicants complying with 14 CFR 2x.1309 (part 23, 25, 27, 29) must show that “the occurrence of any failure condition which

would prevent the continued safe flight and landing of the airplane is extremely improbable.” It is unclear how the UAS control uplink will be treated from a system safety perspective relative to manned aircraft control systems. UAS will likely require entirely new policy to accommodate control uplink dropouts, covering a wide range of human factors areas such as:

- Prediction of control uplink dropouts
- Indication and alerting of control uplink dropouts
- Distinguishing feedback (downlink) dropouts from control uplink dropouts
- Control uplink dropout transitions between fully functional and degraded link
- Aircraft automation behavior during control uplink dropouts

Aircraft automation behavior is particularly critical, not only for appropriate behavior during fully automated periods, but also during intermittent dropout periods. Aircraft automation behavior also affects air traffic controllers (see Sect. 88.3.3 in this chapter).

88.2.3 Gap: Control Loop Degradation – Latency

Latency in the control loop can be problematic in both manned aircraft and UAS, but for different reasons. In the manned aircraft control loop, for example, latencies did not present challenges until the incorporation of automation and computers in control systems. These introduced small signal delays in various ways, including filtering, processing, and networking. Manned aircraft simulators were especially prone to time delays in the presentation of electronic visual imagery. From the human factors perspective, time delays can lead to increased workload, larger flight technical errors, and control instability due to what is commonly known as pilot-induced oscillation (PIO) or aircraft-pilot coupling (APC). Generally, time delay effects in manned aircraft control are well-understood problems in the context of defined physical attributes (aerodynamics, mass distribution), control tasks (e.g., landing), control system design (e.g., gain), and disturbances (e.g., crosswinds). Therefore, regulations such as 14 CFR 2x.143 and flight test procedures such as those described in AC 23-8C and AC 25-7B address overall aircraft controllability and stability, but not the specific role of latency effects.

Unmanned aircraft introduce a new regime of control loop latency due to the wireless link. Two classes of wireless links can be considered for simplicity, each at opposite latency extremes: line-of-sight and satellite. Line-of-sight links produce the smallest time delays (usually less than a few tenths of a second) with signal transport delays accounting for a negligible contribution to the total delay. However, line-of-sight operations are limited in the distance between control station and aircraft. For beyond-line-of-sight, satellite links produce the largest time delays (often on the order of a second), in which signal transport delays are a non-negligible portion of the total latency. Latency is not necessarily due to degradation, but degradation can exacerbate latency effects.

The consequences of control loop latency depend on many factors, such as the pilot task and aircraft dynamics. For a given time delay, adverse effects in flight

control tend to increase with dynamic tasks such as landing, and aircraft that are highly responsive. In contrast, sluggish aircraft and steady flight without rapid maneuvers are more tolerant to time delays. This is a key reason why today's UASs often use satellite-based control links for the relatively static maneuvers and flight phases (e.g., enroute), whereas line-of-sight links are often used for takeoff and landing.

Because of the interdependencies of many factors, tomorrow's UAS might need to address time delay effects through combinations of aircraft design (responsiveness and stability), control link architecture and performance, control station feedback, control input devices, maneuver limitations and pilot training, and automated "inner-loop" aircraft control. In addition, novel techniques such as model-based feed-forward control may provide further mitigation of time delays when pilots are in the control loop. A more extreme mitigation, out of the scope of this section, is to remove the human from certain control tasks altogether, thereby circumventing the latency effects of a remote operator (see also Sect. 88.2.5 in this chapter). But for UA control tasks in which the human is in the loop, a key challenge for NAS integration will be to develop regulations and standards to address control loop time delays, despite the many variables that contribute to these delays and their effects.

88.2.4 Gap: Link Monitoring

A wireless data link for aircraft control is unique to unmanned aircraft and therefore not addressed in today's manned aircraft regulations and standards. Because the data link is critical for safe operation, yet is subject to degradation and failure modes very different from control links in manned aircraft (e.g., cables, fly-by-wire), link monitoring might be needed by the pilot or other flight crew members. However, the scope of this section is limited to link monitoring by the UAS pilot using minimal automation because it is a new and significant task relative to manned aircraft pilot duties. The term "link monitoring" is used in this chapter to include tasks that maintain link health as well.

The task of link monitoring requires both system knowledge and human interface equipment at the control station. System knowledge can include an understanding of the available architectures (e.g., satellite, line-of-sight, ground based), signal-in-space behavior, aircraft orientation and range effects, weather and ground effects, data degradation observability, and random dropout behavior. In today's UAS, dedicated link specialists are often responsible for link system knowledge, coordinating with the pilot either remotely or near the control station. In other UASs, pilots – not dedicated link specialists – accommodate the additional tasks associated with link monitoring. It has not yet been determined whether these additional tasks impose unacceptable workload on the pilot. For example, 14 CFR 2x.1523 for manned aircraft requires a determination of the required minimum crew to operate the aircraft. Applicants complying with these regulations must consider individual pilot workload, accessibility and ease of operation of control by the appropriate

crew member (including the possibility of one being incapacitated), and certain operations (see also ACs 23.1523 and 25.1523-1). When adapting these regulations to UAS, analyses should include the added workload of link monitoring and control access in order to establish minimum crew requirements for safe operation.

The link-monitoring task will also require equipment in the control station that involves a human interface. Manned aircraft, even with advanced fly-by-wire systems, have no equivalent to this, outside of extremely improbable system failures of the primary flight controls and their annunciations. Yet, the control station might have to include displays and controls for control link monitoring, in addition to equipment for typical aviation functions such as communications, navigation, and surveillance. Standards will need to be developed to address, at a minimum, data link display location and information and controls requirements, with considerations for the context of the control station (see ACs 25-11A, 23-1311C, 20-175 for flight deck displays and controls and their integration in the flight deck).

88.2.5 Gap: Automation and Automated Systems

UAS designs require the use of many types of automated systems, some different than those used in manned aircraft. The term “automation” is used frequently in UAS discussions, but can mean different things to different people. An automated system or function can generally be defined as one that is performed by a system, which would otherwise be performed by a human operator. Although, in the context of UASs, the broad terms, “automation” or “automated,” are often used to refer to the aircraft as a whole, it is more useful to refer to the specific functions or systems, such as the control of navigation and energy states (e.g., speed, position, flight path). It is also useful to distinguish along other dimensions such as “information automation” versus “control automation.” Often information automation is used to describe systems or functions that process and organize information that would otherwise need to be processed or organized by the human in the system. Likewise control automation is used to describe those functions or systems that are used to control the aircraft or other elements of the UAS (e.g., autoflight or autothrust). The functions can fall under classic categories such as “aviate,” “navigate,” and “communicate,” as well as “hazard avoidance,” “systems management,” “preflight planning,” and other areas. For each of the systems, a design decision must be made about how and when to automate each function – whether it will be accomplished exclusively by a system, exclusively by the pilot (or other human operator), by some combination – or how and when to transition from one to the other. The approach to these design decisions should be consistent for all systems in the UAS; the description of this is often referred to as the automation design philosophy.

The incorporation of advanced automated systems in manned aircraft is a useful analogy for unmanned aircraft. While it is often thought that UAS is unique for its extended use of automated systems, it is important to understand and appreciate the highly sophisticated automated systems that are common to many types of manned aircraft and learn from lessons acquired through the many years of design and implementation of those systems. Flight management computers and integrated

modular avionics are examples of highly complex hardware and software for both information and control automation, including self-monitoring for detection and isolation of faults that would otherwise ripple through other systems.

Most of the same issues with automated system use, risks, and benefits found in manned aircraft also apply to UAS, but UASs present additional and unique challenges. Many of these unique automation challenges can be notionally classified as either pertaining to intelligence limits that drive the “maximum” levels of automation, or latency effects that drive the “minimum” levels of automation.

88.2.5.1 Intelligent Automation (Maximum Levels of Automation)

UAS has automation needs that push the limits of system performance toward more intelligence and sophistication, beyond what is currently used today in manned aircraft. The driver for this is primarily the potential for lost control link (“lost link”). Under lost link, humans are no longer functionally part of the decision process and control loop, and the UA’s onboard automated systems function completely without humans during these non-normal conditions. This is not to say that automated systems are going to “replace” humans in function and performance, but that they must be designed to be able to operate at times without the human complement. This is a critical difference. In today’s manned aircraft, automated systems are regulated and approved within the paradigm of colocated human interaction. An important part of safety analysis, regulatory compliance, and design is the underlying assumption that pilots are able to mitigate certain equipment failures and errors from interaction with automation (14 CFR 2x.1309, 14 CFR 25.1302). For example, pilots monitor autoland systems during automated landings, with the ability to immediately intervene as necessary if a system failure occurs or in any situation that can compromise continued safe operation. Another example is alerting systems, which typically are designed with an acceptable proportion of false/nuisance alerts and to which pilots apply additional information, context, and judgment when determining the appropriate response. When automated systems are designed to operate “autonomously” – without the option of human intervention – there are a number of decision-making consequences to performance and safety. These decision-making consequences can include the loss of:

- Judgment that comes with pilot expertise and survival instinct
- Responsibility and accountability
- Access to additional information sources
- Context
- Understanding and prioritization of goals
- Adaptability to unforeseen events
- Visual pattern recognition for identifying features
- Air traffic communication using natural language

A critical regulatory challenge for UAS might be not only to adapt the current design regulations from manned to unmanned use but also perhaps to use an *operational* requirement, such as 14 CFR 91.111 (a) – “No person may operate an aircraft so close to another aircraft as to create a collision hazard” – to create an equivalent *equipment* requirement. This would ultimately call for deriving

well-defined functional and performance criteria for equipment, from operational requirements that were intended to be complied with by human operators and not systems.

While there might not be hard theoretical limits to automation achieving certain functions or behaviors, there are “soft” limits due to practical factors such as design knowledge, assumptions of future environments, and software validation and verification. These practical factors establish, for the time being, what is essentially an approximate upper limit or the “maximum automation” level in NAS-integrated UAS.

88.2.5.2 Latency Effects (Minimum Levels of Automation)

In contrast to the upper limits in the incorporation of UAS automation due to the lost value of the human complement, there might also be lower limits of automation due to the remote pilot’s limited ability to perform inner loop control. One reason is latency effects from the human being remotely located; some UAS links introduce delays in the control or communications loop that limit the degrees to which humans can be effectively involved (see also Sect. 88.2.3 in this chapter). The lowest level of automation that is often referred to as “manual” control, which is standard in nearly every manned aircraft, might not even be an option in unmanned aircraft due to the time delays associated with the control link. For many control tasks, automated systems could be needed to augment human control, such as through inner-loop automation with human supervisory control, through manual control with feed-forward compensation, or other means. The elimination of manual control, which is one example of raising the “minimum automation” threshold, will likely affect regulations that govern primary flight controls, such as 14 CFR 23.143 and 23.155. The elimination or limitation of manual control will also affect policy that govern pilot responsibilities in rapid response operations, such as maneuvering due to traffic, terrain, windshear, unusual attitude, stall, aircraft system failures, and perhaps even compliance to air traffic control. Time delays in the control link therefore have significant effects in human-automation interaction, and could drive the establishment of a new minimum automation level.

Extensive use of aircraft system automation is not unique to UAS. However, for UASs that are integrated in the NAS, both the minimum level and maximum levels may necessarily be shifted upward, toward higher levels of automation, when compared to manned aircraft. This in turn has human factors implications for pilots at the control station because of human-automation interaction effects. It also has human factors implications for air traffic controllers (see Sect. 88.3.3 in this chapter).

88.2.6 Gap: Information Formats

The manner in which information is presented to pilots, and input from pilots, may differ between manned and unmanned aircraft. While information requirements dictate “what” is needed on a display, information formats dictate “how” that

information is represented. Hence, the same information may be needed by pilots of both manned and unmanned aircraft, but the unique characteristics of UAS may call for different formats.

88.2.6.1 Example: Aircraft Attitude Format

One example is the reference frame for aircraft attitude. Attitude indicators show aircraft orientation relative to the earth or, specifically, the roll and pitch angles of the aircraft relative to the horizon. The two primary components of an attitude indicator are the aircraft symbol, or “miniature wing,” and the horizon bar. In manned aircraft, it is most common to fix the aircraft or “miniature wing” symbol to the airframe or body axis, such that it maintains the same orientation relative to the actual aircraft and normally seated pilot. A key reason for this is to match what the pilot sees out the window. That is, the horizon as seen out the window moves similarly to the horizon bar, from the pilot’s perspective. This “egocentric” format is the common format for attitude indicators (some Russian aircraft, for example, are notable exceptions).

The attitude indicator in a control station is not necessarily in the context of an aircraft-centric, out-the-window view, as in manned aircraft, and therefore could warrant a different attitude display format. Although much less common in (western) manned aircraft, exocentric format attitude indicators are allowable. For example, AC 25-11A states that both fixed airplane reference and fixed earth reference bank pointers are acceptable for primary attitude information, although “a mix of these types in the same flight deck is not recommended.” UAS pilots, being physically remote from the aircraft, do not use natural vision through a windshield to sense the environment local to the aircraft, although this view can be replicated with the appropriate sensors and displays (see Sect. 88.2.1 in this chapter). It may be more appropriate to display unmanned aircraft attitude with an exocentric view, in which the horizon bar is fixed, and aircraft symbol appears to move relative to that (and relative to the pilot). Exocentric formats inherently reflect the nonmoving and remote nature of the UAS pilot, which is a key difference between manned and unmanned aircraft operation. However, it is not clear which format is the most appropriate, and other factors such as negative transfer of learning must also be considered.

88.2.6.2 Environmental Information Format

Beyond attitude indicators, other format examples to consider include displays that represent the external environment, such as traffic (FAA Technical Standard Order (TSO)-C147, -C118, -C119c, -C195a), weather (TSO-C63d, -C105), and terrain (TSO-C151b). With manned aircraft, such displayed information is often comprehended in the context of natural vision out the windshield, as in the case with aircraft attitude. Traditionally, it has been common to provide this information on exocentric views (e.g., planview moving maps). Recent trends in manned aircraft to display environmental information on forward-looking egocentric-format displays might not be as appropriate for UAS.

88.2.6.3 Other Displayed Information Formats

It is likely that much of the displayed information at a control station can benefit from the application of manned aircraft display standards, most of which derive from highly evolved designs based on sound design principles and best practices, and years of operations. For example, altitude and speed dials, tapes, and numeric indicators likely do not appear to present the need for UAS-specific changes. A similar argument might also apply to the “basic T” arrangement, the standard primary instrument display arrangement for manned aircraft, (as required in 14 CFR 23.1321, 25.1321, 27.1321), particularly when considering negative transfer of learning effects on UAS pilots with manned piloting experience (assuming such information is required for pilot control). The determination of new information formats for UAS control station displays should be derived, such as from the fundamental differences between manned and unmanned aircraft.

88.2.6.4 Control (vs. Display) Formats

Lastly, information formatting regarding *controls* (i.e., input device) versus displays may also differ between manned and unmanned aircraft. It is first helpful to distinguish aircraft *systems* controls (such as for transponder settings) from *flight* controls. While there are unique considerations for UAS systems controls such as the lack of vibration, maneuver g-forces, and ambient noise that can affect pilot performance, most aircraft systems controls such as buttons, knobs, touch screens, and cursor control devices (AC 20-175) do not appear to be fundamentally affected by the remote nature of the UAS control station. UAS primary and secondary flight controls might benefit from compensation for the loss of natural sensing, such as force feedback to comply with 14 CFR 23.255, but such techniques are already employed in manned aircraft, as in fly-by-wire control systems. New considerations for UAS flight controls include control link latency compensation, and effects of control device misalignment with the vehicle axis. The level of automation in UAS flight guidance and control is often cited as a reason for new flight control formats (e.g., supervisory control via a cursor control device), but manned aircraft offer multiple automation levels as well. Rather, a case for new UAS control formats might be based more on the lowest level of control automation, not the highest (see Sect. 88.2.5 in this chapter). For example, manned aircraft flight control systems are highly automated yet still provide the options for manual or quasi-manual control through control formats offered by yokes – a feature that might not exist with UAS. Therefore, an important consideration for integrating UAS in the NAS is for aircraft that no longer have traditional control formats (e.g., yokes) for primary flight control due to automated inner loop control systems.

88.3 Air Traffic Control

The second category of UAS NAS integration human factors considerations pertains to air traffic control. “Controller” is used generically here to include the many types

of air navigation service providers in various facilities, to whom FAA Order JO 7110.65 applies.

88.3.1 Gap: Different Aircraft Performance and Missions

The flight performance of UAs, such as speed, climb and descent rates, and altitude envelope, can be significantly different from manned aircraft. Air traffic controllers expect certain aircraft performance levels in the NAS in order to orchestrate traffic safely, efficiently, and under acceptable workload. Although FAA Order JO 7110.65, Appendices A–C, list performance values for a large variety of aircraft, controllers typically deal with an expected and well-known variety of performance groups. Aircraft that cannot meet the expected performance, or are significantly different, are potentially disruptive to controllers as well as pilots of nearby manned aircraft.

UAs therefore present NAS integration challenges because of performance differences from manned aircraft, both directly and indirectly. Although unique aircraft performance is not an inherent aspect of UAs, the lack of onboard pilots and cockpit equipment allows for comparatively small aircraft and power plants relative to manned aircraft, each with performance consequences. This has the potential to significantly increase the range of aircraft performance values that will be present in the NAS. For example, the lightest manned airplane weight category used in wake turbulence separation is currently “small” ($\leq 41,000$ lb, FAA JO 7110.65; FAA Aeronautical Information Manual) and “light” ($\leq 15,000$ lb, ICAO) maximum certified takeoff weight, yet UAs can easily weigh below 1,000 or 100 lb. (A special FAA rulemaking committee has defined “small” in another context, but “small-UASs” (FAA Order 1110.150) are not considered here to be NAS integrated and not in the scope of this chapter.) Such small weights, odd sizes, and other physical attributes can lead to a variety of aircraft performance not seen before, most notably in lowering the range of aircraft air speed and change rates (vertical rates). As an example consequence, a slow aircraft can require increased controller monitoring and workload, with necessary clearance amendments issued to move traffic around it (increasing fuel burn) or to decelerate traffic (leading to delays). As another example consequence, sector controllers that need to issue an altitude restriction prior to delivery to an adjacent sector will issue descents accordingly; UAs or any aircraft that are performance outliers can make it difficult for controllers to predict trajectories and separation and can furthermore result in additional workload and coordination if an altitude restriction cannot be met. Expected responses to controller instructions (e.g., “climb and maintain one four thousand”) can also be affected because UAs may not be able to comply in a timely manner due to aircraft performance and other factors. Other consequences include new considerations for wake vortex separation (JO 7110.65, paragraph 5-5-4) and visual/radar detection (see also Sect. 88.3.6 of this chapter).

The absence of onboard pilots not only allows for UAs that have unique physical and performance attributes but also allows for unique operations or missions, such as multiday endurance or high altitude. In these cases, typical manned

aircraft performance may not be achievable without considerable design trade-offs that compromise mission-specific performance. Furthermore, UA missions (e.g., surveillance, inspection) often call for atypical flight profiles such as circles and spirals or unpredictable paths. As with UA performance, UA flight profiles are not necessarily specific to UAS versus manned aircraft, but the missions allowed by remote pilots and unique aircraft performance enable and foster these profiles, possibly to the extent that the aircraft cannot be exclusively contained in restricted airspace. In comparison to typical point-to-point operations, an increase in atypical missions and flight path geometries can be overall disruptive to controllers and other traffic.

88.3.2 Gap: Visual Instructions

UASs currently cannot accept visual instructions from air traffic controllers. An important part of controller communication with manned aircraft is that a pilot can visually acquire an object or feature that is verbally described to them by the controller. For example, JO 7110.65, Chap. 3-1-6, states that controllers describe “vehicles, equipment, or personnel on or near the movement area in a manner which will assist pilots in recognizing them.” More importantly, visual separation can be used to temporarily separate aircraft, in which the controller receives positive acknowledgement that one pilot has the other aircraft in sight (JO 7110.65, Chap. 7-2-1). Although a number of criteria must be met (e.g., other approved separation is assured before and after the application of visual separation; direct communication is maintained with one of the aircraft involved), visual separation operations can be routinely applied to an extended sequence of aircraft, which is particularly helpful to the controller in high-workload situations.

Because UAs do not have a pilot onboard, the operational paradigm of visual instructions for UAS has to be reconsidered, which presents many challenges for UAS integration in the NAS. One solution might be to keep the UA pilot in the loop by providing natural vision “equivalent” information at the control station, such as through UA cameras. However, the use of electronic imaging technology to replace versus complement pilot natural vision has not yet been achieved (see Sect. 88.2.1 in this chapter). Another possible solution is to represent appropriately equipped traffic with symbology on suitable control station displays, as with ADS-B (automatic dependent surveillance-broadcast) applications and CDTIs (cockpit display of traffic information). Current approved ADS-B applications (RTCA DO-317A) designed for use in the visual separation regime have so far used CDTIs only *with* visual acquisition. However, future applications may allow for IFR use without visual acquisition requirements, for specific, limited operations. Such CDTI-based operations would not provide “equivalence” to visual operations, but could offer similar operational advantages through specific procedures that leverage aircraft equipment and pilot qualification. These kinds of CDTI-based operations would also introduce a number of human performance and system safety concerns, in comparison to natural vision. Another potential and longer-term solution for UAS

is for aircraft automation to comply with visual instructions without involving the pilot, using appropriate sensing technology, but this has automation challenges as well (see Sect. 88.2.5 in this chapter). The inability of UAs to “see” like manned aircraft pilots presents many challenges for UAS integration in the NAS, not only for UA/pilot decision-making and control but for air traffic controllers as well.

88.3.3 Gap: Lost-Link Predictability and Procedures

“Lost link,” defined here for brevity to mean the lost control uplink, is one of the key hurdles with UAS integration in the NAS. As mentioned in Sect. 88.2.2.2 of this chapter, there is not a direct analogy to manned aircraft, and the event is unique to UAS. During lost link the aircraft is autonomous, even though it is not by choice of the designer or pilot.

A lost-link aircraft can be a burden to controllers and a safety hazard to the NAS if controllers are not able to 1) issue its instructions or clearances, or 2) readily predict its next steps.

88.3.3.1 Loss of ATC Instructions

First, the inability of ATC to issue instructions is a fundamental risk, even when the lost-link behavior is readily predictable. This is because a controller’s primary responsibility of aircraft separation must be commensurate with the ability to “control” aircraft through instructions to the pilot, who actually controls the aircraft during nominal operation. Controller instructions are not rare events that reflect poorly defined flight plans, but, rather, are ubiquitous in the complex and unpredictable details of controlled airspace and through all flight phases. Therefore, it is not unlikely that a lost-link period will overlap with a controller’s need to issue a clearance amendment, for example, yet such amendments cannot be executed during lost link. A similar situation exists with observed clearance deviations. JO 7110.65, paragraph 2-1-26, states, “When it appears that the actions of a pilot constitute a pilot deviation, notify the pilot, workload permitting.” But “notify the pilot” implies a pilot’s ability to comply with a controller instruction through flight controls. Furthermore, the loss of voice communications often is associated with the loss of UA control so that without alternate means of communication (e.g., ground network), pilot notification and communication might not be possible, and emergency determination as described in JO 7110.65, Chap. 10-1-1, may be left to the judgment of the controller. Any resulting traffic restrictions (JO 7110.65, Chap. 10-4-1) are disruptive to controllers and other aircraft in the area and can pose a significant safety risk to other aircraft as well.

88.3.3.2 Loss of Predictability

A further problematic aspect of lost-link events is that, at some point, the UA automation will typically discontinue the original trajectory and control the aircraft on a new one. This is somewhat analogous to lost communications in manned aircraft, in which controllers must still predict what the aircraft will do (JO 7110.65,

paragraph 10-4-4, notes that “when an IFR aircraft experiences two-way radio communications failure, air traffic control is based on anticipated pilot actions.” See also FAA Aeronautical Information Manual, paragraph 6-4-1). However, lost-link behavior for any particular UA might not be easily predicted because the procedure the UA automation will initiate in that situation could be based on factors such as its specific communication architecture, systems that have failed, operational priorities, and the contingency plans incorporated within the UAS automation. The most intelligent behavior may therefore be too complex to sufficiently precoordinate with ATC. Hence, it may be necessary for NAS-integrated UAS to ensure UA predictability through an understandable set of predefined contingency information that is pre-coordinated with the appropriate ATC facility (current FAA policy requires coordination of lost link route of flight, transponder use, lost link orbit points, communications procedures, and pre-planned flight termination points in the event recovery of the UAS is not feasible). The degree of pre-coordination needed to ensure predictability might decrease as controllers are provided with improved tools to obtain information during lost-link events.

Without a functional pilot in the control loop, the most appropriate UA behavior, even from the ATC perspective, is not likely to be one-size-fits-all, but will be specific to the airspace, traffic, and other factors. On one hand, the UA often needs to maneuver and reestablish the link in order to be controllable, and on the other hand, the UA behavior needs to be appropriate to the airspace, yet predictable. A key challenge for UAS integration in the NAS is to find a solution within that trade-space that yields appropriate, predictable, and ultimately ATC-controllable UA behavior.

88.3.4 Gap: Communications

Voice communications between controllers and manned aircraft pilots yield human-system performance that may be difficult for UAS to meet. Communications with manned aircraft is based in part on equipment standards, but the human element of the overall performance is not well defined. Nevertheless, overall human-system communications performance is based on expectations of latencies and rhythms that can be sensitive to the changes from UAS.

Notionally, UASs introduce at least a third basic node in the communications architecture. The three nodes are ATC, the UA, and the control station. It is assumed here that the control station is very remote from both ATC and the UA, possibly precluding the use of standard aircraft-ATC communications equipment at the control station.

In the simplest case, the three-node network presents two basic options for linking controller with pilot. The first is to use the UA as the middle node and relay. This relay method has the potential benefit of transparency to ATC since human-to-human communications are preserved with no new equipment or procedures. It also preserves “party line” communication, which has well-recognized benefits. However, the relay method adds communications complexity that, compared to standard pilot-controller communication, can lead to higher potential for dropouts

and latency – both of which can introduce step-ons and errors, delay aircraft compliance, and increase controller’s workload. The communications link also is typically affected by the same factors as the control/data link, such that lost link and lost communications can occur simultaneously and exacerbate their individual effects.

Another option for linking controller with pilot is to not involve the UA at all, and instead rely on a separate infrastructure for alternate communications. This may be a more reliable method in the future since it can involve multiple wired and wireless networks and achieve acceptable communications performance that is not as dependent on the UA position or maneuvers. However, it might require new equipment and/or procedures (such as for sector handoffs) for both controllers and pilots and can therefore be considered challenging to the concept of NAS integration. A separate communications infrastructure might also adversely affect airspace awareness if party line information is not maintained, as compared to standard radio communications.

Additional communications options include manned aircraft NextGen technologies such as data communications (“Data Comm”), which use alphanumeric displayed messages instead of voice, using protocols that accommodate asynchronous communication. Although Data Comm offers many advantages over voice, it can inherently introduce time delay (through asynchronous dialog) and the loss of party line awareness, both of which are already attributes of the UA relay architecture. Hence, the suitability of Data Comm for UAS compared to manned aircraft remains to be determined. A challenge for UAS integration in the NAS is to leverage UAS’s unique communications infrastructure to maintain an acceptable level of communications performance, including human performance, in both normal and non-normal conditions.

88.3.5 Gap: Workstation Information

Controllers need to know specific flight data about the traffic that they monitor and control, and UAS may introduce further information requirements. For manned aircraft, controllers may have access to information such as aircraft ID, aircraft type, and certain optional onboard equipment. The available information depends primarily on whether the aircraft has filed an IFR flight plan.

It is unclear what additional information controllers will need for UAS operations in the NAS. On one hand, early standardization discussions emphasized transparency so that controllers would not necessarily know if an aircraft is manned or unmanned. On the other hand, it became clear that there are unique aspects of UAS, and controllers may need certain UAS-specific information to maintain safety, efficiency, and acceptable workload. Example UAS-specific air traffic controller information could include but is not limited to:

- Unique code for identifying aircraft as unmanned
- Indication of when UA loses control link with control station
- Flight-specific procedures for lost control link and lost communications (as discussed in Sect. 88.3.3.2 in this chapter)

Unfortunately, planned display changes for air traffic control of manned aircraft are already presenting information management challenges to designers of controller workstations, as more and more technologies and information are made available. UAS-specific information will need justification to earn its way in a datablock or elsewhere, particularly when considering the addition of new training and procedures onto an existing complex set of tasks.

88.3.6 Gap: Detection of Small-Size UAs

UAs can be much smaller than manned aircraft, which not only leads to aircraft performance differences (see Sect. 88.3.1 in this chapter) but also difficulties in detection by ATC and other traffic. Detection difficulties can be both visual and radar based. Manned aircraft have evolved an approximate lower bound in size and radar cross section. For example, controllers in towers therefore expect to visually detect aircraft a certain distance away through the tower window, and pilots of other aircraft are also expected to visually acquire aircraft through the aircraft windshield and sometimes follow them. They not only *detect* aircraft visually but also estimate other states such as range and speed by means of its subtended angle and movement. Radar-based equipment complements or replaces visual detection and state estimation (or vice versa), but this equipment relies on sufficiently large aircraft cross sections (for primary radar) or transponder equipage (for secondary radar).

When a UA is of sufficiently small size, there is risk that its small cross section can cause visual and radar detection difficulties and other state estimation difficulties. For example, a tower controller that expects to see any aircraft on a runway in a given visibility condition might mistakenly assume that a runway is clear, even when it is actually occupied by an unexpectedly small UA. This may compromise a controller's ability to, for example, visually scan a runway for traffic (JO 7110.65, paragraph 3-1-12). Visual state estimation can also be compromised, such as when a manned trailing aircraft is attempting to maintain visual spacing on a leading UA based on erroneous assumptions of its size (see Sect. 88.3.2 in this chapter). Similar concerns arise also with a pilot's ability to maintain a safe distance and see and avoid other aircraft, per 14 CFR 91.111 and 91.113.

Although special operating limitations will address the smallest sized UAs (FAA Order 1110.150), many UAs outside of that category could still be orders of magnitude smaller than manned aircraft. A key challenge for UAS integration in the NAS is to understand the effects that small-size UAs have on the airspace system, such as human-system performance in aircraft detection and other state estimation.

88.4 Conclusions

The purpose of this chapter was to identify human factors challenges to integrating UASs in the NAS, for both pilots and air traffic controllers. The method for identifying these challenges was primarily based on the differences or "gaps"

between manned aircraft in the NAS today and the unique aspects of UAs. The goal was not to generate a comprehensive list of human factors issues, but to focus on gaps that are traceable to fundamental characteristics of UAs (primarily due to the UA pilot being physically remote from the aircraft) and that are also considered challenging from the perspective of the current NAS and its regulatory and policy framework.

The human factors NAS integration gaps discussed in this chapter were:

Pilot operations at the control station

- Loss of natural sensing
- Control loop degradation – data dropouts
- Control loop degradation – latency
- Link monitoring
- Automation and automated systems
- Information formats

Air traffic control

- Different aircraft performance and missions
- Visual instructions
- Lost-link predictability and procedures
- Communications
- Workstation information
- Detection of small-size UAs

There are many other gaps as well. Some (e.g., “sense and avoid”) were not discussed earlier because their gaps can be comprised of elements from the above list. Some common UAS human factors issues were not addressed here because they are not fundamental gaps, but rather the result of design choices that do not follow aviation standards versus the result of the fundamental attributes of UAS.

Notable human factors gaps worth briefly describing here, but not already covered in this chapter, include:

- Sterility and security of the control station. Manned aircraft cockpits are inherently isolated by means of their location within the aircraft and location of the operating aircraft itself (e.g., airborne). UAS control stations do not have these inherent characteristics, and so new considerations are needed to achieve the levels of security and sterility needed for appropriate UAS flight crew performance.
- Pilot complacency and the loss of shared fate. UAS pilots are physically isolated from the aircraft and its local environment, which can exacerbate pilot complacency, boredom, loss of attentiveness, and fatigue. Furthermore, concerns have been raised about safety because aircraft accidents or flight termination do not pose a direct health risk to the pilot, which can be a perceived safety risk when compared to manned aircraft pilots, who are assumed to use survival instincts when necessary. More research is needed to understand these differences.
- Pilot control handoffs. Crew resource management (CRM) is well established with manned aircraft and more straightforward than with UAS due to the colocation of crew members, all of whom use one physical flight deck interface. However, a UAS flight crew can be physically distributed among multiple control stations, in which aircraft control is handed off during operation. This is a new

aviation paradigm that will likely require new design features and flight crew procedures, with added considerations for air traffic controller handoffs between multiple sectors.

- Pilot training and qualification. FAA Notice 8900.227 includes policy on UAS personnel qualifications, including pilot training. However, ultimately, it is conceivable to require some pilots to be trained under an FAA approved training program to operate UASs in the NAS, depending on the type of operation and regulatory requirements developed. For comparison of required training programs, it may be more appropriate to use training for 14 CFR part 135 pilots instead of the more formal training required by 14 CFR part 121. For both types of training, the baseline definition of training requirements is done by a Flight Standardization Board (FSB) convened and led by the FAA Aircraft Evaluation Group (AEG). The FSB produces an FSB report to specify FAA training, checking, and currency requirements and to assist FAA Principal Operations Inspectors (POI) in the administration of approved training, checking, and currency programs for operators of the specified airplanes. An identical or similar process might be used to determine minimum training requirements for UAS pilots. In addition to the FSB report, FAA Order 8900.1 provides guidance on training program details. These documents can point to a likely structure that may be used for UAS pilot training; however, many details are still to be determined about the specific requirements and process that will be implemented. It should also be noted that all manned aircraft pilots are required to be qualified under 14 CFR Parts 61 and 91 with the minimum number of flight hours and pass the appropriate tests to meet the level of operation for which they are being qualified.
- Flight planning. Flight planning is important for any flight, but when the pilot is onboard the aircraft, many contingency decisions can be deferred until operation. With UAS, the potential for lost link places more demands on flight planning (prior to actual operation) in order to account for the remote location and possible functional absence of humans *during* operation (see Sect. 88.2.5 in this chapter). For example, when a manned aircraft engine fails, the pilot might be able to simply look out the window to determine a suitable emergency landing location. With UAS, such real-time decision-making may be precluded, depending on the sensing, automation, and level of pilot involvement at the control station. Therefore, UAS flight planning might need to be much more detailed and rigorous when compared to manned aircraft flight planning.

The challenges presented in this chapter will collectively require significant time and effort by the UAS and the larger aviation community to overcome. Progress can be facilitated by moving toward UASs that are designed specifically to include integration in the NAS, similar to how manned aircraft are designed. This would include human factors considerations for pilots, controllers, and other actors not discussed in this chapter such as observers, airport personnel, and maintenance personnel.

If the significance of human factors is not understood, the NAS integration gaps identified in this chapter may merely be addressed with operational limitations (such

as line-of-sight control) that fall short of true NAS integration when compared to manned aircraft. Human factors is not only central to the very definition of UAS but is also central to some of the most important challenges facing the integration of UAS in the NAS.

Abstract

The rapidly evolving technology of unmanned systems has outpaced the ability of aviation regulators and policy makers around the world to develop reasonable design, production, airworthiness, maintenance, licensing, registration, operational, and crewmember certification regulations and standards. Efforts are underway in several countries, as well as internationally, to develop these regulations and harmonize them across borders. The multiple uses of civil UAS technology compel an approach to regulatory oversight that acknowledges that each system has unique capabilities and characteristics, and that the creation of rigid categories for requirements may inhibit development and innovation. On the other hand, the potential for harm is such that regulations and standards are unquestionably needed. For nations with comprehensive and deeply embedded aviation regulations such as the United States, the beginning point for compliance

D. Marshall

is to understand the regulatory scheme and how the FAA applies the existing rules to UAS operations. This chapter proposes a methodology for analysis of current regulations for applicability to UAS activities. Where the rules are in development, or merely being contemplated, a structure for harmonization with international standards is proposed. The article focuses on the USA as the nation that has the most comprehensive aviation regulations, while also supporting major efforts to promulgate regulations and standards to supplement those regulations with UAS-specific requirements and criteria. To provide global context, the International Civil Aviation Organization's structure and procedures are reviewed in detail, and contrasted with State-sponsored regulatory processes, with an analysis of the applicability of ICAO's standards to UAS operations.

89.1 Introduction

Every civilized nation has some form of rules, regulations, or laws that regulate economic activities and social behavior. The scope and process for the creation of these rules varies widely among nations, depending upon many factors that derive from the form of government that produces those rules. As a society grows more open and more complex, more rules and regulations may become necessary to maintain order and protect people from harm that may be caused by the unrestricted activities of others. Those harms can be physical, health related, economic, environmental, or any number of potentially damaging outcomes from a governmental entity, an organization, or an individual doing or failing to do something that threatens the well-being of others. As the technology of unmanned aerial systems evolves and more potential users seek to deploy them for commercial, scientific or public safety purposes, some governments have attempted to meet the demand and the potential for harm by developing regulations that address the many risk management and policy challenges presented by these devices. Since there is no overarching international law, treaty or set of standards that governs unmanned aerial systems, the developer, manufacturer, and end user must be wary of the potential for inadvertent violations of existing law, or of seeing a formerly legal activity become illegal or proscribed as a result of a change in the rules. Methodologies for understanding the existing rules and participating in the process of developing new or modified rules should be key elements in the business plan for any individual or entity that seeks to participate in the unmanned systems arena.

89.2 A Brief History of Regulation

Regulations, and the supporting standards that help people and organizations comply with them, have been a core element of the legal system in the United States for nearly 150 years. Every Federal regulatory agency promulgates rules that are intended to carry out the agency's Congressional mandates. State and local

regulatory agencies act in much the same way. Congress has neither the time nor the resources to define and monitor every element of the particular industry or activity that it undertakes to regulate through the enactment of federal laws, so the agencies that Congress creates and funds are delegated the legislative powers that Congress has been granted by Article, Sect. 89.1 of the U.S. Constitution. Those delegated powers are implemented through the rule making process. The earliest Federal regulatory agency that still exists is the Office of the Comptroller of the Currency, which was created in 1863 to charter and regulate the nation's banks. The modern era of Federal regulation really began with the creation of the Interstate Commerce Commission (ICC) in 1887, which was directed to protect the public from excessive and discriminatory railroad rates. The regulation was economic in nature, by the setting of rates and by regulating how railroad services were to be provided. The ICC was dissolved in 1995, and its remaining powers were reassigned to the Surface Transportation Board. The ICC's administrative model was that of an independent, bipartisan commission that used an adjudicatory approach to arrive at decisions on contested matters. This structure was adopted by several agencies subsequently created, such as the Federal Trade Commission (FTC), the Water Power Commission (later the Federal Power Commission), and the Federal Radio Commission (which became the Federal Communications Commission). Congress created several other agencies early in the twentieth-century to regulate commercial and financial systems – including the Federal Reserve Board, the Tariff Commission, the Packers and Stockyards Administration, and the Commodities Exchange Authority, all established before 1922. The Food and Drug Administration was created in 1931 to ensure that certain foods and drugs were fit for human consumption.

Many other Federal regulatory agencies were created in the 1930s as part of President Franklin D. Roosevelt's "New Deal" programs. These included the Federal Home Loan Bank Board (1932), the Federal Deposit Insurance Corporation (FDIC) (1933), the Commodity Credit Corporation (1933), the Farm Credit Administration (1933), the Securities and Exchange Commission (SEC) (1934), and the National Labor Relations Board (1935). The jurisdictions of both the Federal Communications Commission (FCC) and the Interstate Commerce Commission were also expanded to regulate other methods of communications (e.g., telephone and telegraph) as well as other transport modes (such as trucking).

The United States' first attempt to regulate commercial aviation arose out of the U.S. Post Office's commencement of airmail operations in 1918. The first published aviation regulations were released in 1926 by the Aeronautics Branch of the Department of Commerce and were known as "Air Commerce Regulations." They consisted of six chapters spanning 45 pages of text, and covered the areas of Licensing, Marking and Operation of Aircraft, Licensing of Pilots and Mechanics, Air Traffic Rules, and rounded out by a miscellaneous section. Aviation is indeed one of the oldest regulated industries or activities in the USA. Presently the Federal Aviation Regulations ("FARs") fill four volumes of the Code of Federal Regulations, consisting of over 460 sections filling more than 3,600 pages, and totaling over 8,000 regulations, counting major subparts and sections.

Outside of the USA, aviation regulations vary from country to country, as can be expected. Some countries have aviation rules and regulations similar to the United States, but none are as comprehensive. In Europe, for example, each individual country ("Member State") has its own set of regulations, developed and enforced by Civil Aviation Authorities ("CAAs") in each country. And there is an additional layer of safety rules that fall under the regulatory and administrative jurisdiction of the European Aviation Safety Agency ("EASA"), an agency of the European Union ("EU"). EASA's role is to provide advice to the European Union for drafting new legislation, implementing and monitoring safety rules, including inspections in the Member States, type-certification of aircraft and components, as well as the approval of organizations involved in the design, manufacture and maintenance of aeronautical products, authorization of third-country (non-EU) operators, safety analysis, and research. The European Organization for the Safety of Air Navigation, known as "EUROCONTROL," is the entity that provides harmonized air navigation services across European skies and is an organization separate from EASA. This structure is to be contrasted with the United States', where all aviation regulations and air navigations services fall under the umbrella of one agency, the Federal Aviation Administration ("FAA"), although investigation of accidents is conducted by the National Transportation Safety Board ("NTSB"), which also provides an administrative, quasi-judicial review of FAA enforcement actions.

Virtually every member of the United Nations (currently numbering 191 countries) has its own version of domestic aviation regulations, which for the most part are patterned after the 1944 Chicago Convention on International Civil Aviation, which established the International Civil Aviation Organization ("ICAO") as a means to secure international cooperation and the highest possible degree of uniformity in regulations and standards, procedures, and organization regarding civil aviation matters. The Chicago Conference laid the foundation for a set of rules and regulations regarding air navigation as a whole, which was intended to enhance safety in flying and set the groundwork for the application of a common air navigation system throughout the world.

ICAO works in close cooperation with other members of the United Nations family such as the World Meteorological Organization, the International Telecommunication Union, the Universal Postal Union, the World Health Organization, the International Maritime Organization, and the Arctic Council. Aviation-related non-governmental organizations ("NGOs") also participating in ICAO's efforts include the International Air Transport Association, the Airports Council International, the International Federation of Air Line Pilots' Associations, and the International Council of Aircraft Owner and Pilot Associations.

A comprehensive analysis of the aviation regulatory schemes in each and every country that publishes some form of regulation is beyond the scope of this chapter. However, since ICAO Member States contract to follow ICAO's rules and supplementary material and to publish for all to see any exceptions taken to any ICAO Article, Annex, Regional Supplementary Procedure ("SUPPS") or Procedure for Air Navigations Services ("PANS"), a beginning point must be the aforementioned ICAO rules and procedures themselves.

A discussion of methods to ensure compliance with applicable aviation regulations by those involved with any aspect of unmanned aerial systems necessarily begins with determining what an “aircraft” is. ICAO’s definitions state that an aircraft is “(a)ny machine that can derive support in the atmosphere from the reactions of the air other than the reactions of the air against the earth’s surface [5]. An “aeroplane” is “a power-driven heavier-than-air aircraft, deriving its lift in flight chiefly from aerodynamic reactions to surfaces which remain fixed under given conditions of flight” [16]. A radio-controlled (“RC”) model aircraft (fixed-wing or helicopter) purchased off-the-shelf from the local hobby shop or airport terminal would be included under either of these definitions. There is no definition of an unmanned aircraft in the Convention or the Annexes to the Convention. However, Article 8 of the Convention states that:

No aircraft capable of being flown without a pilot shall be flown without a pilot over the territory of a contracting state without special authorization by that State and in accordance with the terms of such authorization. Each contracting state undertakes to insure that the flight of such aircraft without a pilot in regions open to civil aircraft shall be so controlled as to obviate danger to civil aircraft [11].

This provision only applies to pilotless [22] aircraft being flown over the territory of a contracting state without the State’s permission, and each contracting state agrees that pilotless aircraft will not be flown in a manner that endangers civil aircraft.

What type of aircraft does the Convention intend to regulate? Article 3 of the Convention states that:

- (a) This Convention shall be applicable only to civil aircraft, and shall not be applicable to state aircraft.
- (b) Aircraft used in military, customs and police services shall be deemed to be state aircraft.
- (c) No state aircraft of a contracting state shall fly over the territory of another State or land thereon without authorization by special agreement or otherwise, and in accordance with the terms thereof [12].

It is thus clear that the ICAO definitions of aircraft that are subject to its Articles, Annexes, and Supplementary Agreements include any man-made contrivance that is capable of sustained flight above the immediate surface level of the Earth. An “aeroplane” is defined as a powered aircraft. No minimum size is described, so even the previously mentioned radio-controlled model aircraft could be covered under a literal definition. Thus, in the ICAO regulatory scheme, no distinction is made between manned and unmanned aircraft.

89.3 Are Contracting States Bound by ICAO Definitions of Aircraft and Aeroplanes?

Another way of stating this question is to inquire if contracting states may create their own definitions of airplanes or aircraft and, if so, whether they can enforce those definitions and any rules or regulations that may apply on operations in ICAO-defined international airspace in which the contracting state provides air navigation

services. Similarly, may a State impose its own regulations on aviation activities engaged in by its own citizens outside of their domestic airspace jurisdiction? In answer to those questions, the ICAO Council adopted a resolution in 1948 alerting contracting states to the desirability of their adopting, in their own national regulations, as far as practicable, the precise language of those ICAO Standards that are of a regulatory character and also of indicating departures from the Standards, including any additional national regulations that were important for the safety or regularity of air navigation. The resolution also noted that, wherever possible, the provisions of Annex 2 were written in such a way that they could be incorporated, without major textual changes, into national legislation [23].

Later, in 1972, when adopting Amendment 14 to Annex 2 relating to authority over aircraft operating over the high seas, the Council declared that the Amendment was intended solely to improve safety of flight and to ensure adequate provision of air traffic services over the high seas. The Council emphasized that the amendment was in no way intended to impact the legal jurisdiction of States of Registry over their aircraft or the responsibility of contracting states under Article 12 of the Convention for enforcing the Rules of the Air [1]. Thus, contracting states are free to create their own definitions and categories of aircraft, and to the extent that those States retain jurisdiction over aircraft registered in their State even if they are operating in international airspace, the States may apply their own laws and regulations.

The issue then becomes whether the aviation laws, rules, and regulations of a contracting state apply to operations in international airspace for which the contracting state provides flight information or air traffic control services. And for operators of unmanned systems, the challenge becomes where to look first for guidance on the rules applying to those systems, that is, locally or globally?

89.4 Where to Find the “Rules of the Road” In Domestic and International Airspace

The Articles in chapter of the Chicago Convention (similar to the Articles in the U.S. Constitution) describe the framework and establish the parameters for the regulatory scheme. Article 1 declares that “*The Contracting States recognize that every State has a complete and exclusive sovereignty over the airspace above its territory.*” This is important to note, as the rules described in the Convention do not apply to the airspace in or over a contracting state’s territory. Article 2 goes on to provide that “*For the purposes of this Convention the territory of a State shall be deemed to be the land areas and territorial waters adjacent thereto under the sovereignty, suzerainty, protection or mandate of such State.*” All other airspace not defined as falling within the sovereign protection of a state (and not necessarily a contracting state) is common, or international airspace.

The Forward to Annex 2 to the Convention states that the Standards in the document, together with the Standards and Recommended Practices of Annex 11, govern the application of the Procedures for Air Navigation Services – Air Traffic Management (PANS-ATM, Doc 4444) and the Regional Supplementary

Procedures – Rules of the Air, and Air Traffic Services, which are to be found in ICAO Doc 7030 [13].

Chapter 2 of Annex 2 defines the territorial application of the Rules of the Air as follows:

- 2.1.1 The rules of the air shall apply to aircraft bearing the nationality and registration marks of a contracting state, wherever they may be, to the extent that they do not conflict with the rules published by the State having jurisdiction over the territory overflown.

Note. – The Council of the International Civil Aviation Organization resolved, in adopting Annex 2 in April 1948 and Amendment 1 to the said Annex in November 1951, that the Annex constitutes Rules relating to the flight and manoeuvre of aircraft within the meaning of Article 12 of the Convention. Over the high seas, therefore, these rules apply without exception.

- 2.1.2 If, and so long as, a contracting state has not notified the International Civil Aviation Organization to the contrary, it shall be deemed, as regards aircraft of its registration, to have agreed as follows: For purposes of flight over those parts of the high seas where a contracting state has accepted, pursuant to a regional air navigation agreement, the responsibility of providing air traffic services, the “appropriate ATS authority” referred to in this Annex is the relevant authority designated by the State responsible for providing those services.

Note. – The phrase “regional air navigation agreement” refers to an agreement approved by the Council of ICAO normally on the advice of a Regional Air Navigation Meeting [10].

In summary, the “Rules of the Air” as defined by ICAO, which consist of general rules, visual flight rules and instrument flight rules, apply to all aircraft bearing registration marks of a contracting state, regardless of where the aircraft is flying, and apply without exception over the high seas, and over national territories to the extent that they do not conflict with the rules of the State being overflown. *The pilot-in-command of an aircraft is responsible for compliance with the rules of the air.* Regardless of the type of flight plan, the pilots are responsible for avoiding collisions when in visual flight conditions, in accordance with the principle of see-and-avoid. Flights operating under instrument flight rules are either kept separated by air traffic control units or provided with collision hazard information by the appropriate air traffic service (ATS) authority.

The world’s airspace is divided into a series of contiguous flight information regions (FIRs) within which air traffic services are provided. In some cases, the flight information regions cover large oceanic areas with relatively low air traffic density, within which only flight information and alerting services are provided. In other flight information regions, large portions of the airspace are controlled airspace within which air traffic control service is provided in addition to flight information and alerting services. Flight information service is provided to aircraft operating in controlled airspace and to others known to the air traffic services units. The prime objective of air traffic services, as defined in Annex 11, is to prevent collisions between aircraft. This Annex also describes ways to expedite and maintain an orderly flow of air traffic and to provide advice and information

for the safe and efficient conduct of flights and alerting service for aircraft in distress. To meet these objectives, ICAO provisions call for the establishment of flight information centers and air traffic control units [20].

Most of the airspace in Oceanic FIRs/CTAs (Control Areas) is high seas airspace within which the ICAO Council has resolved that rules relating to flight and operations of aircraft apply without exception. The majority of the airspace is also controlled airspace, and instrument flight rules (“IFR”) apply to all flights in oceanic airspace when at or above FL060 (flight level 6,000 ft) or 2,000 ft. (600 m) above ground level (AGL), whichever is higher, even when not operating in instrument meteorological conditions (“IMC”).

89.5 Can Unmanned Aircraft Comply with ICAO Rules of the Air?

Unmanned aircraft must be able to comply with the rules of the air set forth in Annex 2 to the Convention before they can be operated in international airspace. ICAO Annex 2 requires that those rules apply to aircraft bearing the nationality and registration marks of a contracting state. What standards then apply if the contracting state that provides flight information, alert, or air traffic control services in the international airspace sector of a Flight Information Region has no specific rules or regulations that address the unique characteristics of unmanned aircraft?

Regardless of whether the flight in international airspace is being conducted under visual or instrument flight plans, the pilot in command is responsible for avoiding collisions when in visual flight conditions, in accordance with the principle of see-and-avoid [21]. Flights operating under instrument flight rules are either kept separated by air traffic control units or provided with collision hazard information. An aircraft shall not be operated in a negligent or reckless manner so as to endanger life or property of others [2]. An aircraft shall not be operated in such proximity to other aircraft as to create a collision hazard [3]. The implication of a literal reading of these rules is that, unless a properly certificated onboard see-and-avoid system is present and operating on the UAS, the aircraft probably cannot comply with the Annex 2 requirements. That may be one of the most challenging ICAO standards to meet, but there are others dealing with airworthiness, navigation equipment, and reliability that would prove equally challenging unless the operator was to secure special permission from the controlling CAA to occupy the airspace.

89.6 Understanding the Regulatory Structure: What to Look For?

In the USA, the Federal Aviation Regulations (FARs) contain two sections that address the basic see-and-avoid obligation:

§ 91.111 Operating near other aircraft.

- (a) No person may operate an aircraft so close to another aircraft as to create a collision hazard.
- (b) No person may operate an aircraft in formation flight except by arrangement with the pilot in command of each aircraft in the formation.
- (c) No person may operate an aircraft, carrying passengers for hire, in formation flight [6].

§ 91.113 Right-of-way rules: Except water operations.

- (a) *Inapplicability*. This section does not apply to the operation of an aircraft on water.
- (b) *General*. When weather conditions permit, regardless of whether an operation is conducted under instrument flight rules or visual flight rules, vigilance shall be maintained by each person operating an aircraft so as to see and avoid other aircraft. When a rule of this section gives another aircraft the right-of-way, the pilot shall give way to that aircraft and may not pass over, under, or ahead of it unless well clear.
- (c) *In distress*. An aircraft in distress has the right-of-way over all other air traffic.
- (d) *Converging*. When aircraft of the same category are converging at approximately the same altitude (except head-on, or nearly so), the aircraft to the other's right has the right-of-way. If the aircraft are of different categories –
 - (1) A balloon has the right-of-way over any other category of aircraft;
 - (2) A glider has the right-of-way over an airship, powered parachute, weight-shift-control aircraft, airplane, or rotorcraft.
 - (3) An airship has the right-of-way over a powered parachute, weight-shift-control aircraft, airplane, or rotorcraft.

However, an aircraft towing or refueling other aircraft has the right-of-way over all other engine-driven aircraft.

- (e) *Approaching head-on*. When aircraft are approaching each other head-on, or nearly so, each pilot of each aircraft shall alter course to the right.
- (f) *Overtaking*. Each aircraft that is being overtaken has the right-of-way and each pilot of an overtaking aircraft shall alter course to the right to pass well clear.
- (g) *Landing*. Aircraft, while on final approach to land or while landing, have the right-of-way over other aircraft in flight or operating on the surface, except that they shall not take advantage of this rule to force an aircraft off the runway surface which has already landed and is attempting to make way for an aircraft on final approach. When two or more aircraft are approaching an airport for the purpose of landing, the aircraft at the lower altitude has the right-of-way, but it shall not take advantage of this rule to cut in front of another which is on final approach to land or to overtake that aircraft [7].

It should be noted that Title 14 CFR, Part 91.113 excludes operations over water, and international airspace, by definition, is over the high seas, or over water, so the section would not apply.

Part 91.1(b) requires that civil aircraft must comply with ICAO Annex 2 when operating over the high seas [8]. Annex 2 requires that "Aircraft shall be equipped with suitable instruments and with navigation equipment appropriate to the route being flown." In addition, Annex 6, Part II, requires that an aircraft operated in international airspace have operating navigation equipment that will enable it to

proceed in accordance with the filed flight plan and with any requirements imposed by air traffic services [4].

Accordingly, any flight operated in international oceanic airspace on an IFR flight plan, a VFR controlled flight plan, or at night, if continued beyond the published range of normal airways navigation facilities (NDB, VOR/DME) is considered to be a long-range Class II navigation operation. Long-range Class II navigation in ICAO Controlled Airspace requires the aircraft to be navigated within the degree of accuracy that is required for air traffic control (the aircraft must follow the centerline of the assigned route, maintain assigned altitude and the speed filed or assigned).

All requirements of Annex 2 (as supplemented by Regional Supplementary Procedures, Document 7030 and Annex 6) are incorporated in 14 CFR 91.1 for those aircraft operating under U.S. civil certifications in international oceanic airspace [15]. In other words, even if a U.S.-registered aircraft leaves U.S. territorial airspace and enters international airspace, it must still be operated under the applicable Federal Aviation Regulations and related orders.

ICAO publishes the SUPPS, which constitute the procedural portion of the Air Navigation Plans developed by Regional Air Navigation (“RAN”) meetings to meet the needs of specific areas that are not covered in the worldwide provisions. The SUPPS complement the statement of requirements for facilities and services contained in the Air Navigation Plan publications. Procedures that apply worldwide are included either in the Annexes to the Convention on International Civil Aviation as Standards or Recommended Practices (“SARPs”), or in the published PANS.

The prospective UAS operator is cautioned that the SUPPS do not have the same status as SARPS. The PANS are recommended to contracting states for worldwide use, while the SUPPS are recommended to contracting states for application in the groups of flight information regions to which they are relevant. PANS originally were developed from common recommendations of regional meetings and were given worldwide application by the ICAO Council after action thereon by ICAO Divisions. Subsequently, there has been a gradual evolution of procedures from the regional to the worldwide category as ICAO Divisions have adapted regionally developed procedures to broader worldwide requirements. Concurrently, some of the worldwide procedures have been found suitable for classification as SARPS and therefore are gradually being incorporated into the Annexes to the Convention [18].

89.7 What Applies and What Does Not?

In the international arena, contracting states that provide air traffic control or information services in international airspace Flight Information Regions can, through the mechanism of supplementary agreements, establish additional rules or procedures for aircraft entering and transiting the airspace in which the contracting states have agreed to provide services. The answer to the question of whether those States can impose their own domestic aviation regulations on aircraft and pilots operating in those FIRs depends upon whether those local regulations conflict with ICAO’s Rules of the Air and other Annexes to the Convention. Examples of

potentially inconsistent application or interpretation of ICAO rules can be found in Canada, Denmark, and Iceland, three nations that control or provide services in North Atlantic, North American, and Arctic airspace. All three States require that pilots and aircraft be IFR (instrument flight rules) rated for trans-oceanic flight, regardless of the altitude to be flown, making no distinction between higher-flying commercial airliners and lower-flying general aviation aircraft. However, other North Atlantic States allow Visual Flight Rules (“VFR”) flight at or below FL055 (5,500 ft above the surface), which means that no services such as navigation vectors or separation between aircraft are provided [14].

The “see-and-avoid” requirement that is both implied and explicitly stated in the Annexes to the Convention presents a challenge and possibly a threshold barrier to anyone wishing to operate unmanned aircraft in international airspace. A remotely piloted aircraft by definition has no human onboard to provide the see-and-void capability that a pilot brings to manned aviation, that is, the ability and the legal requirement to look for and see another aircraft, mentally process the information, and then initiate the necessary steps to avoid a collision. Although many unmanned aircraft are equipped with a camera or visualization device, the equipment is generally used for surveillance or observing whatever the aircraft has been deployed to observe. Others carry remote sensing instruments that may not include a camera and are navigated through the air semi-autonomously on preprogrammed flight plans that rely upon Global Positioning System technology and other sensors that monitor the aerodynamic performance and system health of the aircraft. Remotely situated pilots operating a combination of computerized navigation systems, synthetic vision, and onboard forward-looking cameras operate a variety of military grade UASs, but typically not in nonsegregated civil airspace (there may be exceptions in some European countries). To date, an airborne “see-and-avoid” system that has been certified by any civil aviation authority as being capable of replacing the ability of a human pilot onboard the aircraft to provide the see-and-avoid capability that is required for flight in international airspace has yet to emerge.

As discussed above, contracting states retain the right to publish exceptions to ICAO standards, recommended practices, and procedures as set forth in the Annexes and Supplementary documents [9]. This does not mean that ICAO’s regulations do not apply without exception to international airspace, but rather that they apply in territorial airspace only to the extent that they do not conflict with the regulations of the contracting state. Each contracting state thus retains sovereignty over its own airspace and aviation regulations. In the USA, the FAA publishes and keeps current an extensive list of exceptions to ICAO’s Annexes. Currently no exceptions published by the FAA address the operation of unmanned aircraft in international airspace or airspace in which the USA provides air traffic services. The Regional Supplementary Procedures document published by ICAO sets forth all procedures that have been developed by each contracting state for the Flight Information Regions or Control Areas for which their Air Traffic Service units provide service. As of this writing, none of the regional agreements address flights of unmanned aircraft in their control or information areas.

As ICAO is the standardizing body for international air transportation, its primary goal is to develop the core principles and safe procedures of air navigation and to promote continued cooperation among nations to further evolve those standards as technology changes and improves. The top-level priority is to ensure the safe and orderly growth of civil aviation worldwide, and that now includes unmanned systems.

Ongoing efforts in Europe and several other ICAO states (United States, Canada, Australia, Great Britain, Norway, Greenland/Denmark, and Sweden, to name a few) have focused on developing specific UAS regulations, and in some cases to harmonize them with the ICAO UAS Study Group's recommendations. ICAO released UAS Circular 328 in March of 2011; a 46-page "must read" document that is ICAO's first step towards harmonizing UAS regulations and standards throughout the world. As stated in the forward, "(T)he goal of ICAO in addressing unmanned aviation is to provide the fundamental international regulatory framework through Standards and Recommended Practices, with supporting Procedures for Air Navigation Services and guidance material, to underpin routine operation of UAS throughout the world in a safe, harmonized and seamless manner comparable to that of manned operations. This document is the first step in reaching that goal" [17].

Proposed amendments to Annex 2 (Rules of the Air) and Annex 7 (International Standards Aircraft Nationality And Registration Marks) addressing some UAS-related issues are in circulation, but nothing has been approved, so the diligent operator will want to continue to monitor the ICAO effort, as the outcome will impact development of UAS regulations in the contracting states.

89.8 Role and Development of Standards

As ICAO is a standards making organization, so is the FAA, but in a different sense. ICAO publishes its rules for air navigation in international airspace, and all contracting states agree to abide by them. The contracting states participate in the standards development process and have an equal say in the final product. In the USA, the FAA makes rules (FARs) through a complex and time consuming procedure that allows for broad participation by all citizens, and is guided by the Administrative Procedures Act [24]. To support the regulations, the FAA also engages the services of groups of experts, working through the protocols of organizations such as ASTM, RTCA, and SAE, to create standards that describe methods to comply with the requirements of particular provisions of the FARs. These standards are then published as Advisory Circulars ("ACs"). The ACs usually have some language to the effect that the circular is not mandatory and is not a regulation, but merely describes an acceptable means, but not the only means, of compliance with the subject regulation. It may also state that if the described means of compliance is utilized, it must be followed entirely.

Whether developed at a national level, as in the USA, or internationally, the standards processes are typically consensus based, relying upon the expertise of people who are engaged in the particular field or industry and who have special

knowledge about the subject that they are willing to share. The published standards are especially useful to the proponent or applicant for permissions to operate an unmanned system in nonsegregated airspace, as a tool to convince the controlling civil aviation authority that they can safely operate their system in a manner that does not interfere with navigation or present an unreasonable risk of harm to persons or property in the air or on the ground.

The FAA's general guidelines for UAS standards development are focused on the agency's safety assessment of the potential risks presented by the introduction of unmanned aircraft into the National Airspace System ("NAS"). Standard bodies are to associate standards with hazard causal events (after a hazard has been identified, assess what causes that hazard). For example, a hazard might be identified as a loss of control of the aircraft, causing it to divert from its intended flight path and "fly away" to an unpredictable termination of flight. The causes of such an event could be many; among them a failure of the power source that drives the telemetry or data link that connects the aircraft with the ground control station. That failure in turn could be due to the exhaustion of battery power, a structural battery failure, or a wiring disconnect between the battery and the onboard navigation package, and so on. The regulatory agency or body may impose a general requirement that such an event or series of events be "highly improbable" or "extremely unlikely." Or the requirement could be more specific, such as that the battery must have a life cycle of so many hours of use. If the requirement is general, a supporting standard could be that the data link architecture be tested to achieve some mathematical equation or number that is equivalent to "highly improbable." If the requirement is more specific, the standard might suggest a method to test the life cycle of the battery or put it under some form of stress environment until it fails.

A critical element of a useful standard is that it must be understood. If standards are too abstract, or cannot be tested using conventional scientific methods, there is no way to demonstrate that "acceptable" has been achieved. Thus, for each standard, a number of questions must be answered (a "standard for a standard," so to speak). First, what does the standard aim to achieve? Is it a general standard, or specific to a particular hazard? Is it directed towards design, production, operations, or some other requirement? Second, how is the standard relevant to UAS safety? If the standard is not safety related, but only addresses commercial viability, it may not be an appropriate aviation standard. Third, which hazard causal events are addressed? Fourth, is the standard clear? Can it be reasonably achieved? Is the standard complete? And lastly, does the standard have sufficient content and structure to be usable? The bottom line is that the system or component must be both safe and reliable, and the standards should be constructed to assist the public in achieving both requirements.

89.9 A Suggested Method for Compliance

For the uninitiated or unwary, aviation rules, regulations, laws, and standards present a minefield of possible violations or dead-end paths.

To determine the potential applicability of current Federal Aviation Regulations to all aspects of unmanned aircraft systems, operations and manufacturing, a top-level review of each section of Title 14 of the CFRs was conducted to determine which, if any, of the FARs could be directly applied to UAS. The review further separated these regulatory sections and subsections into four categories: *Clearly Applies*, *May Apply by Interpretation*, *Does Not Apply*, and *Could Apply with Revision*. The total number of sections, subsections, and parts that were so categorized exceeded 8,400.

Follow-on studies of Parts 43, 61, and 91 of the FARs developed and further explored the rationale behind each designation, taking into consideration the intent of the entire Part, so far as the intent is known from Federal Register publications, the Preambles to the published Parts, and other historical or archival documents. The analysis approached the applicability of each section of the relative Part to UAS operations and airworthiness requirements from the perspective of the original intent and safety implications of the relevant sections and endeavored to clarify technical issues raised by the application of known UAS technology to existing regulations.

For example, the 132 subsections of Title 14 CFR Part 61 (Certification of Pilots, Flight Instructors and Ground Instructors) each have multiple subsections, so to the extent that a “scientific method” can be applied to the analysis that underlies this study, each major section was examined holistically, acknowledging that the system as a whole determines in an important way how the parts should be interpreted (“The whole is more than the sum of its parts” – with apologies to Aristotle). However, “reductionism” (holism’s opposite) in science holds that a complex system can be explained by reduction to its fundamental parts. The approach of the study was to assess each major section initially in the context of the overarching purpose of the CFRs (aviation safety), to look behind the section by examining the intent of the rule makers in adopting the language that they did (if evidence of that intent is available), and then to reduce the section and its subsections in the manner that might be employed by a court in interpreting the language of the regulation. Although it would be extremely time consuming and potentially confusing to attempt to identify every possible or reasonably foreseeable scenario that could invoke an interpretation of the regulation, an attempt was made to analyze each section from the perspective of known and contemplated unmanned aircraft applications, drawing upon the materials presented at UAS-focused conferences, symposiums, workshops, and committee meetings as well the multitude of white papers, treatises, thesis, promotional materials, and briefings that are commonly available on public domain websites.

A comprehensive and sustainable analysis of a complex body of regulations necessarily requires much more than just looking at the language in each regulation. In the U.S. system of aviation regulations, some sections cross-reference to other sections or subsections within the Part or to other parts of 14 CFR. For example, Subpart K, Parts 61.401–431 refers to Flight Instructors with a Sport Pilot Rating, but the Subpart does not define a “Sport Pilot” or a “Light Sport Aircraft.” To determine whether any or all of this Subpart applies to unmanned aviation, one must refer to a number of other Subparts to obtain the necessary definitions, but must also

look at the entire history of Light Sport Aircraft regulation to determine relevance to the issues proposed in the study.

Other sections and Subparts require extensive historical analysis that can only be developed through archive searches or anecdotal sources. The overarching consideration is how specific regulatory language might be interpreted by the FAA's (or any CAA's) enforcement organization, the user community that desires UAS access to a nation's airspace and the adjudicators who may be called upon to arbitrate or decide disputes arising from those interpretations. This approach, to be comprehensive and useful, requires the evaluator to wear three hats: The FAA/CAA enforcement staff and legal counsel (if any), the pilot, operator or instructor who may be most directly affected by an interpretation of a rule or regulation, and the Administrative Law Judge, NTSB Member or appellate court justice (in the American system) who may ultimately be called upon to decide the issue in an adversarial proceeding.

The sources for interpretation of U.S. Federal Aviation Regulations can be identified in 11 categories:

- The language of the regulation itself
- Explanations of the meaning of the regulation that may be contained within the regulation's language
- Guidance offered in the Preambles, if any
- Cross-references to other regulations and their respective guidance
- Advisory Circulars that represent the FAA's interpretation of regulatory language, often with reference to a particular incident or situation, and contain explanations of regulations, other guidance material, best practices, or information useful to the aviation community (as noted above, Advisory Circulars are not regulatory, do not create or change a regulatory requirement, and are not binding on the public)
- FAA Notices and Orders (published)
- FAA Policy Statements and Guidance Documents (published)
- Legal interpretations contained in NTSB case reports or in published opinions from the courts of general jurisdiction
- Language in the Aeronautical Information Manual ("AIM")
- Other agency interpretations (often published, but not binding on the public)
- FAA Chief Counsel opinion letters

The available resources in other countries may not be as extensive as in the USA, and the best resource for guidance for UAS activities will most likely be the language of the regulation itself, perhaps informally supplemented by a conversation with a knowledgeable representative of the CAA.

The requirement for this type of regulation study is to provide an analytical tool, employing system safety analysis methodology, as well as sound legal interpretive principles, that will enable the interested party to identify and appreciate the gaps, overlaps, consistencies, and inconsistencies in the current regulatory scheme that serves as the framework for oversight of involved in unmanned aviation. Evaluating a body of regulations that is comprised of over 8,000 sections that is supplemented by thousands of pages of Orders, Advisor Circulars, guidance documents, and is

continually in the process of revision, is a daunting task. And that only describes the challenge in the United States. For a UAS manufacturer, developer, or operator to compete their product or service in a global market, the challenge may be to perform or engage the performance of similar top-down studies in every potential arena of use. Because there is little or no global harmonization of UAS rules other than those that ICAO is developing for service providers in international airspace, with potential application or adoption in territorial airspace, a methodical approach facilitated by a strong analytical device becomes the tool of choice for the diligent UAS proponent.

89.10 Is Full Global Harmonization Realistic and Achievable?

A wildly optimistic answer would of course be “Yes.” There are no fewer than a dozen UAS harmonization and standards efforts underway as this book goes to press, both on an international level and localized within individual countries. In the USA, the President signed into law legislation in February of 2012 that specifically mentions unmanned aircraft systems and directs the FAA to perform certain tasks and achieve specific benchmarks (including full integration of UAS into the national airspace) before September 30, 2015 [19]. In 2008 the FAA chartered a sUAS (small UAS) Aviation Rulemaking Committee (“ARC”) to recommend a set of rules to govern smaller categories of unmanned systems. Simultaneously, a safety risk assessment was performed, and the ASTM organization was later engaged to develop a set of standards that would provide guidance on means of compliance with the new rules when they are published in the NPRM (Notice of Proposed Rulemaking), which is a legal requirement that the FAA must meet before the rules can be finalized.

Elsewhere, the work goes on in many countries that have responded to the demands of the commercial and scientific UAS community to promulgate rules and standards that will allow them to carry out a wide variety of useful purposes for UAS, such as climate and atmospheric research, marine and terrestrial mammal observation, fisheries monitoring, migratory bird surveys, sea ice analysis, pipeline and power line inspection, agricultural remote sensing, wildlife and forest monitoring, law enforcement, etc., and the list goes on. The work undertaken by the ICAO UAS Study Group, as seen in ICAO Document 328, may provide a starting point for nations that have not begun to address the UAS issue, a global context for those that have so begun, and a roadmap for compliance for nations such as the United States that have progressed the farthest in developing a comprehensive framework for regulatory oversight over this rapidly evolving technology.

Conclusion

For both the novice and the seasoned professional, the task of finding, understanding, and incorporating into UAS development and operations all of the applicable rules, regulations, standards, and guidance can be somewhat

overwhelming. Some aviation regulations are voluminous (the United States), some short and sweet (e.g., Iceland), and others quite incomprehensible (Russian Federation, among others). The methodology suggested in this chapter works especially well for complex regulatory environments, but can be useful as well for those that are less cumbersome. The important element to remember is that all rules and regulations are subject to interpretation, and the person or entity that chooses to engage in UAS activities without a thorough understanding of the rules and requirements does so at their peril. In the USA, the peril can mean significant monetary penalties, revocation of certificates and licenses, and even jail time. One bad event or accident involving a UAS operating outside of agreed upon rules and standards could set the industry back several years, in the opinion of many experts in the field. Flying first and begging forgiveness later if something goes wrong may work in limited circumstances, but as a long-term business practice, it is a risk that may not be worth taking.

Harmonization on a global scale is indeed achievable, and the processes tend to be relatively transparent and friendly to all comers who have an interest in the issues. The best way to ensure that your voice is heard is to participate in the rulemaking at some level, and to bring your experiences and knowledge to the table for the benefit of all.

Abstract

This chapter discusses the specifics of the Certificates of Authorization (COA) that were obtained for the second Verification of the Origin of Rotation in Tornadoes Experiment (VORTEX2) project and how the operations were conducted to satisfy the COA requirements. A strategy is outlined for operating these nomadic missions with small UAS within the confines of FAA regulations. This includes information on getting FAA COAs for a large area, specifically focusing on area selection, airworthiness, and emergency procedures, which are the keys to these applications. Interacting with the FAA once COAs have been granted is very important to the success of such a mission and is included in this chapter along with some lessons learned to improve future projects with similar goals.

90.1 Introduction

On 6 May 2010, on the plains of west Kansas, the Tempest unmanned aircraft system (UAS) made the first ever intercept of a supercell thunderstorm as part of the VORTEX2 field campaign (Elston et al. 2011b). This was surpassed on 10 June 2010, on the plains of eastern Colorado, with the first ever UAS intercept of a tornadic supercell (Elston et al. 2011b). With more than 100 scientists and engineers deploying more than 40 instrument platforms, VORTEX2 was the largest effort in history dedicated to the study of tornadoes (Oceanic and Association 2010). Two field campaigns were conducted 1 May–13 June 2009 and 1 May–15 June 2010; the Tempest UAS was deployed for the 2010 field campaign. The VORTEX2 participants maintained a completely nomadic program, roaming the Great Plains to track supercell thunderstorms. Supercells are the most violent form of severe convective storms, often producing the most violent and damaging tornadoes. The purpose of VORTEX2 is to study these storms for a better understanding of the ingredients that create supercells and to try to answer the question of why some supercells produce tornadoes while others do not (VORTEX2 SPO).

The development of the Tempest unmanned aircraft system (Fig. 90.1) addressed a variety of scientific, technical, logistical, and regulatory issues. Science drivers for the Tempest UAS focused on the need to sample pressure, temperature, humidity, and wind velocity in the rear-flank downdraft of supercell thunderstorms. Current models suggest that this area plays a causative role in tornadogenesis, and these models cannot be evaluated without in situ data. In turn, the science drivers lead to the requirement to sample the storm in areas where little is known about the flight conditions that will be encountered. As a result, the Tempest aircraft was developed for robust flight across a range of expected flight conditions. The dynamic nature of supercell thunderstorms necessitated a mobile concept of operations such that the unmanned aircraft could be stowed and transported by ground and then launched as quickly as possible. Finally, additional limitations were imposed by the Federal Aviation Administration (FAA) in order to satisfy regulatory requirements for the operation of unmanned aircraft systems.

Fig. 90.1 The Tempest unmanned aircraft (note the funnel cloud on the horizon, aligned with the midpoint of the aircraft)

The operations of unmanned aircraft systems in the U.S. National Airspace System (NAS) are governed by the Federal Aviation Administration, with guidelines established in *Interim Operational Approval Guidance 08–01, Unmanned Aircraft Systems Operations in the U.S. National Airspace System* (Policy 08–01) (Davis 2008). This document was created to define requirements and procedures for the operation of unmanned aircraft systems and it specifies that special approvals are required for the operation of UAS in the NAS (outside of active restricted, prohibited, or warning areas) because unmanned aircraft systems, are not compliant to many sections of Title 14 of the Code of Federal Regulations (14 CFR) (<http://www.gpoaccess.gov/cfr/>) and thus require an alternate means of compliance. This compliance is demonstrated by receiving a certificate of waiver or authorization (COA) or by obtaining a special airworthiness certificate—experimental category, the only two available methods of approval.

For public institutions, defined as *one that is intrinsically government in nature*, approval for operations of UAS is obtained through the COA process (Davis 2008). A COA defines operational requirements, emergency procedures, airworthiness requirements, an area of operations, and ground crew proficiency requirements for the operation of a single class of UAS. The overarching goal of the COA application is to demonstrate that the operations of the UAS have an equivalent level of safety to manned operations. In contrast to public institutions, private institutions and commercial companies (Ballinger and Bossert 2007) must also obtain a special airworthiness certificate, typically an experimental airworthiness certificate, for legal operations of their unmanned aircraft systems.

A recent FAA Aviation Rulemaking Committee (Tarbert and Wierzbanski 2009) reported “a comprehensive set of recommendations for small UAS regulatory development.” These regulatory recommendations have yet to be adopted, even in part. The regulations that must be satisfied for the operation of UAS remain those developed for manned aircraft resulting in a COA application process for UAS that is not straightforward. Prior to the 2006 “grounding” of UAS for those operating without a COA or an experimental certificate, many

small UAS operators claimed permission to operate according to FAA Advisory Circular AC 91–57 (Van Vuren 1981), which provides guidelines for the operation of hobbyist model aircraft according to the rules of the Academy of Model Aeronautics (AMA). With the creation of the Unmanned Aircraft Program Office (UAPO) in 2006 came enforcement of the COA and special airworthiness certificate requirements for public and civil UAS, respectively. The UAPO and the FAA Air Traffic Organization (ATO) were unprepared for the widespread misunderstanding of the COA application process, the subsequent onslaught of COA applications, and an almost complete misunderstanding of the requirements for civil entities to obtain UAS certification (Murphy and Argrow 2009).

Although the UAPO has worked to clarify regulations and submission requirements, rather than define a complete set of sufficient conditions for receiving a COA, the UAPO approach is to evaluate submitted UAS, operations, and procedures individually. As a result, information provided from the online application portal (http://www.faa.gov/about/office_org/headquarters_offices/avs/offices/afs/afs400/afs407/) can be vague, and determining the appropriate level of detail and requirements for each section of the application often requires several submissions, rejections, and subsequent iterations of the application.

In the interest of illuminating this process, this chapter describes the construction and subsequent use of 59 COA applications for the Tempest UAS used during the VORTEX2 field experiment. This chapter presents the information used to complete the COA application process and identifies decision and methods employed for a successful application, including the specification of operations area, how the airworthiness of the system was derived, the emergency procedures that were used, and the evolution of the actual operations and reporting requirements under the COA. The guidance given in this document follows that of Policy 08–01 (Davis 2008). It must be stressed that the information described here only pertains to the Tempest UAS, and the specific details included in our applications were based on the judgements of the authors and do not reflect definitive standards for a successful application.

90.2 Motivation and Application Strategy

The primary engineering objective for the Tempest UAS deployment was to develop a small UAS networked into a mobile command, control, and communications (C3) infrastructure that could meet the requirements for supercell penetration, specifically in the rear-flank downdraft (RFD), a region considered critical to the understanding of tornado formation. The UAS would also have to meet requirements for portability, with the mobility to target and track supercell thunderstorms, then enable rapid launch, storm penetration, and recovery of the unmanned aircraft.

Fig. 90.2 Three sampling scenarios designed for use in the 2010 VORTEX2 campaign (Elston et al. 2011b) (a) S1 = standard inflow launch parallel to storm motion (b) S2 = inflow launch perpendicular to storm motion (c) S3 = outflow launch parallel to storm motion

Although the engineering requirements for the Tempest UAS were ultimately driven by the meteorological science objectives, for VORTEX2 the purpose was to demonstrate the feasibility of a small UAS for supercell sampling, so the science objectives were secondary to the engineering objectives. The primary science objective was to collect in situ measurements of pressure, temperature, and humidity, targeted in the rear-flank downdraft (RFD) and its outflow (VORTEX2 SPO). The RFD generally forms on the southwest portion of the storm, and when the downdraft approaches the ground, it spreads horizontally to form the RFD gust front. The focus of the Tempest UAS science mission is to fly into the RFD from the east or the south, crossing the gust front during the ingress.

Figure 90.2 from Elston et al. (2011b) illustrates three sampling scenarios. In S1 the UA is launched from the east of the supercell, then flies beneath the hook of the mesocyclone, near the tornado indicated by the small red triangle, into the RFD. The UA then proceeds to fly multiple transects, where the different colors of the trajectories indicated transects at different altitudes. For S2, the UA approaches the mesocyclone hook from the south, crossing the RFD gust front with its horizontal outflow before the UA makes contact with the main downdraft of the RFD and the tornado. S3 is the most difficult of the three scenarios, with an approach from the southwest which means that the UA is chasing supercells that typically move on northeast to easterly tracks.

Development of the concept of operations (CONOPS) for the Tempest UAS, and subsequent COA applications, focused on safe, assured operations by maintaining situational awareness of the UAS and airspace at all times. The main barrier to safe operation that satisfies FAA regulations is the ability to perform “sense and avoid” whereby the operational airspace is continually monitored and deconflicted, i.e., the UAS is kept clear of other airborne traffic. Though the FAA allows different options for providing sense and avoid, (e.g., stationary visual observers on the ground, visual observers in a chase aircraft, ground-based radar, radio transponders, and direction from air traffic control), stationary ground observers were used as the only solution during VORTEX2.

A second major factor in the COA application process was the dynamic, mobile pace of operations required to sample supercell thunderstorms. The conditions for supercell thunderstorm formation can become evident several days in advance. However, pinpointing the location and trajectory of a particular storm is difficult. Further, the onset of tornado formation cannot be predicted reliably in advance (the whole point of the VORTEX2 mission). Tornadogenesis within a supercell thunderstorm has been observed to occur in as little as 13 min from the first manifestation of potential tornadic activity (Erickson and Brooks 2006). As a result, successful operation during VORTEX2 required the ability to establish flight profiles with minimal advance notification. The standard provisions for most COA's require at least 48 h notification to activate a COA area through Notice to Airman (NOTAMS) along with contacting other groups such as ATC or military operations groups depending on the area. This provision would make these types of operations impossible.

Many of the FAA requirements that needed to be satisfied affected directly the design of the Tempest system. These design decisions were a direct result of a previous project, the Collaborative Colorado-Nebraska Unmanned Aircraft System Experiment (CoCoNUE), that acted as a precursor to the VORTEX2 campaign with the goal of using a UAS to sample across an air mass boundary. One of the important lessons learned during these experiments is that maintaining eyes on the aircraft from a chase car (an FAA requirement to ensure airspace deconfliction) is only feasible if the aircraft is tasked to orbit the chase car. This coupled with the requirement of a stationary ground station led to the use of a tracker vehicle which needed to maintain a data link with the aircraft to share its GPS position and led to the use of an ad hoc network to allow the UA to simultaneously communicate with both the ground station and the tracker vehicle; see Elston (2011) for more information on the communication subsystem.

Some subsystems had to be added to the Tempest UAS to either satisfy FAA requirements or to increase safety to expedite the COA process including a 900 MHz tracking antenna with Yagi for up to 20 miles of range to ensure communication over the maximum range of COA area from stationary ground station, a 2.4 GHz data link with ad hoc communication and multi-hop routing protocol for communication from the aircraft to both the tracker vehicle and the stationary ground station, a COTS autopilot and airframe for self-certification, a tracker vehicle to stay with the UA, and a scout vehicle to check the roads ahead for the tracker vehicle.

90.3 COA Application

90.3.1 COA Area Selection

Certificates of authorization are issued for specific areas of operation. The FAA requires that the UA position be known with enough accuracy that air traffic controllers can inform nearby aircraft. To satisfy this requirement, UAS operators

are generally required to file a Notice to Airmen (NOTAM) 72–48 h in advance of operations. The NOTAM specifies the location and time of the flight within the area specified by the COA. Several institutions have obtained COAs to perform prolonged flights over large distances by filing specific flight plans 72–48 h before the intended operation (Ambrosia and Hinkley 2008). In contrast, the work motivating this work required flight within 3,000 ft of the ground with much shorter notification constraints. Therefore, the focus of COA area selection presented here is on flights with small UAS through class G and E airspace without a predetermined flight plan.

Since NOTAMs could not be issued far in advance, COA application size was kept small enough to insure that the position of the UA was known relatively well and to minimize the workload on air traffic controllers who must notify pilots approaching the active COA airspace. Given the context of the VORTEX2 mission (Elston et al. 2011b), it was desirable to operate the UAS in an area over 24,000 square miles (62,000 sq km) in size (the green box in Fig. 90.3). Based on informal discussion with the FAA Unmanned Program Office, it was determined that this area was too large for a single COA.

To obtain permission for flying in this large area, the authors followed the example of the University of North Dakota's successful COA applications in multiple locations across their state (Douglas Marshall and Benjamin Trapnell, personal communication, 17 Dec 2008.), where they broke an area into several COA areas made up of approximately 10×10 mile (16×16 km) polygons. In the case of the Tempest COAs, the domain of operation was split into 59 areas approximately 20×20 miles (32×32 km) in an attempt to balance the size of the areas with the number of COA applications that would be needed to cover the complete mission domain (Fig. 90.3). In a debrief to the Denver Air Route Traffic Control Center (ARTCC) following the VORTEX2 operations, air traffic controllers indicated that circular areas are the preferred shape to issue a conventional NOTAM, specified by a radial distance from a geographic point. (Denver ARTCC, personal communication, 14 Oct 2010.) Future applications and renewals will follow this guidance.

After selecting the maximum size of the bounding polygon, the following additional items were considered to determine its shape: population density, major roads, airports, and airspace (Fig. 90.4). These were used to restrict the polygons to regions that could be shown to have low potential for property damage or human injury in the case of a failure of the UAS. The specific values were chosen heuristically with the expectation that they would satisfy the FAA UAPO. The minimum limits are 3 miles (5 km) from any town of significant size (population >1,000), 3 miles (5 km) from any airport, 1 mile from any major road (such as an interstate highway), and within class E or G airspace.

The FAA determines the maximum altitude for operations based on an estimate of the ability of an observer with a class 2 medical certification to see the UA and be able to ensure airspace deconfliction with other aircraft. The Tempest COA applications requested a flight ceiling of 3,000 ft above ground level (AGL). However, with its 10.5-ft (3-m) wingspan and slender fuselage, the FAA imposed a

Fig. 90.3 Vortex 2 operations area (*red*), desired UAS operations area (*green box*), actual COA areas (*blue polygons*)

Fig. 90.4 Considerations for the sizing, shape and location of each *polygon*, with green arrows indicating minimum distances and obstacles including 5 miles or more from both airports and built-up areas, 1 mile from major highways, and consideration for Victor airways, which the FAA does not allow loitering in

ceiling of 1,000 ft (300 m) AGL for operation of the Tempest UAS, with some areas limited to a 400-ft (120-m) ceiling based on proximity to specific airport approach airspace. Victor airways must also be considered, and in some cases impact the decisions to provide permission for flights over 400 ft (120 m) AGL.

90.3.2 Airworthiness Statement

Policy 08–01 (Davis 2008) outlines the procedure to create an airworthiness statement and lists several standards that have acceptable criteria for the self-certification of a public aircraft. The Tempest airframe airworthiness statements are based upon the Department of Defense (DoD) handbook MIL-HDBK-516A ([http://www.everyspec.com/MIL-HDBK/MIL-HDBK+\(0500+-+0599\)/MIL-HDBK-516A-2069/](http://www.everyspec.com/MIL-HDBK/MIL-HDBK+(0500+-+0599)/MIL-HDBK-516A-2069/)), which is superseded by MIL-HDBK-516B ([http://www.everyspec.com/MIL-HDBK/MIL-HDBK+\(0500+-+0599\)/MIL-HDBK-516B-10216/](http://www.everyspec.com/MIL-HDBK/MIL-HDBK+(0500+-+0599)/MIL-HDBK-516B-10216/)). Although the following discussion refers to MIL-HDBK-516A, the reader should refer to the more recent MIL-HDBK-516B when preparing a new COA application.

These handbooks were created for the certification of military aircraft, including manned and unmanned aircraft that carry ordnance, so the user must determine the criteria that are relevant for civilian applications. Sections 4–19 of MIL-HDBK-516A contain criteria specific to the different systems and operational procedures that must be addressed for airworthiness, though it is clear that Sections 9, 17, and 18 of MIL-HDBK-516A do not apply to unmanned aircraft.

The Tempest airworthiness document submitted to the FAA contained the heading of each subsection (e.g., 12.x) followed by statements explaining how each criterion is addressed to guarantee airworthiness. In many cases the subsection was not pertinent to the Tempest UAS, and it was sufficient to include a statement indicating this fact. Examples of criterion in MIL-HDBK-516A that were not necessary to satisfy for the Tempest UAS are structural fatigue, flight envelope, aircraft stability, and avionics architecture. It is, however, necessary to outline the procedures and analyses that are used to guarantee these criteria or steps used to mitigate risks from possible failures.

Airworthiness of the Tempest UAS was demonstrated based on three main factors. First, the airframe was developed in collaboration with a commercial manufacturer with experience designing and constructing competition radio-controlled sailplanes. In particular, Skip Miller Models (Skip Miller) modified an existing design based on specifications for the VORTEX2 mission. Successful demonstration in remote control dynamic soaring (RCS [2011](#)), where aircraft routinely obtains high air speeds and accelerations, validates the ability of the construction techniques used in the Tempest airframe to provide sturdy and durable aircraft. Second, the commercial Piccolo SL autopilot (Cloudcap) used for the Tempest UAS has an established record of success, both in military systems and other unmanned aircraft that have obtained COAs, including other UAS operated by the authors. Third, the complete Tempest UAS avionics system, which includes redundant wireless communication channels, onboard supervisory computer, ground control station, and operator interface, has been demonstrated through flight operations of other aircraft (Brown et al. [2007](#); Frew et al. [2008](#); Houston et al. [2012](#)). An appendix with examples of checklists, flight logs, maintenance logs, and operational procedures was included in the COA application to document those items used to support safe operations and maintenance. General guidelines for preparing an airworthiness statement based on lessons learned from VORTEX2 and other flight operations are given in Elston et al. ([2011a](#)). Excerpts from the Tempest UAS airworthiness statement are given here to show the level of detail required. Heading titles correspond to the sections of MIL-HDBK-516A.

6. Flight Technology

6.1 Stability and Control

The airframe used for the Tempest UA is the Tempest glider, commercially available from Skip Miller Models. The Piccolo Light autopilot control system ensures stable flight characteristics when coupled with a stable aircraft such as the Tempest UA as

required in Sect. 6.1.2.3. The envelopes, as outlined in 6.1.6, will be safe because the Tempest airframe is a commercially available glider.

6.2 Vehicle Control Functions (VCF)

The physical components of the VCF (i.e., the servos, control links, control surfaces, and electrical connections) employ high-grade commercial components sized for the maximum GTOW. All control surfaces are fully articulated during preflight checks to visually verify clearances. The control link to the Piccolo Plus on the Tempest UA is a single point of failure, but contingencies are in place in case of failure as outlined in the Lost Communication section. Preflight checklists for the Tempest UA are used to minimize the risk of failure as per 6.2.2.36. The emergency procedures, as outlined in the Emergency Procedures section, are appropriate and address the full range of possible emergencies as required in 6.2.55.

The Tempest subsystems are powered by a lithium-ion battery packs. Power is monitored from the UAS ground station to indicate primary power loss. The contingency is to immediately power-down any payload and return the Tempest UA for immediate landing. In the unlikely event of complete power loss, the UA servos reset the control surfaces to a default setting for spiral glide to the ground to prevent an uncontrolled excursion outside the primary area of operations. The VCF software is provided commercially by Cloudcap for the Piccolo Plus autopilot. This software is extensively tested and is safe in all normal flight conditions. For emergency situations, the procedures used are outline in the Emergency Procedures document.

9. Crew Systems

The Tempest is unmanned; therefore, there are no crew systems.

90.3.3 Lost Communications and Emergency Procedures

Lost communications and emergency procedures are specified as part of the COA application. The contents of these sections of the COA application pertain to the operations during abnormal and emergency situations. It is impossible to develop guidelines and procedures to deal with all situations, so the Tempest UAS application enumerated them as best as possible and stated that the judgement, skill, and training of all persons involved in flight operations were necessary to bring an abnormal or emergency situation to a safe conclusion.

The policies and procedures used for the Tempest UAS were developed and refined through previous flight experiences with other aircraft (Brown et al. 2007; Frew et al. 2008; Houston et al. 2012). In general, the response to an in-flight emergency or severe change in weather is to bring the UA back to the main landing site and to begin landing procedures, using either manual or automatic landing. The COA applications stated that all incidents and accidents would follow reporting and notification processes and requirements as laid out in FAA Orders 8020.11,

7210.56, and in NTSB 830. During the VORTEX2 mission, there were no incidents that required reporting under these rules.

The Tempest UAS COA application was written specifically for a three-person team piloting an unmanned aircraft system using a Piccolo autopilot system ([Cloudcap](#)). FAA regulations require a two-person team consisting of a pilot in-command (PIC) and a trained, medically certified observer (Davis 2008). Typical Tempest UAS operations consist of the PIC acting as a mission commander and two pilots at control (PACs): the PAC-M with manual flight control through a handheld console and the PAC-O who monitors and controls the UA when it is in semiautonomous mode. Only one of these copilots will be the acting PAC at a given time; therefore, the PIC can perform one of the roles. For Tempest UAS flights during VORTEX2, the PIC always served as the PAC-M.

90.3.3.1 Emergency Procedures

Enumerating all the emergency procedures contained in the Tempest COA application is prohibitive here. The emergency procedures for the Tempest UAS COA application follow the general guidelines (Elston et al. 2011a) derived from experience with the Tempest and other UAS. Overall emergency procedures were designed to maintain safe operations when possible with aerodynamic termination utilized if the aircraft becomes uncontrollable.

The COA application states that a handheld VHF radio will be used to broadcast a distress message in some emergency situations to aid in maintaining a safe airspace when traffic is present in the COA airspace. Distress messages will be broadcast on the specified CTAF/UNICOM frequency of the airport listed in the operational summary of the COA application. The distress message will contain the following information and will be given in the order listed below. Once broadcasted, the message will be repeated every 5 min, upon changes in condition or known location or upon any update requests received. Once the urgent condition is over, a final message will be broadcast to notify any traffic that the emergency condition is over.

1. PAN-PAN, PAN-PAN, PAN-PAN
2. "Local traffic"
3. "This is unmanned aircraft Tempest"
4. The nature and type of the distress
5. Pilot's intention request
6. Last known position and heading
7. Altitude
8. Hours and minutes of propulsion battery remaining
9. Weather
10. Other useful information such as visible landmarks, aircraft color, and that no people are onboard

The emergency procedures outlined in the Tempest UAS COA application are broken down into categories. *Operation emergency procedures* describe how the UAS team responds to incidents involving personnel of the general operation of the aircraft. For example, this section outlines how to respond if the pilot is unable to perform duties or if the aircraft leaves the COA boundary. *Ground control station emergency* describes procedures for responding to ground control station failures,

such as loss of power in the various components. Finally, *Tempest UA* describes responses to emergencies derived from the aircraft, such as loss of power or failure of the navigation solution. The following sections provide an overview of some of the main procedures included in the Emergency Procedures.

Operational Emergency Procedures

- Pilot/Operator/Observer Is Unable to Perform Duties

If a crew member becomes incapacitated during a UA flight, then the duties of that person will be transferred to another certified crew member depending upon the status of the current flight and availability of crew members.

- Loss of Visual Line of Sight by Observer

If the observer loses line of sight (LOS) to the aircraft, then another team member will act as the observer if they have LOS. If no team member has LOS, then the PIC will initiate landing procedures if the airspace is deemed safe or the PIC will command aerodynamic termination if the airspace is not deemed safe.

- Loss of Communication Between PIC and Observer(s)

If there is a loss of communication between the PIC and observer with handheld radios, a backup method such as cell phones shall be used.

- Loss of Communication with ATC

Operations of the *Tempest UAS* will be conducted in class E or G airspace under VFR conditions. Due to these conditions, it is assumed that communications with the local ARTCC or Terminal Radar Approach Control (TRACON) will not be required, but a handheld VHF radio will be used to maintain situational awareness and direct communication to local air traffic if necessary.

- UA Leaves COA Boundary Uncontrollable

In this situation, the first priority of the PIC is to maintain as safe an airspace as possible surrounding the UA. Procedures described here should include broadcasting a PAN-PAN message and using all reasonable effort to maintain VLOS and to terminate the flight.

Ground Control Station Emergency

- Operator Interface Software/Computer Failure

Failure of the operator interface software or the computer running it means that the PAC-O no longer has situational awareness of the UA and can no longer command or control the UA. Procedures for this emergency consider both the case where the UA is in VLOS of the PAC-M and beyond. Communication procedures to the team members are outlined, along with appropriate steps to safely terminating the mission, including automated return to the location of the ground control station, automated landing, remote landing, and finally aerodynamic termination.

- Ground Station Failure

Procedures for ground station failure consider the devices connected (e.g., pilot console, ground station GPS) and the possibility of device disconnection or failure. They also address the possibility of total ground station failure. Appropriate actions include switching of flight modes, turning off DGPS, or terminating the mission.

Unmanned Aircraft Emergency

- Engine-Out

In the case of engine failure, if the aircraft altitude is high enough, the standard landing procedure is initiated. If the altitude is too low, the aircraft is brought down quickly and safely and with the observer helping locate landing areas that consider cases when property, people, or other manned aircraft are in the vicinity.

- Autopilot/Servo Power Loss

Complete loss of power to the autopilot (or servos if on a separate power source) is a catastrophic failure, resulting in the UA being uncontrollable and unpredictable in its flight path. In this situation, the first priority of the PIC is to maintain as safe an airspace surrounding the UA as possible and issuing the appropriate distress messages.

- Degrading Performance of the Autopilot

Degrading or poor performance of the autopilot can be caused by bad or failed sensors, actuators, or by improperly set or adjusted feedback gains. It is expected that most failures that show as degraded autopilot performance are primarily due to the failure of onboard sensors such as the rate gyros, accelerometers, a poor or bad GPS solution, circuit board temperature failure, or failure of the air data system (dynamic and static pressure). Procedures include assessing the failure and determining the appropriate action in a per-sensor manner.

90.3.3.2 Lost Communication and Lost Link Procedures

The Tempest UAS uses a primary communication channel for command and control uplink as well as data downlink. The primary communication link is provided by a 1-W 900 MHz spread-spectrum modem manufactured by Microhard Corp. and is supplied with the Piccolo SL autopilot system as original equipment. The same modem is used in the autopilot and in the Ground Control System (GCS). A lost link on the 900-MHz primary link is considered a lost communication event. Depending upon the operational mode of the UA, the Piccolo autopilot detects two types of lost communications: one is when the aircraft is under manually piloted mode and the other is when the Piccolo is operating under semiautonomous control. In either case, in the event of a lost communication emergency, the UA is no longer under control of the PAC and collision avoidance capability has been compromised. In this situation, the first priority of the PIC is to maintain as safe of an airspace surrounding the UA as possible. This is done by broadcasting a PAN-PAN message to any nearby traffic as described in the Emergency Procedures document.

When the autopilot is under manual pilot (or manual-assisted) control, a lost link is determined by the UA as not receiving any decodable manual pilot control packets for 2 s, referred to as the *pilot time out*. Once this condition is met, the autopilot will automatically switch to autopilot mode and enter into the closest waypoint plan at the time of the pilot time out.

If communications fail entirely for 10 s (defined as the *communication time out*), either under manual or semi-autonomous modes, the autopilot will take automatic action depending upon the status of the GPS time out. If the GPS time out has

been asserted prior to the communication time out, then when the communication time out occurs the autopilot will issue an aerodynamic termination. If the GPS time out has not occurred, then the autopilot will switch from the current flight plan to the emergency waypoint plan, defined by the lost communication entry point. If communication is reacquired during the orbiting phase of the emergency flight plan then the PAC can initiate landing procedures. If communication is not reacquired after 2 min of orbiting at the lost communication waypoint, the autopilot will automatically switch to the autoland segment of the emergency flight plan, and will begin an autonomous landing.

Finally, since the operation of the Tempest UAS will be well within the communication range of the 900 MHz link, failure of the communication link will tend to be hardware based. Therefore, after a lost communication event is detected, a crew member who is not currently tasked as the observer or PIC will be directed by the PIC to inspect the communication hardware in the GCS to make sure there is no visible problems with the 900 MHz antenna, its location, or in the cabling.

90.4 Using COAs and FAA Interaction

This section describes additional provisions included in the actual COAs issued for the Tempest UAS and notification procedures prior to flight. In general, there is little interaction between the FAA Unmanned Program Office and the applicant once the COA application was submitted. As a result the final approved Certificate of Authorization could contain additional provisions or changes from the application. Further, the COA describes procedures for interacting with air route traffic control centers (ARTCCs) prior to flight.

90.4.1 COA Provisions

Fifty-nine distinct Certificates of Authorization were issued for the Tempest UAS participation during VORTEX2. The COAs included some changes from the original application and additional provisions that were not stated in the application. The original Tempest UAS COAs required notification 72–48 h in advance of flight operations. However, during the VORTEX2 campaign, the uncertainty of forecasting the time and location of target supercell thunderstorms required shortening the advance notice window. After submitting evidence to the UAPO and the ARTCCs in the COA areas, “pen-and-ink” (A pen-and-ink change is terminology used by FAA to indicate a minor change to a previously issued COA document.) changes were made to the Tempest UAS COAs to shorten the notification requirements to 2 h.

Table 90.1 describes the main provisions directly stated in the COA document. These include weather conditions suitable for flight operations, documentation and additional clearances required by the UAS operations team, and operational requirements. The main significant difference between the final COA and the

Table 90.1 Summary of Main FAA Requirements for Tempest UAS Operations

| |
|---|
| <i>Weather minimums</i> |
| Visibility of 3 statute miles |
| UA must maintain 500-ft below and 2,000-ft lateral separation from clouds |
| Daytime operations only: 1 h before sunrise until 1 h after sunset |
| <i>Required documentation</i> |
| Vehicle airworthiness document |
| Class 2 medicals for both the PIC and observer |
| PIC knowledge of FAR Part 91 (class G airspace) |
| Current private pilot certificate for the PIC (class E airspace) |
| Hard copy of COA document |
| <i>Operational requirements</i> |
| PIC must have 3 qualified events in the last 90 days |
| Single UA operation only |
| No dropping anything from the UA |
| No loitering in Victor airways |
| No operation in GPS test area or degraded RAIM |
| PIC and observer must be in constant two-way communication |
| UA cannot exceed 1,000 ft vertical and 1/2 or 1 mile horizontal from observer |
| NOTAM must be issued 2 h prior to flight operations |
| Incidents, accidents, and COA boundary deviations must be reported 24 h prior to any additional flights |
| Monthly reports of operations must be submitted to the FAA |

application was a reduction in allowable flight altitude (reduced from 3,000 to 1,000 ft) and allowable lateral separation (reduced from 1 to 1/2 mile). Through personal communications, the FAA UAPO indicated that these limits represented their judgement of the ranges at which the aircraft could be seen visually by the ground observer.

The specific requirements and procedures for UAS operations are contained in the COA document. These are the same procedures outlined in Policy 08–01 (Davis 2008) applied to the specific UAS and COA area that include specific statements of requirements for crew proficiency (e.g., PIC, observer, medicals, knowledge of FAR 61.105, 91.(3,7,13,17,111,113), limits, and currency and instructions for contacting an ARTCC or TRACON. The COAs required the pilot in command to have a current private pilot certificate. This requirement was in place to insure that the PIC understood the operational procedures of aircraft in the U.S. National Airspace System, not because the Tempest UAS handled like a manned aircraft. The PIC and the observer, who monitored the aircraft at all times, were also required to pass class 2 medical certification.

90.4.2 Activating COA Areas

Several steps are required prior to flight operation in order to notify air route traffic control centers and local airfields of pending UAS flights. The first step in activating a COA is to issue a Notice to Airmen (NOTAM) (<https://pilotweb.nas.faa.gov/PilotWeb/>) describing the planned activity. For the VORTEX2 mission, NOTAMs could be issued for up to four different COA areas with 2-h advance notice. Because the ARTCCs notify all pilots of NOTAMs in a given area, it was not feasible to issue NOTAMs for all 59 COA areas. The 2-h advance notice was at the limits of the meteorologists' abilities to predict thunderstorm evolution. As a result, NOTAMs could be rescinded and issued for different areas as needed, resetting the 2-h wait time before flight operation could commence.

Although the COA areas in the applications were specified by the coordinates of the bounding polygon, NOTAMs are issued based on radial distance and direction from Very High Frequency Omni-Directional Radio Range Tactical Air Navigation Aid (VORTACs). As a result, a better general strategy for COA applications is the use of circular regions that can be specified easily from a VORTAC. Because the COA areas and VORTACs are stationary, all pertinent information needed to issue a NOTAM for a specific COA could be determined in advance. The example NOTAM in Table 90.2 has all of the necessary information for other pilots operating in the NAS. The NOTAM, number 09/003, informs of UAS operations in a 3NM radius centered around a point that is 15NM from the BJC VORTAC off the 330° radial. The operations are conducted 400-ft AGL and below from time 1500Z to 2100Z on 3 September 2010. See FAA Order JO 7930.2M, section 6-1-7b (<http://www.faa.gov/documentLibrary/media/Order/NTM.pdf>) for more details on NOTAMs for UAS.

The final step in the notification process occurred 30 min before flight operations could commence. At this point it was necessary to contact by telephone the Denver ARTCC and any nearby airport or military operations desks. They will require both the COA number and the NOTAM number associated with the flight.

90.4.3 Reporting

There are three types of reports required by the FAA for UAS operation: accident (NTS 2010), incident (NTS 2010), and monthly operational. These are all accessed through the secure FAA web portal (<https://ioeaaa.faa.gov/oeaaa/>). There are also real-time reporting requirements for loss of communication and/or violation of COA boundaries, which are covered in the Emergency Procedures section. Monthly operational reports were submitted for all active COAs within five business days of

Fig. 90.5 Composite radar, flight path, and COA boundary for supercell intercepts during the VORTEX2 campaign (Elston et al. 2011b) (a) 6 May 2010, sampling scenario S3 (b) 26 May 2010, sampling scenario S2 (c) 6 June 2010, sampling scenario S1 (d) 7 June 2010, sampling scenario S3 (e) 9 June 2010, sampling scenario S2 (f) 10 June 2010, sampling scenario S2

the end of each month. They were submitted even if no operations took place under a specific COA. The reports required information about the COA along with number of operations and total hours.

90.5 Case Study/Lessons Learned

A synopsis of a typical deployment will be presented next to better illustrate the timing and pace of nomadic operations. This will be followed by some of the lessons learned along with specifics on what can be improved for future nomadic sampling missions within the confines of FAA regulations. There were six successful flight experiments flown into storms during the VORTEX2 deployment. Figure 90.5 contains trajectories of six different flight experiments that were done during the VORTEX2 campaign utilizing different sampling scenarios.

The planning phase of the deployment was conducted from 36 to 2 h prior to launch of the UA. This began with VORTEX2 PIs using data and models to predict

storms the evening before flight experiments. It continued the next morning with examining any new data and setting a departure time and initial destination. The entire armada would then begin driving to the destination, with any changes to the target area being relayed to the individual team leaders.

At approximately 2 h prior to the predicted launch time, the meteorology lead of the UAS team would select 4 COA areas that were most likely to be within the target area, and these would be activated using NOTAMs. It should also be noted that there were other notifications that may have to go out depending on the specific COA areas such as nearby airports or Air force bases. Since these were very specific to each COA area, they will not be mentioned in detail here. These groups required anywhere from 2 h to 5 min notice prior to launch. Also, during this phase of the deployment, NOTAMs could be cancelled and new ones put in if the storm changed direction. However, 2 h lead time was required from whenever the new NOTAM was issued.

At 1 h prior to launch the flight preparations would commence for all parties utilizing checklists. An example of one such checklist is given in Table 90.3 for the ground control station operator. Somewhere in this time up to 10 min to launch the meteorology lead would select a launch area and begin preparing the flight plan. The team would then arrive at the location, finishing prepping the UA, deploy all mobile ground vehicles, and launch the UA.

During the flight experiment the flight plan would be changed depending on both RADAR imagery of the storm and in situ data from the UA. Following the flight experiment the UA would return to base, land, and all postflight checklists would be utilized. This would include cancelling any active NOTAMs, notifying any flight service groups as required by the COAs, and logging all necessary data for monthly COA reports. For a more detailed description of the entire CONOPS, see Elston et al. (2011b).

The system designed for VORTEX2 led to six successful and safe flight experiments with no deviation from FAA rules for UAS. There were however several important lessons learned that could lead to improved operations in the future and more useful data for the scientific community.

The first major issue that was encountered was the issue of predicting which COA areas the storms would pass through. The standard provisions require activating a COA area between 48 and 72 h prior to flight operations. The initial solution was to simply activate all 59 COA areas 2 days before we planned on flying. However, this was found to be unsustainable for ATC since each COA area required a separate NOTAM, and this many would overwhelm their system. In order to address this issue, we worked with the FAA to reduce the activation time to 2 h. Permission was also given to activate up to 4 COA areas at a time. However, the dynamic nature of the storms made even this difficult to predict. An example of when this issue came up was during sampling the June 10th storm; the team had to wait for the start of time of the NOTAM while there was already a tornado on the ground from the storm. Being able to deploy sooner than the required-2 h time could potentially lead to more useful data. The FAA has since reduced this time to 1 h for the 59 COA areas.

Table 90.3 Example of One of the Checklists Used

| |
|--|
|  |
| Operator checklist |
| <i>After power on</i> |
| Turn off van Wi-Fi |
| Start averaging groundstation GPS |
| Disable engine |
| Set the pilot address |
| Copy commands and verify all loops are auto |
| Uncheck auto center and zoom as appropriate |
| Verify COA area altitude and mission limits altitude |
| Set up flight plans: lost comm, take-off, landing |
| Zero air data with GPS altitude |
| Test pitot-tube airspeed |
| Turn on APS, verify tracking, and set to take-off orientation |
| Start up B.A.T.M.A.N on focus through ssh |
| <i>Preflight</i> |
| Check Piccolo voltage |
| Check Servo voltage |
| Check UA GPS |
| Set the tracked waypoint to 10 |
| Check Piccolo 900MHz link |
| Verify sonde operation |
| Launch, start NetUAS timer |
| Start APS tracking |
| Notify tracker of handover |
| <i>Postflight</i> |
| Kill engine |
| Save config if it was changed |
| Close OI and save log files to a new (reliable) location |
| Run NetUAS log save scripts |
| Turn off Piccolo GCS |

The second major issue we encountered was the boundaries of the COA areas. [Figure 90.5a, b, f](#) were successful sampling missions that got as far as the active COA boundary and could not sample any further losing out on some more data that may have proved useful. There were also several other potential missions that never flew because the storm was just outside of the COA area, including a very promising one on June 11th. The solution to this problem is not as obvious. The FAA did not want us to have a COA area larger than 20 × 20 miles since that would be too large an area to keep traffic out of. Also, there is the issue of avoiding airports,

we arbitrarily chose 5 miles and major roads. A potential solution to this issue is to grant a single large COA spanning the entire 200×200 mile area and restrict us to activating only a 20-mile diameter circle in that area at a given time where we are responsible for avoiding airports and major roads. This gives the meteorologist more precision to work with when activating COA areas. It was also found that ATC prefers circular areas for the NOTAMS since they can just list a center point and radius in the NOTAMS.

Conclusion

The capabilities of current UAS to perform these nomadic science missions currently exist, and the main bottleneck for these missions is satisfying FAA regulations to perform safe operations. It is important to work with the FAA to reach a compromise that satisfies both the scientific and engineering goals of the project while being able to prove the necessary level of safety for operating in the National Airspace System. This chapter used experience from the VORTEX2 UAS campaign to present information on obtaining COAs, working with the FAA to conduct successful flight operations, and some lessons learned that could lead to improved operations in the future.

Abstract

This chapter presents aspects of risk modeling with a focus on UAS. It provides an overview of the current level of safety of manned aviation in terms of accident statistics. These are then mapped as target levels for UAS under the “Equivalent Level of Safety” principle to provide a glimpse at what that may entail for UAS regulations. Different methodologies are presented for estimating the risk of ground impact and midair collision accidents and how these estimates can be

K. Dalamagkidis
Institut für Informatik I6, Technische Universität München, Garching bei München, Germany
e-mail: dalamagkidis@tum.de

translated to system requirements. The chapter also provides guidelines on the use of different risk models and then applies a selection of them to five different UAS in two distinct scenarios, to compare the results of different choices.

91.1 Introduction

The primary goal of regulating UAS operations is to assure an appropriate level of safety for those directly involved or indirectly affected. Many national aviation agencies have stated that the goal is to achieve an “Equivalent Level of Safety” with that of manned aviation, also known as the ELOS principle.

Since many UAS are based on military or general aviation aircraft, they share aspects of the design and construction of the airframe and mechanical components. This of course does not mean that unique designs have not evolved as well. The key difference between manned and unmanned aviation lies in the separation of the pilot from the cockpit and the level of automation introduced. This difference introduces new failure modes and, as a result, an increased perceived risk that needs to be evaluated and mitigated. Nevertheless, it is noteworthy that manned aviation has also benefited from increased automation. According to Haddon and Whittaker (2002), a considerable percentage of modern commercial aviation operations – including landing – takes place autonomously with the pilots responsible only for monitoring the computers.

This chapter is an analysis of what the ELOS requirement may entail for UAS regulations. To accomplish this, the safety performance of manned aviation is first evaluated. Then, an analysis is carried out to derive a model for estimating UAS risk as the number of fatalities following an accident. Methods to derive estimates for the parameters that affect risk and the rationale for choosing between the alternatives are also presented. This analysis targets two major accidents types, ground impact and midair collisions. It should be noted that actual regulations will need to take into account a number of issues and as a result may in the end diverge significantly from the conclusions of this chapter.

This chapter cites material from two publications of the U.S. Range Commanders Council. The first is the RCC 321-07 titled “Common Risk Criteria Standards for National Test Ranges,” while the second is RCC 323-99 titled “Range Safety Criteria for Unmanned Air Vehicles.” Both are to be used by range commanders to ensure that operations within their ranges adhere to safety standards that are acceptable by the military. The following is quoted from the first chapter of Range Safety Group, Range Commanders Council (2007a):

The policies and criteria in this document are intended for use by members of the DoD national ranges and Major Range and Test Facility Base (MRTFB). These policies and criteria apply to launch and reentry hazards generated by endoatmospheric and exoatmospheric range activities including both guided and unguided missiles and missile intercepts, space launches, and reentry vehicles. This does not include aviation operations or UAV operations. The RCC Document 323-99 (Range Safety Criteria for Unmanned Air Vehicles) provides criteria for unmanned air vehicles.

Although this distinction is made, it was felt that in certain cases, the reader would benefit from a presentation of certain, selected information from RCC 321-07. This is because either this information is general and applies to most risk/reliability assessments or valuable insight is to be gained from contrasting it with information specific to UAS.

91.2 Equivalent Level of Safety

According to Joint JAA/Eurocontrol Initiative on UAVs (2004) and European Aviation Safety Agency (2009), one of the guiding principles for UAS regulation should be *equivalence*, and based on that, they assert the following:

Regulatory airworthiness standards should be set to be no less demanding than those currently applied to comparable manned aircraft nor should they penalize UAS systems by requiring compliance with higher standards simply because technology permits.

This principle has been widely adopted by most national aviation agencies worldwide and is known as the ELOS requirement. For example, the Range Commanders Council in its guidance on UAS operations states:

Any UAV operation or test must show a level of risk to human life no greater than that for an operation or test of a piloted aircraft.

Range Safety Group, Range Commanders Council (1999a).

It should be noted that there is significant criticism aimed at the usefulness of this principle in general. This is because of the difficulty inherent in specifying what exactly the ELOS requirement entails and more importantly quantifying it. In any case, in an effort to better define what the ELOS could be, the next section investigates the requirements of current regulations for manned aviation.

91.2.1 Manned Aviation Requirements

Manned aviation is regulated through a code of requirements, which often refers to standards for various aircraft subsystems as well as for all stages of design, manufacture, and operation (Haddon and Whittaker 2002). Use of standards ensures that the components of the system are reliable enough so that the whole system is compliant with a set target level of safety (TLS). Regulations normally also contain safety targets found in *paragraph 1309* of current CS or the corresponding AMC sections. These targets are typically presented as a risk reference system. Such a system categorizes events based on their severity and assigns a maximum rate of occurrence for each event category.

Figure 91.1 presents the risk reference system proposed in the *1309 AMC* section of EASA CS 25. There, a failure condition that includes injuries and/or fatalities is categorized as hazardous and as such it should be extremely remote ($<10^{-7}$ events per flight hour) (European Aviation Safety Agency (EASA) 2007). On the other

| | | Catastrophic | Hazardous | Major | Minor | No safety effect |
|----------------------|----------------------------|--------------|-----------|-------|-------|------------------|
| Probable | $> 10^{-5} \text{ h}^{-1}$ | | | | | |
| Remote | $< 10^{-5} \text{ h}^{-1}$ | | | | | |
| Extremely remote | $< 10^{-7} \text{ h}^{-1}$ | | | | | |
| Extremely Improbable | $< 10^{-9} \text{ h}^{-1}$ | | | | | |

Fig. 91.1 Risk reference system for large manned aircraft (the *grayed areas* signify unacceptable risk) (Source: European Aviation Safety Agency (EASA) (2007))

Table 91.1 FAR Part 23 aircraft classes and corresponding acceptable failure condition probability based on severity, as defined in AC 23.1309-1C (Source: Federal Aviation Administration (1999))

| Aircraft class | Minor | Major | Hazardous | Catastrophic |
|---|-----------|-----------|-----------|--------------|
| Class I (<2,720 kg, SRE) | 10^{-3} | 10^{-4} | 10^{-5} | 10^{-6} |
| Class II (<2,720 kg, STE, MRE) | 10^{-3} | 10^{-5} | 10^{-6} | 10^{-7} |
| Class III (>2,720 kg, SRE, MRE, STE, MTE) | 10^{-3} | 10^{-5} | 10^{-7} | 10^{-8} |
| Class IV (commuter) | 10^{-3} | 10^{-5} | 10^{-7} | 10^{-9} |

SRE, single reciprocating engine; *MRE*, multiple reciprocating engine; *STE*, single turbine engine; *MTE*, multiple turbine engine

hand, the same publication considers multiple fatalities to be of catastrophic severity with a likelihood requirement of 10^{-9} or less.

The risk reference system presented in Fig. 91.1 does not apply to all aircraft, and variations exist for smaller or different types of aircraft. This is because it was found that applying certification standards developed for transport category aircraft to smaller ones led to unrealistically high equipment reliability requirements (Federal Aviation Administration 1999). In addition to that, the results of accident investigations showed that the main accident cause in manned aviation is pilot error. As such, high equipment reliability would have only a minor effect on overall aviation safety. In 1999, the FAA issued AC 23.1309-1C that contains AMC for aircraft certified based on FAR Part 23. With this AC, four classes of aircraft within that category were defined, each with different acceptable probabilities for failure conditions, as shown in Table 91.1.

91.2.2 Derivation of an ELOS for UAS

Use of the same risk reference system like the one presented in Fig. 91.1 or even Table 91.1 is not straightforward because of the wide range of UAS sizes and characteristics. In addition to that, UAS depend on the onboard flight control system and/or the communication link to operate. This requirement introduces additional failure modes that may increase the total number of accidents for the same reliability requirement. On the other hand, since UAS do not carry passengers, the number of

Table 91.2 Fatality rates from all accidents based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) 2008b) between 1983 and 2006

| Rates per hour | Air carrier | Commuter | General aviation | Total |
|-------------------|----------------------|----------------------|----------------------|----------------------|
| Accident | $2.43 \cdot 10^{-6}$ | $2.37 \cdot 10^{-5}$ | $8.05 \cdot 10^{-5}$ | $5.05 \cdot 10^{-5}$ |
| Fatalities aboard | $8.68 \cdot 10^{-6}$ | $1.64 \cdot 10^{-5}$ | $2.77 \cdot 10^{-5}$ | $2.06 \cdot 10^{-5}$ |
| Ground fatalities | $3.37 \cdot 10^{-7}$ | $8.30 \cdot 10^{-6}$ | $6.54 \cdot 10^{-7}$ | $1.31 \cdot 10^{-6}$ |

people exposed to risk can be significantly lower. As a result, the probability of injuries and fatalities after an accident is greatly reduced when compared with that of general aviation or transport aircraft. The average number and severity of injuries per accident is also expected to be lower.

Since failure frequency requirements prescribed for manned aircraft of the same size cannot be used directly, other means to derive such requirements for UAS need to be employed. A different approach frequently used in safety engineering is to define safety constraints for a specific accident based on the desired likelihood of the worst possible outcome (Range Safety Group, Range Commanders Council 1999b). This can in turn be used to determine maximum failure frequency. For UAS operations, the worst outcome of most accidents is the occurrence of one or more fatalities, and as a result, the ELOS can be based on that. Although the ELOS may be based on the frequency of accidents that result in one or more fatality, such an ELOS would also be inadequate since it fails to consider the effect of multiple fatalities.

Although current manned aviation regulation does not impose limits on fatality rates, a statistical analysis of historical data can provide valuable insight on the fatality rates of manned aviation and be the basis for defining the ELOS for UAS. An analysis of NTSB accident data from 1983 to 2006 is presented in Table 91.2. It should be noted that the exact rates may vary depending on the type of aviation (general, regional/commuter, air carrier). Moreover, the period over which the data are averaged can also play a role (Clothier and Walker 2006), since there is significant variation from year to year, as shown in Fig. 91.2. This is also evident from a U.S. Navy survey (Range Safety Group, Range Commanders Council 1999b) that found an average of 18, 7, and 4.7 ground fatalities per 10 million flight hours for U.S. Navy, commercial aviation, and general aviation, respectively. The survey included data from 1980 to 1998 for U.S. Navy flights and from 1982 to 1998 for civil aviation. In most cases, an individual, annual risk of fatality of 10^{-6} is considered sufficiently low and below that of other typical everyday activities (Range Safety Group, Range Commanders Council 2007b).

Other approaches have employed serious but nonfatal injuries as the basis for their safety assessments, especially when due to the nature of the accident fatalities are unlikely. As an example, Range Safety Group, Range Commanders Council (2007b) proposes the use of casualty limits, the latter defined as the people sustaining injuries of a certain severity and over. A study of NTSB data provided in Range Safety Group, Range Commanders Council (2007b) shows that in aviation, the ratio of casualties to fatalities shows little variation and is close to 2.5. Based on this ratio, casualty limits can be derived from those used for fatalities. A common

Fig. 91.2 Fatality rates from general aviation, commuter, and air carrier accidents as a function of time. Based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) [2008b](#)) between 1983 and 2006

casualty limit is that of 10^{-4} casualties per event, which has been used by a number of agencies like the NASA, the U.S. DoD, and the Space Licensing and Safety Office of Australia (Range Safety Group, Range Commanders Council [2007b](#)). The same limit was chosen in Range Safety Group, Range Commanders Council ([2007a](#)), complemented by an individual casualty risk probability limit of 10^{-6} . Nevertheless, the use of fatalities has also been advised as a supplemental metric, to better assess the risk involved in an activity (Range Safety Group, Range Commanders Council [2007b](#)).

The aforementioned proposed casualty and fatality limits can be contrasted with estimated rates from other sources or activities, provided in Table 91.3, as well as aviation accident statistics given in Table 91.2. When comparing these rates, one must consider that in some activities, a higher risk may be acceptable because of the perceived benefits of participation. It should also be noted that these rates refer to collective risk (Range Safety Group, Range Commanders Council [2007b](#)), i.e., the averaged risk for the entire population. Depending on a person's location, activity, and other factors, the actual individual risk may be significantly higher or lower.

Table 91.3 Estimated injury, casualty, and fatality rates from different sources or activities

| Activity/source | Injury rate (h^{-1}) | Casualty rate (h^{-1}) | Fatality rate (h^{-1}) |
|--|---------------------------------|-----------------------------------|-----------------------------------|
| Motor vehicle accidents (all) ^a | $1.35 \cdot 10^{-5}$ | $1.13 \cdot 10^{-6}$ | $1.40 \cdot 10^{-7}$ |
| Motor vehicle accidents (occupant) ^a | $8.80 \cdot 10^{-6}$ | $6.73 \cdot 10^{-7}$ | $5.89 \cdot 10^{-8}$ |
| Pedestrian involved in collision with motor vehicle ^a | $5.10 \cdot 10^{-7}$ | $8.92 \cdot 10^{-8}$ | $1.04 \cdot 10^{-8}$ |
| Unintentional falls ^a | $2.45 \cdot 10^{-5}$ | $2.20 \cdot 10^{-6}$ | $6.06 \cdot 10^{-8}$ |
| Natural environment ^a | $1.31 \cdot 10^{-7}$ | $1.44 \cdot 10^{-8}$ | $7.59 \cdot 10^{-9}$ |
| Bicycles and accessories ^b | $1.50 \cdot 10^{-6}$ | $8.98 \cdot 10^{-8}$ | |
| Household appliances (ranges, refrigerators, washers) ^b | $4.23 \cdot 10^{-7}$ | $1.81 \cdot 10^{-8}$ | |
| Baseball, basketball, and football combined ^b | $2.59 \cdot 10^{-5}$ | $3.44 \cdot 10^{-7}$ | |
| London Blitz (civilian only) ^c | N/A | $1.04 \cdot 10^{-6}$ | $6.22 \cdot 10^{-7}$ |

^aThe number of injuries and fatalities are from the Web-based Injury Statistics Query and Reporting System available from the Centers for Disease Control and Prevention, National Centers for Injury Prevention and Control and correspond to emergency department admissions in the year 2005. The rates were derived based on an estimated population of 296,410,404 and assuming that every individual (regardless of age, sex, or location) is exposed to hazards involving each activity/source an average of 3 h per day. The casualty rate is based on injury cases that required hospitalization or transfer to other facilities such as trauma centers

^bThe data are from the National Electronic Injury Surveillance System maintained by the U.S. Consumer Product Safety Commission and concern the year 2007. The reported data did not make a distinction between incidents requiring hospitalization and incidents involving deaths. The rates are derived the same way as above, with the exception of the baseball, basketball, and football activities, where an average exposure of 3 h per week is assumed instead

^cFor the London Blitz, the civilian casualties were drawn from historical sources, and the rate was obtained by dividing by the population of London in 1939 and by the number of days the Blitz lasted, assuming continuous exposure

Significant differences can be expected between the effects of various accident types. As a consequence, the ELOS and the risk analysis that will follow need be derived for each accident separately. The following section provides an overview of the accidents of interest in the case of UAS.

91.3 UAS Accident Types

UAS operations are subject to various hazards that can lead to three primary accidents: unintended or abnormal system mobility operation (U.S. Department of Defense 2007), midair collision, and early flight termination (Clothier et al. 2007).

Unintended or abnormal mobility operation refers to accidents that occur when the UAS is still on the ground. In this case, the UAS may move unexpectedly, potentially seriously injuring ground crew members. Such accidents usually happen because of operator error. They may occur when the UAS operator does not have a view of the UAS and incorrectly assumes that everyone has cleared the area. This accident type will not be further investigated since the risk can be adequately mitigated with better management of operations and stricter adherence to standard operating procedures.

Midair collisions may occur between two UAS systems or between a UAS and a manned aircraft. Depending on the nature of the collision, they can result in the loss of one or both of the aircraft. A secondary accident usually following midair collisions is ground impact of debris that may injure people and damage property.

Finally, early flight termination, either controlled or uncontrolled, will result in ground or water impact. Under controlled flight termination, it may be feasible to select the point of impact and possibly the speed and orientation of the aircraft. In that case, this capability can be used to reduce the probability of fatalities as well as damages to property and the aircraft itself.

Potential damages resulting from all these accidents include injury or fatality of people on the ground or onboard another aircraft, damage or loss of the vehicle, and damage to property. An indirect damage is environmental pollution either from the payload of the aircraft or as a result of fuel leakage and/or fire following the accident. This is especially important for UAS that will carry chemicals toxic to human beings, for example, those used in agricultural applications.

A possible damage that is often ignored is that of societal rejection or outrage that may disrupt future operations. This can occur as a consequence of a high accident rate (even if no injuries occur) or if the accident involves cultural-/societal-sensitive areas like national parks or monuments, schools, and churches. Figure 91.3 summarizes possible accidents and corresponding damages stemming from the operation of UAS in the NAS.

The following sections present models to evaluate UAS risk for the two major accident types: midair collisions and ground impact.

91.4 Ground Impact Fatality Risk Modeling

The expected frequency of fatalities (f_F) can be calculated by the following equation:

$$f_F = N_{\text{exp}} P(\text{fatality}|\text{exposure}) f_{\text{GIA}} \quad (91.1)$$

where N_{exp} is the number of people exposed to the accident, $P(\text{fatality}|\text{exposure})$ is the probability a person will suffer fatal injuries given exposure to the accident, and f_{GIA} is the rate of ground impact accidents. The $P(\text{fatality}|\text{exposure})$ depends on the resilience of the human body to injury as well as the level of sheltering.

A similar formulation to the model of (91.1) is provided in Range Safety Group, Range Commanders Council (1999b):

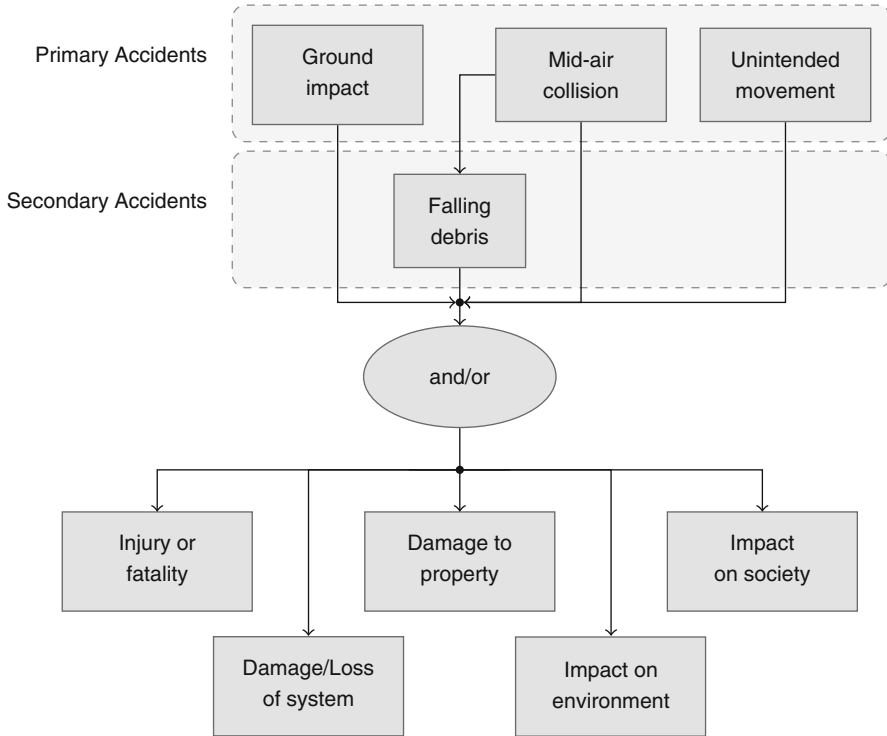

Fig. 91.3 Primary and secondary accidents that can result from the operation of UAS and their possible outcomes

$$f_F = A_{\text{exp}} \rho P(\text{fatality}|\text{exposure}) f_{\text{GIA}} f_{\text{shelter}} \quad (91.2)$$

In (91.2), N_{exp} is replaced by the product of the lethal area (A_{exp}) by the population density (ρ). An additional term, the sheltering factor f_{shelter} , is introduced that takes values from 0, denoting that everyone is sheltered from the impact, to 1, denoting that nobody is sheltered. This formulation implies a type of “absolute sheltering,” where any person considered sheltered is not affected by the impact.

In certain cases, the exposed population can be divided in groups. Each group is assigned a different probability of fatality given exposure. This can occur when, for example, part of the population is inside buildings and part is outside. In this case, (91.1) can be expressed as follows:

$$f_F = f_{\text{GIA}} \sum_i N_{i, \text{exp}} P_i(\text{fatality}|\text{exposure}) \quad (91.3)$$

where subscript i refers to the i th group. Although this approach offers better accuracy, it also requires the availability of a library that contains the number of

people in each location and the level of their sheltering or at least estimates thereof (Range Safety Group, Range Commanders Council 2007b).

Since the acceptable f_F is provided by the ELOS requirement, if the N_{exp} and $P(\text{fatality}|\text{exposure})$ can be estimated, it is possible to determine the target level of safety (TLS) for ground impact accidents given by f_{GIA} . Although (91.1) is simple and straightforward, calculation of the terms involved in it is not. In fact, there is a number of options that have been proposed for calculating both N_{exp} and $P(\text{fatality}|\text{exposure})$. The following section will start with the calculation of the f_F term based on the ELOS principle.

91.4.1 Ground Impact ELOS

In determining the fatality rate requirement after ground impacts, special consideration should be given to the fact that UAS is unmanned. This means that only the number of fatalities on the ground is to be taken into account. According to Table 91.2, this number represents only a very small percentage of the total fatalities, about 6 %. The ground fatality rate calculated is in the order of 10^{-6} h^{-1} , although a more conservative ELOS can be derived based on the ground fatality rate of air carriers, which is in the order of $f_F = 10^{-7} \text{ h}^{-1}$.

It should be noted that Table 91.2 considers all accidents. An alternative analysis can be used by considering only accidents where an in-flight collision with terrain or water occurred (approximately 35 % of the total). The updated fatality rates based on NTSB data for the period 1983–2006 are presented in Table 91.4. In this case, the proposed ELOS would be in the order of $f_F = 10^{-8} \text{ h}^{-1}$, although it does not include fatalities after emergency landings, ditching, and other situations. If the latter are included, the ELOS is closer to $f_F = 10^{-7} \text{ h}^{-1}$ as shown in Table 91.5.

For the subsequent analysis, the value for f_F is set to 10^{-7} h^{-1} , which is the same with that proposed in Range Safety Group, Range Commanders Council (2007b). However, it should be noted that lower or higher acceptable fatality rates have also been proposed in the past. In Weibel and Hansman (2004), although an ELOS of 10^{-7} h^{-1} was derived, a target of 10^{-8} h^{-1} is proposed instead. This choice was made in an effort to account for the fact that the benefits of UAS operations are not evident to the general public, and as a result, the tolerance for fatalities will be lower. In Clothier et al. (2007), analysis is based on multiple acceptable fatality likelihoods ranging from 10^{-6} to 10^{-9} h^{-1} . The Range Safety Criteria for UAS proposed a fatality rate of 10^{-6} h^{-1} or less based on the U.S. Navy survey discussed previously (Range Safety Group, Range Commanders Council 1999b), but their requirements are for military operations that allow higher fatality rates. Finally the NATO USAR adopted a TLS of 10^{-6} h^{-1} for catastrophic UAS accidents (Joint Capability Group on Unmanned Aerial Vehicles 2007), which corresponds to an equal or higher fatality rate.

Although stricter requirements may be attractive, they can seriously impede commercialization of UAS as well as their integration in the NAS.

Table 91.4 Fatality rates for accidents where an in-flight collision with terrain or water occurred. Based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) [2008a](#)) between 1983 and 2006

| Rates per hour | Air carrier | Commuter | General aviation | Total |
|-------------------|----------------------|----------------------|----------------------|----------------------|
| Accident | $2.06 \cdot 10^{-7}$ | $9.33 \cdot 10^{-6}$ | $2.84 \cdot 10^{-5}$ | $1.77 \cdot 10^{-5}$ |
| Fatalities aboard | $4.71 \cdot 10^{-6}$ | $1.32 \cdot 10^{-5}$ | $2.16 \cdot 10^{-5}$ | $1.55 \cdot 10^{-5}$ |
| Ground fatalities | $9.84 \cdot 10^{-8}$ | $2.86 \cdot 10^{-8}$ | $4.46 \cdot 10^{-8}$ | $5.99 \cdot 10^{-8}$ |

Table 91.5 Fatality rates for accidents where one or a combination of in-flight collision with terrain or water, hard/forced landing, runway overrun, or ditching occurred. Based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) [2008a](#)) between 1983 and 2006

| Rates per hour | Air carrier | Commuter | General aviation | Total |
|-------------------|----------------------|----------------------|----------------------|----------------------|
| Accident | $5.64 \cdot 10^{-7}$ | $1.56 \cdot 10^{-5}$ | $5.18 \cdot 10^{-5}$ | $3.21 \cdot 10^{-5}$ |
| Fatalities aboard | $4.85 \cdot 10^{-6}$ | $1.46 \cdot 10^{-5}$ | $2.41 \cdot 10^{-5}$ | $1.71 \cdot 10^{-5}$ |
| Ground fatalities | $1.01 \cdot 10^{-7}$ | $7.63 \cdot 10^{-8}$ | $8.43 \cdot 10^{-8}$ | $8.89 \cdot 10^{-8}$ |

Therefore, a conservative evaluation of the risk from emerging hazards is preferable, since it can be later accommodated as flight hours accumulate and confidence in risk estimates improves.

91.4.2 Exposure to Ground Impact Accidents

Assuming a uniform population density in the area affected by the crash, N_{exp} can be calculated as the product of that area (A_{exp}) by the population density (ρ):

$$N_{\text{exp}} = A_{\text{exp}} \times \rho \quad (91.4)$$

The population density used in [\(91.4\)](#) is typically estimated using the average population density over the area the UAS will operate. Although use of the actual population density will offer better precision, a standard population density can be used as a reasonable estimate instead. Specifically, EASA has proposed the use of a standard density of 200 ppl/km² (European Aviation Safety Agency (EASA) [2005](#)). This density was derived taking into account typical civil aviation operations, where a significant percentage of flight time is spent over less densely populated areas. For UAS designed to loiter over populated areas, a higher density will be necessary to avoid underestimating the risk involved. A worst-case scenario of impact at the most densely populated area within the area of operations may also be used to provide a conservative estimate of ρ (Range Safety Group, Range Commanders Council [1999b](#)).

There are several ways to determine the A_{exp} based on impact characteristics. For a vertical crash, this area may be approximated by the frontal area of the aircraft

augmented by a small buffer to account for the width of an average human (Weibel and Hansman 2003). For a gliding descent, it can be approximated by (91.5), where the wingspan and length of the aircraft have been increased by the radius of an average person (Clothier and Walker 2006):

$$A_{\text{exp}} = W_{\text{aircraft}} \left[L_{\text{aircraft}} + \frac{H_{\text{person}}}{\sin(\text{glide angle})} \right] \quad (91.5)$$

It should be noted that in some cases instead of the area exposed to the impact, a *casualty* or *lethal area* is mentioned. In this case, attention should be given on how these areas are defined. This is because in some cases they are the same as A_{exp} , while other times they are defined as the areas within which 100 % casualties or fatalities are expected, respectively.

For example, Range Safety Group, Range Commanders Council (2007b) defines a casualty area as the area where everyone is expected to receive injuries of such severity that they will require hospitalization. On the other hand, the same organization in Range Safety Group, Range Commanders Council (1999b) defines the lethal area merely as an *area of concern*, obtained by

$$A_{\text{exp}} = (L_{\text{aircraft}} + 2 \text{ ft}) (W_{\text{aircraft}} + 2 \text{ ft}) \quad (91.6)$$

for a vertically falling vehicle and

$$A_{\text{exp}} = (L_{\text{aircraft}} + L_{\text{glide}} + L_{\text{stop}} + 2 \text{ ft}) (W_{\text{aircraft}} + 2 \text{ ft}) \quad (91.7)$$

where L_{glide} is the gliding distance at an altitude of 6 ft and L_{stop} is the distance required for the aircraft to come to a stop.

91.4.3 Probability of Fatality of Exposed Persons

The human body is capable of sustaining a certain level of force or injury, and as a result, presence of a person in an area affected by a crash does not guarantee a fatality. Moreover, obstacles such as trees and buildings may provide shelter, thus, increasing the chances of survival. It is evident, therefore, that the probability of fatality of a person exposed to a crash need be modeled taking into account the aforementioned factors, namely, human vulnerability and sheltering. This section presents some of the approaches available. Nonetheless, a detailed account of the problem of human vulnerability is beyond the scope of this chapter.

Despite the observations above, the most commonly used estimate for the probability of fatality of an exposed person is the number one (Range Safety Group, Range Commanders Council 1999a). This is because it is a conservative measure that is not susceptible to criticism. On the other hand, it can easily be argued that this measure can be overconservative especially in the case of small UAS.

According to the Range Commanders Council, an exception may be made to the use of unit probability in the case of very light systems (Range Safety Group, Range Commanders Council 1999b). In this case, a limit must be defined that divides UAS into two categories, those that do and those that do not cause fatalities. The limit can be based on that used for inert debris, specifically a kinetic energy during impact of 15 J (11 ft lb) for casualty (i.e., reversible injury) and 34 J (25 ft lb) for fatality (Range Safety Group, Range Commanders Council 2007b). The 15 J criterion has been found to be close to the threshold of serious injury for a child (Haber and Linn 2005), and, as a result, it can be stated that it is a conservative measure that protects the entire population.

In an effort to take into account the fact that a person may survive a UAS impact, Weibel et al. introduced a penetration factor for calculating the probability of fatality (Weibel and Hansman 2004). This factor depends on the characteristics of the UAS and aims at taking into account sheltering. Dalamagkidis (2010) argued that Weibel's estimate for smaller vehicles is overconservative while at the same time it underestimates the lethality of larger systems. It was also mentioned that the usefulness of the "penetration parameter" was limited since no method was provided to consistently estimate it.

In a 1968 study, Feinstein et al. investigated the effects of blast, debris, and other factors to people (Feinstein et al. 1968). To correlate the probability of fatality with kinetic energy, log-normal curves were derived for impacts to different body parts. Additionally, an averaged curve was proposed, given by

$$P(\text{fatality}|\text{exposure}) = Z\left(\frac{\ln E_{\text{imp}} - \ln a}{b}\right) \quad (91.8)$$

where Z is the cumulative normal distribution whose value is typically obtained from tables, $a = 103 \text{ J}$ is the energy required for a probability of fatality of 50 %, and $b = 0.538$ is a parameter that affects how fast the probability rises as a function of kinetic energy.

A drawback of Feinstein's model is that it is difficult to adjust it to take into account sheltering. This is because if parameter b was increased so that the curve slope is decreased, the probability of fatality for low kinetic energies would increase. As a result, any change of the b parameter to take into account sheltering would require an adjustment of the a parameter as well.

A model to estimate $P(\text{fatality}|\text{exposure})$ as a function of kinetic energy at impact (E_{imp}) that also takes into account sheltering in addition to human vulnerability was proposed in Dalamagkidis et al. (2008) and then revised in Dalamagkidis et al. (2012). The model is a variation of the logistic growth model that aligns well with other human vulnerability models including models such as Feinstein's. That model is given by

$$P(\text{fatality}|\text{exposure}) = \frac{1 - k}{1 - 2k + \sqrt{\frac{\alpha}{\beta}} \left[\frac{\beta}{E_{\text{imp}}} \right]^{\frac{3}{p_s}}} \quad (91.9)$$

Fig. 91.4 A comparison of the vulnerability models of Feinstein, Dalamagkidis, and Weibel as well as the conservative approach of unit probability above the 34 J kinetic energy threshold

where $k = \min \left[1, \left(\frac{\beta}{E_{\text{imp}}} \right)^{\frac{3}{p_s}} \right]$ is a correction factor k , used to improve the estimates given for low kinetic energies, especially those close to, or below, the threshold limit of 34 J.

The sheltering parameter p_s determines how exposed is the population to an impact and takes values in the range $(0, \infty)$. It is a function of the amount of obstacles in the crash trajectory of the aircraft that can absorb impact energy or deflect debris as well as the ability of people to take shelter behind such obstacles. It takes an average value of 1, with higher values, meaning better sheltering and a lower probability of fatality for the same kinetic energy. The α parameter is the impact energy required for a fatality probability of 50% when $p_s = 6$. Finally the β parameter is the impact energy threshold required to cause a fatality as p_s goes to zero. Based on the fatality limit of Range Safety Group, Range Commanders Council (2007b), the β parameter can be considered to be a constant with value 34 J.

The fatality probability models presented in this section are compared in Fig. 91.4.

91.4.3.1 Kinetic Energy Estimation

Many human vulnerability models involve the kinetic energy at impact or other functions of impact speed and object mass. This speed may vary depending on the UAS and the descent characteristics, and as a result, a suitable estimate must be

used. A useful conservative substitute for the impact speed is terminal velocity. The latter can be calculated from (91.10), where m is the vehicle mass, g is the acceleration of gravity, ρ_α is the air density, A is the cross-sectional area of the vehicle, and C_d is its drag coefficient. The latter two parameters are not always available, since they vary with the orientation of the aircraft during a descent:

$$E_{\text{imp}} = \frac{m^2 g}{\rho_\alpha A C_d} \quad (91.10)$$

The use of the maximum between the terminal velocity and the *velocity not to exceed* provided by the manufacturer is proposed as an alternative in Range Safety Group, Range Commanders Council (1999b).

In Haddon and Whittaker (2002), Joint JAA/Eurocontrol Initiative on UAVs (2004), and European Aviation Safety Agency (EASA) (2005), instead of the terminal velocity, the use of the maximum operating velocity (v_{op}) increased by 40 % is proposed, instead. This choice overcomes the problem of accurately estimating the parameters required to calculate the terminal velocity, greatly simplifying calculations. The kinetic energy can then be calculated as

$$E_{\text{imp}} \approx m v_{\text{op}}^2 \quad (91.11)$$

It may also be argued that when the mass of the impacting object is comparable or larger than that of the body part struck, not all of the object's kinetic energy will be absorbed. In fact, after the impact, the object will continue to move, in unison with the body, retaining some kinetic energy. The energy absorbed during the collision can be calculated based on momentum conservation by Sturdivan et al. (2004):

$$E = \frac{1}{2} m_1 v_1^2 \left(1 - \frac{m_1}{m_1 + m_2} \right) \quad (91.12)$$

where m_1 and v_1 are the mass and velocity of the object and m_2 refers to the effective mass of the body part struck. As a result, when $m_1 \ll m_2$, the effective energy is equal to the kinetic energy of the projectile. It should be noted that when body movement is constrained (e.g., from a wall), then (91.12) no longer applies and the entire kinetic energy is to be used (Sturdivan et al. 2004).

Irrespective of which of the aforementioned methods is used to calculate the kinetic energy of the impacting object, if a person is sheltered within a building or a vehicle, some of the kinetic energy will be exhausted to penetrate the shelter. As a result, the energy used in the vulnerability model may be also adjusted to take into account the effects of sheltering. The following section provides a more detailed account of the factors that need to be considered when incorporating the effects of sheltering, either by kinetic energy adjustments or by estimating the value of a parameter in the vulnerability model.

91.4.3.2 Sheltering Estimation

In certain situations, even when some sheltering is available, a conservative estimate of no sheltering may be used (Range Safety Group, Range Commanders Council 1999b). Nevertheless, this could lead to overconservative results, especially when a significant percent of the population is protected by vehicles and buildings. When estimating the sheltering effect, all the contributing factors need to be evaluated. These factors include the position of the body (standing, sitting, or prone), the sheltering provided by buildings or other structures, and the level of danger awareness.

Body position is normally taken into account in the vulnerability model. This is typically achieved by averaging the injury expectations calculated for different body positions. It should be noted that even when a specific area implies that the majority of the exposed population will be in a specific position (e.g., prone for a beach), using just the prone position parameters may be too conservative (Cole et al. 1997).

Buildings, vehicles, and other objects may reduce the risk of injury by absorbing part of or even the entire impact energy. For buildings the kinetic energy required to penetrate the structure needs to be considered (Range Safety Group, Range Commanders Council 2007b). This energy can be as low as 23 J for a roof made by a sheet of 24 gage corrugated aluminum and can exceed 560 J for roofs made of light concrete on 22 gage corrugated steel decking (Range Safety Group, Range Commanders Council 2007b). Although the examples given concern vertical impacts, in most cases, side impacts will also need to be considered (Range Safety Group, Range Commanders Council 2007b). Additionally, if an object manages to penetrate a structure, it is possible for material from the damaged structure to fall, causing secondary hazards (Range Safety Group, Range Commanders Council 2007b).

It should be noted that the aforementioned limits concern an irregular, compact, tumbling steel fragment (Range Safety Group, Range Commanders Council 2007b). As a result, a UAS may require additional energy to penetrate the same roof. This is because they are constructed from lighter, less dense materials, because their kinetic energy is going to be distributed over a larger area and because some energy may also be expended for fragmentation instead of penetration. If the types of structures in an area vary significantly, it is possible to group buildings into different classes and apply the approach of (91.3), assuming that the distribution of the population within the buildings is known or can be estimated. Accurate prediction of the effect of sheltering with the aforementioned methodology is difficult. This is because it requires precise knowledge regarding the construction of all structures in the affected area as well as the people and their activities during impact. To overcome this limitation, it is generally acceptable to make estimates based on average or worst-case scenarios. Compatible with the worst-case scenario is to assume that all buildings offer the sheltering effect of the worst buildings.

Besides the approach of subtracting the energy required to penetrate the structure from the energy available to cause a fatality that was mentioned in the previous section, a more conservative approach is also possible. The latter assumes that if an

object has sufficient energy to penetrate a structure, everyone inside is going to be a casualty or fatality (Range Safety Group, Range Commanders Council 2007b).

Danger awareness may also significantly improve the odds of a person surviving a UAS impact. This is because a person that is aware of the UAS can react sooner and either avoid the UAS entirely or take better shelter. To account for this, as well as the fact that the risk is taken on a voluntary basis, it has been proposed to use a larger allowable risk of fatality or casualty (Range Safety Group, Range Commanders Council 2007b). On the other hand, it is unlikely that people other than the UAS operating crew will have that benefit.

91.4.4 Frequency of Ground Impact Accidents

The frequency of ground impact accidents (f_{GIA}) is a function of the reliability of the UAS. If a limit for it is known or estimated from (91.1), then the UAS can be designed to meet set TLS. For example, in Range Safety Group, Range Commanders Council (2007b), a limit of 10^{-7} aircraft impacts per mission is proposed that could be used to obtain a limit for f_{GIA} . Alternatively, if the actual f_{GIA} is known, it can be used to determine whether an existing system with known reliability would violate safety limits.

The actual f_{GIA} can be estimated from the history of the UAS itself, provided that a sufficient number of flight hours have accumulated. If the UAS has a long history, the most recent data are to be preferred, since older data may not represent its current performance (Range Safety Group, Range Commanders Council 1999b).

An issue arises with newer systems, with few flight hours that may have not exhibited a failure that led to an accident yet. In this case, if the UAS is based on a previous model and shares a significant amount of design characteristics, its reliability can be assumed to be the same with that of the previous model (Range Safety Group, Range Commanders Council 1999b). Otherwise, the f_{GIA} can be estimated using Table 91.6 (Range Safety Group, Range Commanders Council 1999b). The aforementioned table was derived under the assumption of stochastic system behavior, exponential failure distribution and no significant changes in the system or its environment. As a result, care should be taken when using Table 91.6, especially in the case of UAS that are experimental or still in development, since these assumptions may not hold. In that case or when there is a need for a conservative estimate, worst-case assumptions can be made. Such assumptions may take the form of one crash per flight or per flight hour (Range Safety Group, Range Commanders Council 1999b).

If a formal reliability assessment has been carried out for the particular UAS model that included a Failure Mode and Effects Analysis (FMEA) or similar study, then its conclusions can also be used to estimate f_{GIA} (Range Safety Group, Range Commanders Council 1999b). That estimate may be increased by a safety margin to account for failure modes that may have been overlooked or underestimated.

Table 91.6 Estimate of the expected frequency of ground impact accidents for new UAS. The value shown represents a confidence of 95 % that the actual f_{GIA} is less than or equal to \hat{f}_{GIA} (Source: Range Safety Group, Range Commanders Council (1999b))

| Flight hours without crash | \hat{f}_{GIA} |
|----------------------------|----------------------------------|
| 10 | $3 \cdot 10^{-1} \text{ h}^{-1}$ |
| 30 | $1 \cdot 10^{-1} \text{ h}^{-1}$ |
| 100 | $3 \cdot 10^{-2} \text{ h}^{-1}$ |
| 300 | $1 \cdot 10^{-2} \text{ h}^{-1}$ |

91.5 Midair Collision Fatality Risk Modeling

The expected frequency of fatalities (f_F) following midair collision accidents can be calculated by the following equation:

$$f_F = E(\text{fatality}|\text{collision}) f_{\text{MaC}} \quad (91.13)$$

$$= N_{\text{exp}} P(\text{fatality}|\text{collision}) P(\text{collision}|\text{CT}) f_{\text{CT}} \quad (91.14)$$

where $E(\text{fatality}|\text{collision})$ is the expected number of fatalities after a crash and f_{MaC} is the rate of midair collision accidents. The former can be calculated as the product of the number of people exposed to the accident (N_{exp}) by the probability a person will suffer fatal injuries given exposure to the accident ($P(\text{fatality}|\text{collision})$). The f_{MaC} term can be calculated as the product of the probability of collision given that two aircraft are in conflicting trajectories ($P(\text{collision}|\text{CT})$) by the frequency of occurrence of conflicting trajectories (f_{CT}).

As in the case of ground impact accidents, since the acceptable f_F is provided by the ELOS requirement, it is possible to determine the target level of safety (TLS) for midair collision accidents given by f_{MaC} . Moreover, if the actual frequency of occurrence of conflicting trajectories is known from historical data, the maximum acceptable value of $P(\text{collision}|\text{CT})$ can be determined, which maps directly to the capabilities of the sense and avoid system.

91.5.1 Midair Collision ELOS

In order for an ELOS to be derived, accident statistics involving midair collisions are required. The NTSB has defined two categories of relevant accidents: in-flight collisions with obstacles like birds, trees, and power lines and midair collisions with other aircraft. The results from the analysis of NTSB data involving these two accidents are tabulated in Tables 91.7–91.9.

In contrast to the ground impact accidents, the ELOS for midair collision accidents should include the total number of fatalities. This is because onboard fatalities are possible when the accident is between a UAS and a manned aircraft.

Table 91.7 Fatality rates for accidents where an in-flight collision with obstacles (e.g., birds, trees, power lines) occurred. Based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) 2008a) between 1983 and 2006

| Rates per hour | Air carrier | Commuter | General aviation | Total |
|-------------------|----------------------|----------------------|----------------------|----------------------|
| Accident | $1.34 \cdot 10^{-7}$ | $3.22 \cdot 10^{-6}$ | $1.33 \cdot 10^{-5}$ | $8.17 \cdot 10^{-6}$ |
| Fatalities aboard | $9.67 \cdot 10^{-7}$ | $2.67 \cdot 10^{-6}$ | $6.27 \cdot 10^{-6}$ | $4.25 \cdot 10^{-6}$ |
| Ground fatalities | $5.97 \cdot 10^{-9}$ | $3.81 \cdot 10^{-8}$ | $5.73 \cdot 10^{-8}$ | $3.93 \cdot 10^{-8}$ |
| Total fatalities | $9.73 \cdot 10^{-7}$ | $2.71 \cdot 10^{-6}$ | $6.32 \cdot 10^{-6}$ | $4.29 \cdot 10^{-6}$ |

Table 91.8 Fatality rates for accidents where a midair collision with another aircraft occurred. Based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) 2008a) between 1983 and 2006

| Rates per hour | Air carrier | Commuter | General aviation | Total |
|-------------------|-------------|----------------------|----------------------|----------------------|
| Accident | None | $2.76 \cdot 10^{-7}$ | $5.90 \cdot 10^{-7}$ | $3.74 \cdot 10^{-7}$ |
| Fatalities aboard | None | $6.96 \cdot 10^{-7}$ | $1.04 \cdot 10^{-6}$ | $6.82 \cdot 10^{-7}$ |
| Ground fatalities | None | $1.91 \cdot 10^{-8}$ | $2.86 \cdot 10^{-8}$ | $1.87 \cdot 10^{-8}$ |
| Total fatalities | None | $7.15 \cdot 10^{-7}$ | $1.07 \cdot 10^{-6}$ | $7.01 \cdot 10^{-7}$ |

Table 91.9 Fatality rates for accidents where either a midair collision with an object or another aircraft occurred. Based on analysis of NTSB accident data (National Transportation Safety Board (NTSB) 2008a) between 1983 and 2006

| Rates per hour | Air carrier | Commuter | General aviation | Total |
|-------------------------------|----------------------|----------------------|----------------------|----------------------|
| Accident | $1.34 \cdot 10^{-5}$ | $3.48 \cdot 10^{-6}$ | $1.38 \cdot 10^{-5}$ | $8.53 \cdot 10^{-6}$ |
| Total fatalities | $9.73 \cdot 10^{-7}$ | $3.42 \cdot 10^{-6}$ | $7.40 \cdot 10^{-6}$ | $4.99 \cdot 10^{-6}$ |
| Total fatalities ^a | $5.97 \cdot 10^{-9}$ | $7.53 \cdot 10^{-7}$ | $1.13 \cdot 10^{-6}$ | $7.40 \cdot 10^{-7}$ |

^aExcluding fatalities aboard after collisions with objects other than aircraft

From the NTSB accident data in Table 91.9, it can be argued that the fatality rate following midair collisions with aircraft or other obstacles is in the order of $f_F = 10^{-6} \text{ h}^{-1}$. A more conservative estimate of $f_F = 10^{-7} \text{ h}^{-1}$ can be reached from the same table, if the onboard fatalities after a collision with obstacles other than aircraft are ignored. By deriving the expected number of fatalities after a midair collision accident, it is then possible to determine the maximum acceptable frequency of such accidents.

Another approach is to assume that in the case of midair collisions, the fatality expectation is the same, regardless of whether a UAS was involved in the accident. Although this assumption is more conservative, it simplifies subsequent analysis, since one may directly obtain the accident TLS for midair collisions. Based on the NTSB data of Table 91.9, the average rate of midair collisions involving manned aircraft is $7.40 \cdot 10^{-7}$, and under ELOS requirements, a maximum midair collision rate of $f_{\text{MaC}} = 10^{-7} \text{ h}^{-1}$ can be proposed for UAS.

Table 91.10 Maximum acceptable accident frequency depending on ATC type, flight phase, and aircraft threatened. The collision accident criteria to be applied corresponds to the one for the highest category of aircraft threatened (Source: INnovative Operational UAS Integration (INOUI) (2009))

| ATC type | Flight phase | >2,730 kg | MEP/SET <2,730 kg | SEP <2,730 kg |
|--------------|---------------------|-------------------|-------------------|-------------------|
| Area control | En route inbound | $3 \cdot 10^{-9}$ | $3 \cdot 10^{-8}$ | $3 \cdot 10^{-7}$ |
| | En route outbound | $1 \cdot 10^{-9}$ | $1 \cdot 10^{-8}$ | $1 \cdot 10^{-7}$ |
| | En route transit | $3 \cdot 10^{-9}$ | $3 \cdot 10^{-8}$ | $3 \cdot 10^{-7}$ |
| Approach | Departure | $1 \cdot 10^{-9}$ | $1 \cdot 10^{-8}$ | $1 \cdot 10^{-7}$ |
| | Init and interm app | $3 \cdot 10^{-9}$ | $3 \cdot 10^{-8}$ | $3 \cdot 10^{-7}$ |
| | Final approach | $3 \cdot 10^{-9}$ | $3 \cdot 10^{-8}$ | $3 \cdot 10^{-7}$ |
| Tower | Landing | $8 \cdot 10^{-9}$ | $8 \cdot 10^{-8}$ | $8 \cdot 10^{-7}$ |
| | Line-up | $3 \cdot 10^{-9}$ | $3 \cdot 10^{-8}$ | $3 \cdot 10^{-7}$ |
| | Start-up/push-back | $8 \cdot 10^{-9}$ | $8 \cdot 10^{-8}$ | $8 \cdot 10^{-7}$ |
| | Takeoff | $8 \cdot 10^{-9}$ | $8 \cdot 10^{-8}$ | $8 \cdot 10^{-7}$ |
| | Taxiing | $6 \cdot 10^{-8}$ | $6 \cdot 10^{-7}$ | $6 \cdot 10^{-6}$ |

MEP, multiengine piston; SET, single-engine turbine; SEP, single-engine piston

Other accident frequency limits proposed for UAS take into account both the manned aircraft threatened and the phase of flight. Such an approach was taken by INOUI that proposed the limits presented in Table 91.10.

Finally, it should be noted that not all collisions lead to catastrophic accidents. The large variability of aircraft sizes and designs, whether manned or unmanned, and the fact that not all their systems are critical for remaining airborne, means that certain collisions may be survived by one or even both of the aircraft involved. Nevertheless, since it is nearly impossible to account for every possible collision scenario and its effects, every collision is considered a catastrophic accident for both aircraft.

91.5.2 Exposure and Risk of Fatality

The number of people exposed to the accident, as well as the probability of them sustaining fatal injuries, depends on the aircraft that are involved in the accident and the passengers they carry. As a result, it is difficult to get a good estimate without a priori knowledge of all air traffic in the area of operations.

A more general estimate can be derived by noting that the product of N_{exp} and $P(\text{fatality}|\text{collision})$ is in fact the expected number of fatalities per accident. Using the NTSB accident data of Table 91.9, this product is higher for commuter aviation where it takes a value of one, while on average it is closer to 0.58. Moreover, if the onboard fatalities after a collision with obstacles other than aircraft are ignored, the expected number of fatalities per accident drops to below 0.09. It should be noted that this estimate can be considered conservative because in contrast with the accident data it was derived from, the midair collisions of interest will always involve at least one aircraft that is unoccupied.

91.5.3 Conflicting Trajectory Expectation

In Weibel and Hansman (2004), the midair collision risk assessment was based on the use of a gas model of aircraft collisions to estimate the number of expected collisions per hour of flight (f_{MaC}) from

$$f_{\text{MaC}} = \frac{A_{\text{exp}} d}{V \times t} \quad (91.15)$$

where A_{exp} is the exposed area of the threatened aircraft, d is the distance traveled, V is the airspace volume, and t is the time required to travel the distance d .

It should be noted that this model estimates the number of midair collision hazards due to insufficient spatial and temporal separation given predetermined flight paths or simply the number of *potential* collisions. An additional term is then required to take into account the fact that one or both of the aircraft in a collision course may attempt maneuvers to avoid each other. As a result, the expected number of collisions should be calculated from

$$f_{\text{MaC}} = \underbrace{\frac{A_{\text{exp}} d}{V \times t}}_{E(\text{CT})} \times P(\text{collision}|\text{CT}) \quad (91.16)$$

where CT denotes a conflicting trajectory.

The use of the model in (91.16) to assess $E(\text{CT})$ presents significant difficulties since it requires the exact trajectories (both in space and time) of all air traffic in the area where UAS operations will take place. This requirement is almost impossible to meet because air traffic is dynamic and never identical from day to day. Furthermore, not all traffic is monitored by ATC. In addition to that, in the event of a deviation from the predefined trajectory, the number of collision hazards following that event may change. Thus, a worst-case $E(\text{CT})$ may be assumed, instead.

Based on the analysis in Weibel and Hansman (2004), high $E(\text{CT})$ is found in proximity of major airways. The highest was found at FL370, where it is approximately 4×10^{-5} CT/h. Since the results were obtained by averaging data over a 24-h period, a process that can hide higher peaks, a worst-case $E(\text{CT}) = 10^{-4}$, or even higher can be chosen to also account for future traffic growth.

91.5.4 Collision Probability

Even when two aircrafts are on conflicting trajectories, a collision is not guaranteed. One or both of the pilots may take action to avoid a hazardous situation by maintaining the required separation between the two aircrafts. As a result, the collision probability depends on the collision avoidance capabilities of all the aircraft involved as well as the measures taken to assure proper separation. If a maximum allowable collision probability is known, it can be used instead of

the maximum acceptable accident frequency to determine minimum performance requirements of UAS sense and avoid systems. In fact its use offers advantages because it maps better to what such a system should be capable of accomplishing. To evaluate the actual $P_{\max}(\text{collision}|\text{CT})$, every possible scenario involving a potential conflicting trajectory can be simulated. The results are then aggregated and tested to see whether the target safety levels are accomplished.

It should be noted that when evaluating the sense and avoid system, the worst-case $E(\text{CT})$ may be overconservative. This is because it corresponds to Class A airspace where separation is provided by and is the responsibility of ATC. In the analysis presented in Weibel and Hansman (2004), the worst-case conflicting trajectory expectation falls by about an order of magnitude in Class E airspace. If the target safety level is assumed to be a collision rate of 10^{-7} h^{-1} , then the “see and avoid” capability requirement may be based on achieving $P_{\max}(\text{collision}|\text{CT}) = 1\%$. Nevertheless, the same cannot be assumed for Class G airspace because traffic in that region is not always monitored and accurate estimates on its density are not possible. In addition to that, and especially in very low altitudes, the risk of collision with birds, power lines, trees, and buildings may be higher than that of a collision with other air traffic.

91.6 Model Choice

Tables 91.11 and 91.12 summarize the parameters involved in modeling risk from UAS ground impact and midair collision accidents, respectively, as well as the alternatives presented for estimating their values. It is evident that there are several choices available to an engineer tasked with assessing the risk of UAS operations. The subject of this section is what criteria should drive the selection of one alternative over another.

There is a multitude of modeling options available to estimate risk, each with different levels of detail and accuracy. According to Range Safety Group, Range Commanders Council (2007b), any model used for risk/reliability assessment should be based on four basic standards: transparency, clarity, consistency, and reasonableness.

A number of different models may be used in a risk evaluation involving UAS operations depending on the objective and requirements of the risk study in question. A common use of risk models in the UAS domain is for building a safety case that is then used for obtaining a permit to operate in the national airspace system. As a result, the models used must be clearly presented so that they can be reviewed by the regulators, and the assumptions and limitations contained therein must be succinctly expressed. This would lead to compliance with the clarity and transparency standards.

Typically, the regulatory framework does not specify the use of a particular modeling choice over another. Nevertheless, every choice must be defensible. This is achieved by compliance with the consistency and reasonableness standards. The former refers to the use of models that are in use and accepted by the scientific

Table 91.11 A summary of the methods presented to estimate the terms involved in ground impact risk modeling when their values are not known a priori, Eq. (91.1). Some terms can be estimated with multiple methods

| Term | Estimate |
|----------------------|---|
| f_F | Based on ELOS requirements with typical values in the range of 10^{-6} – 10^{-9} h ⁻¹ |
| N_{exp} | The product of the population density (ρ) and the area affected by the impact (A_{exp}) |
| ρ | <ul style="list-style-type: none"> (i) Assuming uniform population density (ii) Using a standard population density (e.g., 200 ppl/km²) (iii) Assuming a worst-case scenario of impact at the most densely populated area |
| A_{exp} | <ul style="list-style-type: none"> (i) The area presented by the aircraft perpendicular to its path and augmented by the width of an average person (ii) The aforementioned area, including the area the aircraft traverses on the ground until it stops |
| $P(\text{fatality})$ | <ul style="list-style-type: none"> (i) Probability of one as a conservative estimate (ii) Zero or one, based on whether the kinetic energy at impact (E_{imp}) exceeds a pre-specified threshold (e.g., 34 J) (iii) From a vulnerability model based on kinetic energy at impact (E_{imp}), e.g., Feinstein et al. (1968) (iv) From a vulnerability model that also includes the effects of sheltering, e.g., Weibel (2005) or Dalamagkidis et al. (2012) |
| E_{imp} | <ul style="list-style-type: none"> (i) Kinetic energy at terminal velocity (ii) Kinetic energy at VNE (velocity not to exceed) (iii) Kinetic energy at 140 % operational velocity (iv) The difference between kinetic energy at impact and kinetic energy remaining post-impact (combined human/object) (v) The kinetic energy calculated with one of the aforementioned means, reduced by the energy required to penetrate sheltering |
| Sheltering | <ul style="list-style-type: none"> (i) Using a conservative value that assumes little or no sheltering (ii) Based on average sheltering provided by structures, vehicles, and other objects (iii) Based on the building with the worst sheltering (iv) Using a database containing structure characteristics and population distribution |
| f_{GIA} | <ul style="list-style-type: none"> (i) From previous accident statistics, if sufficient flight hours have accumulated (ii) Assuming an exponential accident distribution for new vehicles without accidents so far (iv) Using a conservative estimate of one crash per flight or per flight hour (v) Based on the results of a formal UAS reliability assessment |

community. The latter means that model selection should be based on rational criteria, risk is not underestimated, and a potential review would not raise concerns. As a result, the easier and in fact a common approach is to make conservative estimates.

Conservative estimates are also attractive because of their simplicity and of the associated ease of achieving clarity and transparency. In general, even when high fidelity modeling is possible, a balance must be struck between precision

Table 91.12 A summary of the methods presented to estimate the terms involved midair collision risk modeling when their values are not known a priori, Eqs. (91.13) and (91.14)

| Term | Estimate |
|-----------------|--|
| f_F | (i) Based on ELOS requirements with typical values in the range of 10^{-6} – 10^{-8} h ⁻¹ (ii) As above but considering only fatalities on the ground for calculating ELOS (valid when the accident involves only UAS) |
| E (fatality) | (i) Estimated from historical data, e.g., based on NTSB data from Table 91.9, it takes values in the range 0.02–1 (ii) Estimated from the product of N_{exp} and P (fatality) |
| N_{exp} | The number of people onboard the aircraft involved in the collision as well as in the area exposed to debris |
| P (fatality) | (i) Use of the number one as a conservative estimate (ii) Estimate from historical data, if available |
| f_{MaC} | (i) From historical data with typical values in the range of 10^{-5} – 10^{-7} h ⁻¹ (ii) As the product of P (collision) with f_{CT} |
| P (collision) | (i) A conservative estimate of probability one (ii) Estimated based on the capabilities of the S & A system |
| f_{CT} | (i) Based on the gas model of aircraft collisions using actual traffic data (ii) Using worst-case air traffic density either at the flight level of operations or the entire airspace |

and limitations relevant to cost, resources, and time (Range Safety Group, Range Commanders Council 2007b).

On the other hand, conservative estimates may lead to irrationally high reliability requirements and/or very strict operational restrictions. This occurs as a consequence of a problem known as compounding conservatism, where use of successive conservative estimates can lead to overconservative results (Range Safety Group, Range Commanders Council 2007b). To illustrate this issue, consider the modeling of a ground impact accident scenario using (91.1). In addition, assume that the actual population and area affected by the crash are overestimated by 50 and 20 %, respectively, and the probability of fatality is considered to be 1 when in fact it is only 20 %. In this case, the fatality expectation will be nine times higher than what it really is. Moreover, if conservative estimates are used for evaluating the possible hazards that may lead to a crash, the reliability requirements for the various aircraft parts can be higher by two or more orders of magnitude. Although such an aircraft would be capable of performing well within the target safety levels, the higher production and maintenance costs could mean that it may never get built.

The problem of compounding conservatism may be addressed by avoiding to take conservative estimates and, instead, opting for the best available estimate (Range Safety Group, Range Commanders Council 2007b). Such an approach has also been advocated by the U.S. Nuclear Regulatory Commission (Range Safety Group, Range Commanders Council 2007b). Of course, when best or mean estimates are used, the uncertainties and possible inaccuracies affecting the final result should be clearly documented (Range Safety Group, Range Commanders Council 2007b).

This would also allow adjustments at a later stage to account for newer data as they become available. Moreover, if the uncertainties can be quantified through simulation, sensitivity analysis, or other methods, then confidence intervals can be determined. The latter can then be used to adjust results so that proposed reliability targets can be achieved with arbitrary confidence.

As an example, it will be assumed that a probability of fatality of 0.4 was estimated for a particular accident scenario. Further analysis of the model showed that for a confidence level of 95 %, the actual value is expected to be between 0.3 and 0.5. In this case, the 0.5 value may be used instead of 0.4 to determine UAS reliability requirements. If higher confidence is required, the range will be larger and the value used more conservative.

In certain cases – especially when required data are missing – a safety case can be made by comparing the UAS under investigation with a different system already authorized to fly (Range Safety Group, Range Commanders Council 1999b). Qualitative arguments may also be made without a complete analysis of the risk involved (Range Safety Group, Range Commanders Council 1999b). For example, the UAS may be too light to cause an injury or the area of operations may be so sparsely populated that the risk to the general public is too low under any conditions.

The modeling techniques described in the previous sections produce an average risk estimate from the operation of a UAS, especially when best estimates are used instead of conservative. What should be mentioned is that in certain cases when using a casualty or fatality metric, particularly catastrophic accidents involving multiple fatalities can occur without violating the target safety levels on average (Range Safety Group, Range Commanders Council 2007b). Such accidents of course are best to be avoided, and as a result, it is useful to incorporate catastrophe aversion in the models used (Range Safety Group, Range Commanders Council 2007b). The latter is accomplished by assigning activities that can be particularly dangerous to lower acceptable probabilities of occurrence. This in turn may be done either by creating a risk profile if sufficient data are available or easier by using functions of the N_{exp}^k type for expressing the affected population (Range Safety Group, Range Commanders Council 2007b). Of course the latter methodology should be employed with care and for high risk activities only, so as not to unnecessarily inflate the risk in other less dangerous activities. A risk profile gives the function between the number of expected casualties and the expected frequency for each casualty size due to various future incidents (Range Safety Group, Range Commanders Council 2007b). Although this profile is useful for obtaining a better view of the associated risks, it is usually costly and time consuming to obtain.

91.7 Case Studies

Using the methodologies described in Sect. 91.4, it is possible to derive the reliability requirements with respect to ground impact for various types of UAS and under different scenarios.

Table 91.13 Characteristics of five UAS of various sizes, used for the case analysis (Source: FSF editorial staff (2005) and U.S. Department of Defense. Office of the Secretary of Defense (2005))

| | Weight (kg) | Dimensions (m) | Oper. speed (m/s) | Oper. altitude (ft) |
|------------------|-------------|-----------------------|-------------------|---------------------|
| RQ-4 Global Hawk | 11, 612 | 35.4 (wingspan) | 177 | 65, 000 |
| MQ1 Predator | 1, 021 | 14.8 (wingspan) | 70 | 20, 000 |
| RQ-2 Pioneer | 205 | 5.2 (wingspan) | 41 | 15, 000 |
| RQ-11 Raven | 1.9 | 1.3 (wingspan) | 15 | 1, 000 |
| Rmax IIG | 94 | 3.12 (rotor diameter) | 5.6 | 500 |

Table 91.14 The parameters used for each test case and a description of a possible corresponding scenario

| Scenario | Pop. density (ppl/km ²) | p_s | Description |
|-----------------|-------------------------------------|-------|---|
| 1 – Optimistic | 50 | 7 | Low population density area. It is also assumed that people are afforded significant sheltering either by natural obstacles (e.g., trees) or they can be trained to avoid or take cover when required. This scenario may correspond to surveillance of a remote military installation or to a forest monitoring application |
| 2 – Pessimistic | 5,000 | 1 | This scenario features very high population density. Additionally the sheltering factor used corresponds to no protection from sheltering at all. This case corresponds to the scenario of a search and rescue operation in a metropolitan area, where several people are in open areas preoccupied with other tasks |

To illustrate the differences between vulnerability models, an optimistic and a pessimistic scenario were investigated using five UAS. The systems were chosen to span all sizes, and their basic characteristics are shown in Table 91.13. A description of the scenarios and the parameters used are provided in Table 91.14. Although the results are subject to the uncertainties inherent in the parameters and the models themselves, they should be accurate in terms of order of magnitude and for comparisons between different vulnerability models as well as between UAS types and sizes.

For each case, the probability of fatality was first estimated. To illustrate the different results that may be reached due to the choice of a model, three different modeling options were employed:

1. The probability of fatality was based on the vulnerability model of (91.9) using a kinetic energy estimate based on (91.11).
2. Using the same model as above, but with a more conservative kinetic energy estimate based on terminal velocity.
3. The probability of fatality is 0 or 1, based on the kinetic energy threshold of 34 J, initially presented in Sect. 91.4.3. The kinetic energy is calculated using the terminal velocity.

^aUsing vehicle kinetic energy estimated from (91.11)

^bWorst-case vehicle kinetic energy estimate

For the first three options and under both scenarios, parameter α was chosen to be 100 kJ and β equal to 34 J.

In addition to the probability of fatality, the required system reliability was also calculated for each of the aforementioned fatality probability models as well as for the conservative estimate of probability of 1. The UAS reliability requirement has been given in minimum hours between ground impact accidents, and its calculation is based on a target level of safety of 10^{-7} fatalities per hour of flight. The system reliability requirement was derived since it allows a comparison with the current performance of manned and unmanned aviation. The results for each UAS and each case are summarized in Tables 91.15–91.18.

In the pessimistic scenario, the probability of fatality associated with each UAS is, almost in every case, 100 %. As a result, there are no differences between the reliability requirements calculated from the different models. Considering that current manned aviation accident rates are in the order of 10^{-7} h^{-1} for air carriers and 10^{-5} h^{-1} for general aviation (Table 91.4), it is obvious that for operations in high population density areas, certain UAS will need to exceed this performance.

In the optimistic scenario, the most striking differences between vulnerability models can be seen! This is due to the effect of the sheltering factor, which is not taken into account when using a threshold kinetic energy. Smaller systems feature

fatality probabilities of 10–25 % that are further reduced to 4–10 % when using a less conservative estimate for the kinetic energy at impact. This is also evidenced in the system reliability requirement, which is at least an order of magnitude smaller compared to that obtained using the threshold function. The benefits are evidenced in larger systems as well, where the reliability requirement is lower by a factor up to 3.

91.8 Conclusion

This chapter has investigated ways to calculate the target level of safety requirement for UAS based on the current levels of safety of manned aviation. As mentioned before, actual regulations will need to depend on a number of factors, and as a result, it is possible that they will contradict the results shown. Nevertheless, the methodologies are still useful for getting an idea of the relevant risk imposed by UAS as well as for arguing a safety-based authorization for operations.

Moving beyond the actual risk model and target safety level chosen, it is normally necessary to obtain design specifications and requirements on the hardware and software components that comprise the UAS rather than restrictions on the UAS as a whole. The way to derive these requirements is beyond the scope of the chapter,

but it normally involves a lengthy, formal process of identifying the hazards, the resulting failure conditions and their likelihoods, and then working backwards, derive requirements for the system, subsystems, and individual components. Even when a UA is designed in such a way that safety requirements are met for every conceivable application, additional risk mitigation measures may still need to be taken depending on the actual operating scenario.

Abstract

The safety risk management process describes the systematic application of management policies, procedures, and practices to the activities of communicating, consulting, establishing the context, and assessing, evaluating, treating, monitoring and reviewing risk. This process is undertaken to provide assurances that the risks associated with the operation of unmanned aircraft systems have been managed to acceptable levels. The safety risk management process and its outcomes form part of the documented safety case necessary to obtain approvals for unmanned aircraft system operations. It also guides the development of an organization’s operations manual and is a key component of an organization’s safety management system. The aim of this chapter is to provide existing risk practitioners with a high level introduction to some of the unique issues and challenges in the application of the safety risk management process to unmanned aircraft systems. The scope is limited to safety risks associated with the operation of unmanned aircraft in the civil airspace system and over inhabited areas. This chapter notes the unique aspects associated with the application of the safety risk management process to UAS compared to that of conventionally piloted aircraft. Key challenges discussed include the specification of high-level safety criteria; the identification, analysis and evaluation of the risks; and the effectiveness of available technical and operational mitigation strategies. This chapter also examines some solutions to these challenges, including those currently in practice and those still under research and development.

92.1 Introduction

Unmanned aircraft systems (UAS) are one of a number of emerging sectors of the aviation industry. The potential benefits from the use of UAS have been demonstrated in a variety of civil and commercial applications including crop and infrastructure management, emergency management, search, and rescue, law enforcement, environmental research, and many other applications often described as being too *dull, dirty, dangerous, or demanding* for conventionally piloted aircraft (CPA). However, as well as benefits, the operation of UAS has associated risks.

Intrinsic to the realization of any system is a finite degree of risk; subsequently, accidents involving UAS will occur no matter how stringent the conditions prescribed or draconian the regulatory oversight provided. One could argue that the only way to assure absolute safety is to prohibit the deployment of UAS altogether.

However, to justify this argument, one must also address the philosophical question of *what are the risks of not using UAS technologies?*

The starting premise of this chapter, and one which is consistent with modern aviation safety thinking (ICAO 2009) is that UAS operations, like CPA operations, are not currently, and never will be, absolutely safe (i.e., have zero associated risks). The challenge for UAS stakeholders is to establish a safety case detailing how these inherent risks can be managed to an acceptable level.

Achieving an *acceptable level* of risk is a multidisciplinary problem. It requires a balancing of complex social, psychological, technical, political, and economic factors arising due to the following:

- Limited knowledge and resources available to identify characterize, and treat the safety risks associated with a technology
- Subsequent need to make trade-offs between available risk mitigation strategies based on assessments of the associated costs and benefits
- Potentially conflicting values, beliefs, perceptions, objectives, and expectations held by the different stakeholder groups involved in the decision-making process (e.g., those held by the UAS industry, other airspace user groups, and the general public)
- Conditions and environment under which the decisions are made (e.g., hidden political or time pressures)

Achieving a balanced outcome from such a problem space is the objective of the safety risk management process. This objective is achieved through the application of the safety risk management process (SRMP), which can be described as

the systematic application of management policies, procedures and practices to the activities of communicating, consulting, establishing the context, and identifying, analyzing, evaluating, treating, monitoring and reviewing risk. [Definition 3.1, (ISO 2009)]

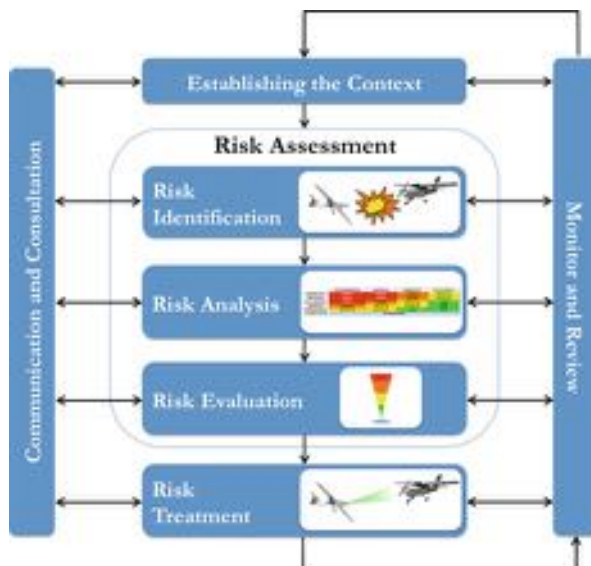

This chapter explores some of the unique aspects, issues, and challenges associated with application of the SRMP to the safety risks associated with UAS operations.

92.1.1 Scope

Discussion in this chapter is limited to the safety risks associated with civil UAS operations. There are a variety of descriptions of the SRMP, and these descriptions can differ in their scope, subprocesses, and structure. For the purposes of this chapter, the generalized and domain-independent description of the SRMP provided in ISO 31000:2009 is used and illustrated in Fig. 92.1 (ISO 2009). Some aviation-specific descriptions of the SRMP can be found in references (FAA 2000; ICAO 2009; CAA 2010b).

Establishing, maintaining, and improving safety requires more than the application of an SRMP. The SRMP is conducted as part of an organizational risk framework developed in accordance with a fundamental set of organizational risk principles (ISO 2009). In aviation parlance, these principles and the organizational framework in which the SRMP is applied are part of an organization's safety

Fig. 92.1 The safety risk management process, based on ISO (2009)

management system (SMS) (ICAO 2009). The scope of this chapter does not include the SMS. For general information on the components of the SMS, the reader is referred to the references (ICAO 2009; ISO 2009).

92.1.2 Aim and Overview of Chapter

The aim of this chapter is to provide existing risk practitioners with a high-level introduction to some of the unique issues and challenges in the application of the SRMP to unmanned aircraft systems. This chapter does not provide a comprehensive description of the SRMP itself. The discussion is intentionally high level in its nature to ensure applicability to a broad range of UAS and their potential concepts of operation.

The structure of this chapter follows the SRMP illustrated in Fig. 92.1. The first step in any SRMP is to establish the context, which is described in Sect. 92.2. This is followed by the risk assessment process. The objective of the risk assessment process is to comprehensively characterize the safety risks associated with UAS operations and, based on this information, determine which of the characterized risks can be tolerated and which of the characterized risks require mitigation (treatment). As illustrated in Fig. 92.1, the risk assessment process comprises the subprocesses of risk identification, risk analysis, and risk evaluation. These are discussed in Sects. 92.3–92.5, respectively. The objective of the risk treatment process (described in Sect. 92.6) is to identify, implement, and evaluate suitable measures to reduce (mitigate, modify, treat, or control) the risk. The SRMP is a *living* process being a key component of an organization's overarching SMS. The process of monitoring and reviewing (Sect. 92.7) is pivotal to maintaining

and improving the management of the risks. Finally, there is the process of communication and consultation (Sect. 92.8). The communication and consultation process is key to addressing broader stakeholder concerns and those issues that stem from a lack of knowledge of the risks and benefits associated with civil UAS operations.

92.2 Establishing the Context

Understanding the complexity of challenges to be faced in the safety risk management of UAS requires consideration of the social, psychological, political, and economic factors associated with the broader integration of UAS into society. These factors are identified as part of the context for the SRMP and are commonly overlooked in UAS safety discussions. Establishing the context is the process of “defining the external and internal parameters to be taken into account when managing risk, and setting the scope and risk criteria for the risk management policy” (ISO 2009). This subprocess of the SRMP involves consideration of the “cultural, social, political, legal, regulatory, financial, technological, economic, natural, and competitive environment, whether international, national, regional or local; the key drivers and trends having impact on the objectives of the organization; and relationships with, and perceptions and values of external stakeholders” (ISO 2009).

92.2.1 Safety Risk Management Process and UAS

The SRMP can be used to support a range of operational, financial, or regulatory decisions concerning UAS. Here, we will focus on those decisions made in relation to the management of the safety risks associated with their operation. In this context, the SRMP provides an accepted and systematic means for providing assurances that the risks associated with UAS operations have been managed to an acceptable level. The SRMP and its outcomes form part of the documented safety case necessary to obtain approvals for UAS operations. It also guides the development of an organization’s operations manual and is a primary component of an organization’s SMS. The SRMP is also used to guide the safety policy, rulemaking, and oversight activities of a national aviation authority (ICAO 2009).

The Civil Aviation Safety Authority (CASA) has released draft guidance material describing the application of SMS principles to civil UAS operators (CASA 2011). The guidance material is believed to be the first of its kind specifically targeted to civil UAS operations. Drawing on ICAO SMS principles and internal CASA policy, the guidance material includes recommendations on how UAS operators should approach the safety risk management of UAS operations (ICAO 2009). Although not a regulatory requirement, CASA actively encourages UAS operators to develop an SMS due to the potential benefits of improved safety and reduced costs.

92.2.2 The Objective

One of the first steps is to define the objectives of the activity. The general overarching objective is to provide assurances in the safety of a particular UAS operation or organization's activities. Objectives also need to be defined in relation to the expected benefits of the operation to the different stakeholders involved. For commercial UAS operations, these objectives can often be derived from the corporate and strategic objectives of the organization (e.g., profitability, market growth, reputation). As well as being a goal, objectives can also act as constraints on decisions made throughout the SRMP. All objectives should be clearly defined to ensure transparency in decision-making to help identify potential conflicts in the SRMP.

92.2.3 Considerations and Constraints on the UAS Safety Risk Management Process

Constraints bound the decisions made within the SRMP and can arise due to a variety of financial, legal, social, psychological, technological, temporal, or spatial limitations or requirements. For example, the national aviation authority (NAA) functions of safety policy, rulemaking, and oversight must be defined in consideration of ICAO Standards and Recommended Practices (SARPS); the safety performance objectives established within a State Safety Plan (SSP); the legal, political, economic, and cultural requirements specific to their respective state; and the internal resources and capability of the NAA to define and execute these functions. Constraints are typically categorized as being either internal or external to the organization. Internal constraints are those that arise due to limits in the capability or resources of the organization or due to the organization's existing policies, procedures, or objectives. External constraints include existing regulations (e.g., existing civil aviation safety, environmental protection, or workplace health and safety legislation) or other social, cultural, political, or economic expectations held by other stakeholders (including the members of the general public).

92.2.4 Stakeholders

A stakeholder can be defined as "an individual, group of people, organization or other entity that has a direct or indirect interest (or stake) in a system" (Hull et al. 2011). An *interest* may arise through the stakeholder using, benefiting from, being disadvantaged by being responsible for, or otherwise being affected by the system (Hull et al. 2011). Stakeholders in the UAS SRMP can include other airspace users, the general public, air traffic service providers, the end users of UAS services or their data products, the aviation safety regulator, landowners, and members of the UAS

industry (inclusive of equipment and airframe manufacturers, operators, training, and maintenance organizations). Stakeholders will have their own objectives, information needs, and expectations in terms of the safety performance of UAS. These need to be identified and considered at all stages of the SRMP.

The acceptance of UAS operations requires more than a solid safety case. Understanding stakeholder concerns, the motivation for them and how they influence their decisions in relation to safety, is key to achieving the broader acceptance of UAS operations. Clothier et al. (2008) use the situation faced by horseless carriages in the 1800s as an analogy to the situation being faced by UAS today. As described in Clothier et al. (2008), there are hidden factors concerning the integration of UAS into society that can influence stakeholder decision-making in relation to their safety. UAS are a new user within an existing airspace system. Further, there exist potentially competing industries, whose value and safety performance is already widely known and tolerated by society. These and other factors (e.g., the unemployment of pilots) can manifest as hidden objectives and constraints on the SRMP. Effective stakeholder communication is pivotal to the identification, characterization, and resolution of the potential conflicts that can arise in the SRMP.

92.2.4.1 Perception

A distinction is often made between those stakeholder assessments of the safety risks that are formed through the use of *objective* data, expert domain knowledge, models, or formal assessment techniques, and those assessments that are based on the *subjective* knowledge, beliefs, emotions, values, and needs of the individual. The latter of these types of assessments is commonly referred to as perceived risk. There is a range of factors that influence how different stakeholders appraise and respond to the safety risks associated with UAS operations. Importantly, these appraisals and responses can be different to those they would make for the safety risks associated with CPA operations. These perceptions give rise to different stakeholder expectations in terms of the safety performance of UAS.

At the time of writing, no significant body of research into the perception of the safety risks associated with UAS operations could be found. Clothier and Walker (2006); Clothier et al. (2008) provide limited discussion on factors likely to influence the perception and acceptability of the risks associated with UAS operations. Also worth noting is the survey of air travelers conducted by MacSween-George (2003). This survey attempted to characterize the willingness of people to travel onboard a pilotless passenger aircraft.

In the absence of a risk perception study specific to UAS, general factors taken from existing psychometric modeling studies (Fischhoff et al. 1978; Slovic et al. 1979; Slovic 1987, 1999) are used to hypothesize the public's perception of the safety risks associated with UAS operations. An analysis of the UAS safety paradigm with respect to the factors of voluntariness of exposure, control of exposure, awareness of benefits, and uncertainty is described below.

Voluntariness. The primary risks of concern due to CPA operations are to the crew and passengers onboard the aircraft. The individuals exposed voluntarily

undertake these risks in return for a direct benefit. On the other hand, for UAS operations, the primary risks are to members of the general public overflown who are largely involuntarily exposed to the risks.

Control. The members of the general public overflown by UAS operations are largely unable to influence the level of their exposure. Whereas passengers of CPA have greater control over the level of risk they are willing to tolerate through the number and type of aircraft operations (e.g., gliding, sport aviation, or scheduled passenger flights) they partake in and through choice of a particular air service provider.

Benefit. The knowledge of the benefits of CPA operations (e.g., efficient transportation of people and freight) is broadly understood and widely known. Further, there is a direct and identifiable relationship between the individuals exposed and the benefits they receive. However, the routine operation of UAS for civil and commercial applications has yet to be realized, and as a consequence broader society has limited, if any, knowledge of the benefits. For UAS, the connection between benefits and the individual exposed may not always be identifiable to the individual exposed.

Knowledge and Information. In relation to UAS, there are limited sources of information available to stakeholders. The quality of the information that is available to stakeholders is variable, biased, and often unverified. For example, the movie *Stealth*TM portrays UAS with unrealistic capabilities. The information available predominantly relates to military UAS operations and their roles in recent conflicts (e.g., as weapons of war). This can create a bias in stakeholder knowledge of UAS. There is also a significant knowledge gradient between stakeholders (i.e., a difference in the amount and quality of knowledge held by the different stakeholder groups). The general public and the NAAs have less personal knowledge that they can use to contrast/verify the information available to them. Whereas the industry stakeholders have much more experience and knowledge relating to UAS operations and their safety performance. This knowledge gradient can lead to issues of trust and in turn higher stakeholder uncertainty in assessments of the risks. Finally, the above factors can lead to lower stakeholder certitude (e.g., belief in their self-knowledge), and potential issues of trust can lead to higher perceptions of the risk. These and other factors give rise to stakeholder uncertainty. The higher the uncertainty, the higher the perception of the risks.

Based on the above factors, it is hypothesized that stakeholder perceptions of the risks associated with UAS operations will be higher than that for a comparable CPA operation. Addressing the issues relating to risk perception requires the development of communication strategies (Sect. 92.8). Psychological factors influence not only stakeholder assessments of the risks but also their appetite for them. It has been proposed that stakeholders will expect UAS to demonstrate a level of safety performance better than that currently expected of CPA operations. If true, this expectation will need to be taken into consideration when defining high level safety criteria (HLSC) for UAS. Most qualitative specifications of HLSC for UAS express a desire for UAS to exhibit a level of risk less than, or equal to, that currently demonstrated by CPA. Some quantitative specifications of HLSC for UAS include

a multiplicative factor to account for the hypothesized difference in stakeholder appetite for risk, for example (Weibel and Hansman 2004).

92.2.5 High-Level Safety Criteria

HLSC are qualitative or quantitative statements describing “the terms of reference against which the significance of a risk is evaluated” (ISO 2009). A review of regulations, regulatory guidance material, and industry position papers yielded a disparate array of qualitative and quantitative statements of the HLSC for UAS. Based on this review, the existing HLSC can be broadly categorized into one of two general categories: acceptable level of safety (ALoS) and equivalent level of safety (ELoS) criteria. These HLSC are not to be confused with equivalent level of performance (ELOP) requirements, which are briefly described in Sect. 92.2.5.3.

92.2.5.1 Acceptable Level of Safety Criteria

The first category of HLSC for UAS are those defined in relation to an ALoS. Examples of existing qualitative statements of ALoS HLSC are provided in Table 92.1. Although ALoS HLSC avoid many of the issues associated with making a direct comparison to the safety performance of CPA (discussed in the next section), they provide no guidance as to what constitutes an *acceptable* level of safety.

Table 92.1 Examples of qualitative specifications of the acceptable level of safety criteria for UAS

| Statement | Reference |
|--|---|
| “UAS must operate safely, efficiently, and compatibly with manned aircraft operation in the airspace so that the overall safety of the airspace is not degraded. The fundamental safety requirement for the UAS is to provide an acceptable level of risk for people and property in the air and on the ground” p. 1 | RTCA Guidance Material (RTCA 2007) |
| “... UAS are to provide and acceptable level of risk for people and property on the ground and in the air and to operate without adversely affecting the existing users of the NAS.” p. 11 | |
| “Enable the operation of sUAS [<i>small UAS</i>] by mitigating, to an acceptable level of risk, the hazards posed to manned aircraft and other airborne objects operating in the National Airspace System (NAS) as well as the public on the surface.” p. iii | Recommendations from the Aviation Rulemaking Committee, FAA (SUAS 2009) |
| “Any sUAS may be operated in such a manner that the associated risk of harm to persons and property not participating in the operation is expected to be less than acceptable threshold value(s) as specified by the Administrator.” p. 53 | |
| “Regulations are intended to ensure that the UAV systems and their operations achieve an acceptable level of safety for people and property in other aircraft and on the surface.” pp. 2–46 | MITRE Issues paper (DeGarmo 2004) |

One approach for qualifying/quantifying *acceptable* is to base it on the de facto levels of risk determined for other activities (e.g., smoking or riding a bike) or naturally occurring events (e.g., death due to being struck by lightning). For example, the Swedish Aviation Authority use the probability of someone dying in a road accident to guide the setting of ALoS criteria for UAS (Wiklund 2003). Another approach is to directly adopt existing safety criteria specified in the regulation of other industries (e.g., as used for land use planning, space launch activities, and nuclear energy industry).

92.2.5.2 Equivalent Level of Safety Criteria

The second and most common category of HLSC for UAS qualifies *acceptable* through reference to the safety performance currently exhibited by CPA. Safety performance is expressed as the level of risk or the potential for harm (i.e., the existence of hazards). These comparative HLSC are widely referred to as ELoS criteria, and some qualitative examples are provided in Table 92.2.

There are a number of critical assumptions that need to be considered in the use of ELoS HLSC. Firstly, there is the foundational assumption that risks as tolerated or accepted in the past (i.e., those associated with CPA operations) provide a suitable basis for judging the acceptability of future risks associated with a different technology (i.e., those associated with UAS operations). Many of the factors discussed in Sect. 92.2.4 would challenge this assumption.

Secondly, ELoS criteria require a mechanism for making comparisons between the different categories of CPA and of UAS. For example, CASA states that HLSC for UAS should be defined in relation to CPA of *equivalent class or category* (CASA 2002). A range of mechanisms for making such a comparison have been proposed and include those based on similarities in the maximum takeoff weight of the aircraft, the maximum kinetic energy of the aircraft under different failure modes (JAA/EUROCONTROL 2004) or in the expected number of casualties (Grimsley 2004). For some UAS, it is not possible to establish an equivalent type within the CPA fleet on the basis of a similarity in the attributes of the aircraft alone. This issue is clearly illustrated in the comparative histogram plots of the UAS and CPA fleets presented by Clothier et al. (2011). Even if equivalence in terms of a similarity in aircraft attributes can be made, such attributes may not account for the differences between the safety risk profiles associated with the two different aviation concepts. These differences are discussed in the risk assessment subprocesses of Sects. 92.3, 92.4, and 92.5.

A range of measures, reference data, and approaches have been used to quantify ELoS criteria and some examples are provided in Table 92.3. There are a number of issues associated with the use of these measures. Firstly, most of the ELoS HLSC were determined through an historical analysis of CPA accident and incident data. As discussed by Clothier and Walker (2006), this quantification approach can be sensitive to the period over which the historical analysis is conducted and the type of CPA activity considered. Averaging over a historical period does not reflect trends in the safety performance of CPA operations or the infrequent nature of the events being characterized. Further, the averaged/aggregated measures do not

Table 92.2 Examples of qualitative specifications of the equivalent level of safety criteria for UAS

| Statement | Reference |
|--|---|
| <p>“The principal objective of the aviation regulation framework is to achieve and maintain the highest possible uniform level of safety. In the case of UAS, this means ensuring the safety of any other airspace user as well as the safety of persons and property on the ground.” p. 4</p> <p>“[<i>this framework</i>] ... will provide, at a minimum, an equivalent level of safety for the integration of UAS into non-segregated airspace and at aerodromes.” p. 4</p> <p>“The introduction of RPA [<i>remotely piloted aircraft</i>] must not increase the risk to other aircraft or third parties and should not prevent or restrict access to airspace.” p. 17</p> | ICAO circular (ICAO 2011) |
| <p>“UAV operations should be as safe as manned aircraft insofar as they should not present or create a hazard to persons or property in the air or on the ground greater than that created by manned aircraft of equivalent class or category.” p. 11</p> <p>“When considering a request for approval to conduct a particular operation with a UAV, CASA must ensure that the operation of the UAV will pose no greater threat to the safety of air navigation than that posed by a similar operation involving a manned aircraft. This characteristic may be termed ‘acceptable’.” p. 18</p> | CASA advisory circular (CASA 2002) |
| <p>“... UAS operations must be as safe as manned aircraft insofar as they must not present or create a greater hazard to persons, property, vehicles or vessels, whilst in the air or on the ground, than that attributable to the operations of manned aircraft of equivalent class or category.” Sect. 1, Chap. 1, p. 1</p> | CAA-UK Guidance material (CAA 2010a) |
| <p>“A civil UAS must not increase the risk to people or property on the ground compared with manned aircraft of equivalent category.” p. 4</p> | EASA Policy statement (EASA 2009) |
| <p>“UAV Operations shall not increase the risk to other airspace users or third parties.” p. 12</p> <p>“If civil UAV Systems are to become a reality the industry must gain the acceptance and confidence of these people [<i>general public and existing airspace users</i>], and this could be achieved by demonstrating a level of safety at least as demanding as the standards applied to manned aircraft.” p. 12</p> | JAA and EUROCONTROL, Report (JAA/EUROCONTROL 2004) |
| <p>“... it is broadly accepted by European military authorities that UAV operations outside segregated airspace should be conducted at a level of safety equivalent to that for manned aircraft. Similarly, UAV operations should not increase the risk to other airspace users and should not deny the airspace to them.” p. 6</p> | EUROCONTROL Specifications (EUROCONTROL 2007) |
| <p>“... UAVs must demonstrate that they do not pose an undue hazard to other aircraft or persons on the ground. They must, in short, provide for an equivalent level of safety to manned aircraft.” pp. 2–1</p> | MITRE Issues paper (DeGarmo 2004) |
| <p>“UASs shall operate to equivalent levels of safety as manned aircraft in regard to the risk they pose to people on the ground, other aircraft and property.” MILAVREG 7.1 p. 1, Sect. 2, Chap. 7</p> <p>“The objective of the unmanned aerial systems (UAS) airworthiness regulations is to ensure that UAS operations present no greater risk to personnel, other aircraft and property than that accepted for the operation of manned aircraft, without undue compromise to operational flexibility.” Sect. 5, Chap. 3, p. 1</p> | Australian Defence Force airworthiness regulations and guidance material (ADF 2009) |

(continued)

Table 92.2 (continued)

| Statement | Reference |
|--|---|
| “Any UAV operation or test must show a level of risk to human life no greater than that for an operation or test of a piloted aircraft.” p. 3 | U.S. Range Commanders Council, Flight test range safety requirements (RCC 1999) |
| “The hazards associated with a specific UAV are defined in the hazard analysis (risk management criteria). The range must ensure that the risks to people identified in the hazard analysis are reduced to an acceptable level. . . .The criteria is[sic] met if the hazard is confined to unpopulated areas (2.1) or if the combined vehicle reliability and population distribution results in a risk is[sic] no greater than that for manned aircraft operations (2.2).” p. 4 | |
| “The Army vision is to have “file and fly” access for appropriately equipped UAS by the end of 2012 while maintaining an equivalent level of safety (ELOS) to aircraft with a pilot onboard.” p. 105 | U.S. Army, Unmanned systems roadmap (DoD 2010b) |
| “... it is MoD policy that the operation of a RPAS [Remotely Piloted Air Systems] should be no more likely to cause injury or fatality to personnel or the general public than the operation of a manned aircraft.” | UK Mod 1000 Series (GEN) (MAA 2011) |

Clarifications indicated in [bracketed] and *italicized* text

account for peak risks that can occur due to geospatial or temporal concentrations in aviation activity or variations in the level of exposure of different subgroups within the populations exposed to the risks (e.g., the level of risk to pilots and aircrew compared to the level of risk to members of the general flying public).

To ensure a more comprehensive management of the risks associated with UAS operations and to be consistent with the safety risk management of other industries (see HSE 2001b), Clothier et al. (2011) propose that the specification of HLSC for UAS includes measures indicative of the individual and societal risk, in addition to the measures of group/collective risk that have been previously proposed. Further, it is recommended that the HLSC for UAS be defined based on the peak risks associated with CPA operations as opposed to averaged values.

Irrespective of the measures used or where the baseline level of safety is set (e.g., equivalent to that of CPA or not), there is the inherent difficulty of verifying that a system or operation actually satisfies the HLSC.

92.2.5.3 Equivalent Level of Performance Requirements

The ELoS criteria described in the previous section should not be confused with the requirement for an ELoS as described in (FAA 2009, 2011b; Wolfe 2009) which are referred to here as ELoP requirements. Whereas ELoS criteria are expressed in terms of levels of safety or of risk, ELoP criteria are typically expressed in terms of equivalence to the following:

- Existing regulations, standards, or procedures for CPA (e.g., design or operating requirements)
- Functions or functional performance (e.g., UAS must demonstrate a *sense and act* function equivalent to the *see and avoid* function provided by a human pilot).

ELoP requirements are not HLSC but lower-level requirements mandated to control (or mitigate) the risks associated with UAS operations (discussed further

Table 92.3 Examples of quantitative specifications of the equivalent level of safety criteria for UAS

| Value | Measure | Method and data used | Reference |
|----------------------------------|--|--|---|
| Ground Fatality Criteria | | | |
| 1.0×10^{-06} | Number of ground fatalities per flight hour | Based on civil aviation and U.S. Navy aviation accident data compiled over the period 1982–1998. Used by Grimsley (2004) to determine permissible system failure rates for UAS. Also used in Appendixes 3–5, enclosure 3 of (JAA/EUROCONTROL 2004) | U.S. Range Commanders Council (RCC 1999, 2001) |
| 1.0×10^{-07} | Number of ground fatalities per flight hour | Based on references to existing historical studies | Dalamagkidis et al. (2008) |
| 8.4×10^{-08} | Number of involuntary ground fatalities per flight hour | Derived directly from an analysis of aviation accident and incident data compiled by the NTSB over the period 1984–2004 | Clothier and Walker (2006) |
| 1.0×10^{-08} | Number of involuntary ground fatalities per flight hour | Based on analysis of aviation accident and incident data compiled by the NTSB over the period 1983–2003. Includes multiplicative factor to account for differences in the public’s appetite for UAS risks | Weibel and Hansman (2004) |
| 1.0×10^{-08} | Nominal likelihood of a mishap causing serious injury, loss of life, or significant damage per flight hour | Interim/recommended level for management of all UAS hazards (including risks to people on the ground). Reference level based on existing Australian Defence Force (ADF) aviation risk management guidelines and assumptions made in relation to the average duration of UAS operations | Australian Defence Force airworthiness regulations (ADF 2009) |
| Midair Collision Criteria | | | |
| 4.10×10^{-07} | Midair collision rate per flight hour | Determined directly from an analysis of aviation accident and incident data compiled by the NTSB over the period 1984–2004 | Clothier and Walker (2006) |
| 2.32×10^{-07} | Fatal midair collision rate per flight hour | Determined directly from an analysis of aviation accident and incident data compiled by the NTSB over the period 1984–2004 | Clothier and Walker (2006) |
| 1.0×10^{-07} | Midair collision rate per flight hour | Based on aviation accident and incident data compiled by the NTSB over the period 1983–2006 | Dalamagkidis et al. (2008) |
| 1.0×10^{-08} | Nominal likelihood of a mishap causing serious injury, loss of life, or significant damage per flight hour | Interim/recommended level for management of all UAS hazards (including midair collisions). Reference level based on existing ADF aviation risk management guidelines and assumptions made in relation to the average duration of UAS operations | ADF airworthiness regulations (ADF 2009) |
| 1.0×10^{-09} | Midair collisions per flight hour | Existing target level of safety criteria provided in Federal Aviation Administration (FAA) System Safety guidelines (FAA 2000) | Weibel and Hansman (2004) |

in the Section 92.2.5.3). Satisfying an ELoP does not necessarily give rise to an ELoS. The use of ELoP as de facto safety criteria requires assumptions to be made in relation to the nature of the relationship between system performance (e.g., reliability) and the level of risks to different entities of value (e.g., the potential damage to people and property).

92.2.6 Summary

Establishing the context defines the inputs, desired outputs, and the boundaries and constraints on decisions made throughout the SRMP. It is important to note that obtaining a *public license* for UAS operations must take into consideration a broad range of issues. The integration of a new technology into society is subject to a wide range of broader social, political, cultural, and economic considerations. For example, one of the primary concerns identified in the survey of air travelers conducted by MacSween-George (2003) was the potential unemployment of pilots. A search of mainstream media sources reveals numerous articles identifying a broad range of public concerns including privacy, noise and public disturbance, and the potential misuse of UAS by drug traffickers or terrorists. Such concerns can be as significant as those issues relating to their safety. Further research is needed to characterize the safety criteria for UAS and to better understand different stakeholder concerns, perceptions, and expectations. In the interim, guidance can potentially be found through exploring the safety risk management of other new technologies, such as genetically modified foods, nanotechnologies, stem cell research, nuclear power, and the use of automation in the rail and shipping industries.

92.3 Risk Identification

The objective of the risk identification process is to identify how the system can fail, how these failures and conditions manifest as hazards, and the potential undesired outcomes that can result from the occurrence of the hazards. The identification of a specific combination of these three components describes a risk scenario. The set of all risk scenarios can be defined through the identification of the set of hazards, and for each particular hazard the associated sets describe the following:

1. The different conditions, failures, and events contributing to the occurrence of the particular hazard
2. The potential types and levels of consequential outcomes associated with the occurrence of the particular hazard

The set of all scenarios identified with a given activity is described as the risk profile. By way of general introduction, the high-level UAS and CPA risk profiles are illustrated in Figs. 92.2 and 92.3, respectively. Illustrated in Figs. 92.2 and 92.3 are the primary and secondary hazards and their potential consequential outcomes to people and property. Not shown are the conditions, failures, and events contributing to the occurrence of the hazards. The profiles, and the tools, data, and techniques that can be used to identify and characterize them are described in the following subsections.

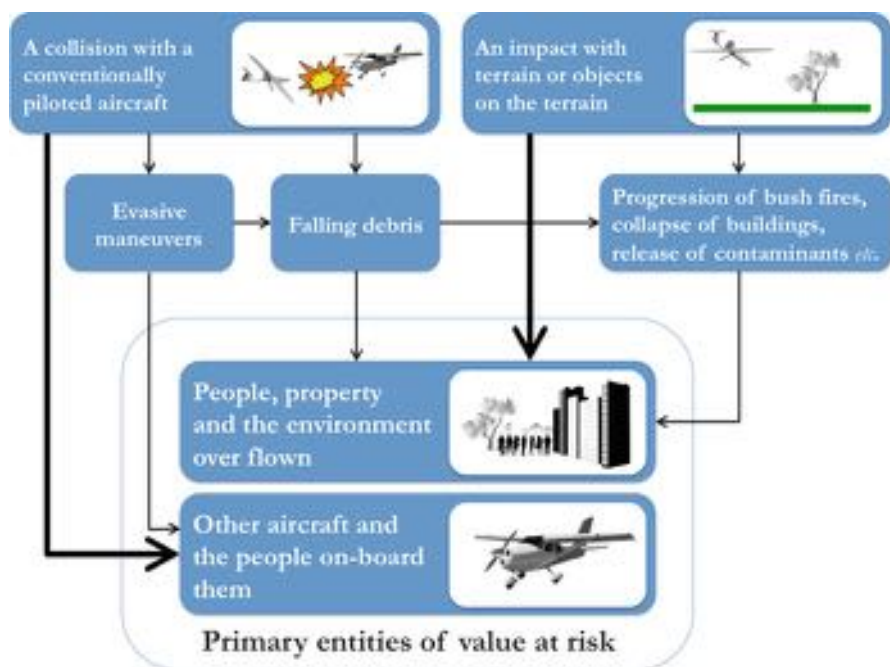

Fig. 92.2 Illustration of the high-level risk profile associated with UAS operations

92.3.1 Risk Identification Tools

A range of techniques can be used to identify and characterize the risk scenarios associated with UAS operations. The CAA categorizes these techniques into historical (e.g., a review of accident and incident data), brainstorming (e.g., elicitation of knowledge from domain experts), and systematic (e.g., formal tools and processes) techniques (CAA 2010b).

A typical starting point for any risk identification process is a review of existing accident and incident data. Such a review can provide general insights into the key hazards and their likely consequential outcomes and, depending on the scope and quality of the investigative reports available, the factors contributing to their occurrence. Some notable examples of UAS accidents and incidents are provided in Table 92.4.

There is limited data on UAS accidents and incidents. The majority of publicly available data relate to military UAS operations primarily because of the limited amount of nonmilitary UAS activity to date (a product of the current regulatory environment) and that mandatory reporting of accidents and incidents involving nonmilitary UAS has only recently come into force (refer to Sect. 92.7.1). Seldom does a review of accident and incident data provide a *comprehensive* identification of the potential hazards and their outcomes. This is particularly the case for UAS,

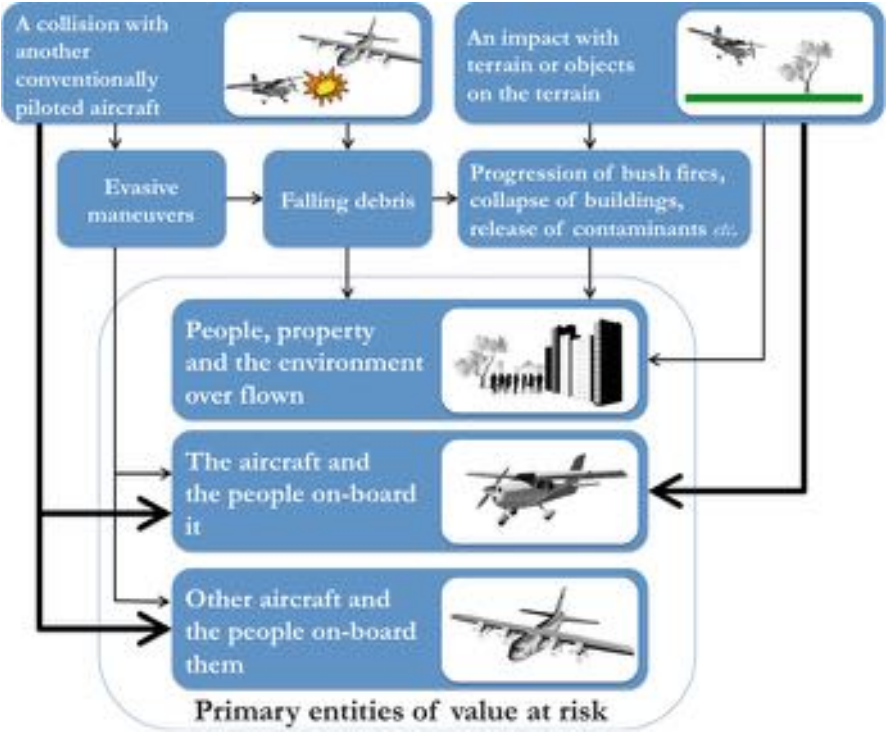

Fig. 92.3 Illustration of the high-level risk profile associated with CPA operations

where there is limited data available and the primary hazards are inherently rare events. Further, the ability to identify the complexity of factors contributing toward the occurrence of an accident or incident is often restricted by the method and quality of the records available. Incidents occur more frequently than accidents. Incidents provide valuable information as precursor or *lead indicators* for accidents; however, less information is typically available in incident reports due to the limited amount of resources available to investigate them. There is also a bias in the data toward military UAS operations, and therefore, when using this data, it is important to consider some of the differences between military and nonmilitary UAS operations. For example, the potential differences:

- Between the design and operational philosophies adopted for military and nonmilitary UAS (e.g., trade-offs made between survivability and mission risk vs. public, and personnel risk)
- Between the environments they are operated in (e.g., natural environment, mix and types of other airspace users, and electromagnetic environment)
- In how they are managed within the airspace system (e.g., procedures for separation, the situational awareness available to air traffic control, the UAS operators and other airspace users, and the type of services provided)

Table 92.4 Notable accidents and incidents involving UAS

| | Date | Location | Description of accident/incident | Reference |
|----|-------------------|--|--|--------------------------------------|
| 1. | May 10, 2012 | Incheon, South Korea | A Schiebel S-100 Camcopter crashed into its ground control station, killing one crew member and injuring two others. The cause for the crash is still being investigated | Mortimer (2012) |
| 2. | Aug 17, 2011 | Afghanistan | RQ-7 Shadow and a C-130J military transport aircraft both operated by the U.S. Department of Defense collided over Afghanistan. The C-130J made an emergency landing. The RQ-7 was destroyed on impact with the ground. No casualties were reported | Hodge (2011) |
| 3. | July 19, 2011 | Karachi, Pakistan | An Uqab UAS operated by the Pakistan Navy encountered bird strike and subsequently crashed in the vicinity of an oil refinery. No casualties or damage to the refinery was reported | Siddiqui (2011) |
| 4. | December 17, 2010 | El Paso, USA | An Aeronautics Orbiter Mini UAS operated by the government of Mexico crossed the U.S. border and crashed in a residential area. No injuries resulted | Washington Valdez and Borunda (2010) |
| 5. | May 10, 2007 | Dili, East Timor | A SkyLark UAS operated by the Australian Defence Force during a peacekeeping mission crashed into a house. The house was unoccupied at the time | Fitzpatrick (2007) |
| 6. | October 05, 2006 | Kinshasa, Democratic Republic of Congo | A Belgian B-Hunter UAS operated as part of the European Union Force peacekeeping mission crashed shortly after takeoff. The crash and ensuing fire killed one civilian and injured at least three others | La Franchi (2006a) |
| 7. | April 25, 2006 | Arizona, USA | A General Atomics Aeronautical Systems MQ-9 Predator UAS crashed near Nogales, Mexico, in the USA while on a U.S. Customs and Border Patrol mission. The aircraft was destroyed on impact with no casualties reported | NTSB (2007) |
| 8. | August 30, 2004 | Afghanistan | A near midair collision between a Luna UAS operated by the German Army and an Ariana Afghan Airlines Airbus A300B4 with over 100 passengers and crew onboard. The two aircraft passed within 50 m of each other. The wake turbulence from the A300B4 caused the Luna UAS to crash. No casualties were reported | La Franchi (2006b) |
| 9. | December 06, 1999 | Edwards Air Force Base, USA | RQ-4A Global Hawk autonomously responded to an erroneous command to taxi at a speed of 155 knots. The aircraft left the taxiway before ground crew could respond. The aircraft sustained substantial damage, but no injuries or damage to other aircraft occurred | AIB (2000) |

(continued)

Table 92.4 (continued)

| | Date | Location | Description of accident/incident | Reference |
|-----|----------------|-----------------|---|----------------------------|
| 10. | March 29, 1999 | China Lake, USA | A RQ-4A Global Hawk received and executed a command to terminate flight. The aircraft was destroyed on impact with the ground, and no casualties were reported. The command was sent by operators conducting radio testing at a neighboring test range. The high altitude of operation of the global hawk was not considered as part of the frequency management plan | Drezner and Leonard (2002) |

- In the nature of the missions performed (e.g., low-level flights, maneuver, and mission profiles)
- In their hazards (e.g., for military UAS, there are unique hazards associated with the carriage of ordinance, self-protection systems, and payload self-destruct mechanisms)

These and many other differences can give rise to unique sets of risk scenarios for military and nonmilitary UAS operations. Although a valuable input to the risk identification process, UAS accident and incident data should not be used as the sole means for risk identification. This data should be complemented by other risk identification techniques to ensure a comprehensive identification of the risks. References (SAE 1996; FAA 2000; FAA and EUROCONTROL 2007) describe a number of tools, and that can be used in the identification and analysis of aviation safety risks. A domain-independent review of over 100 different risk identification and analysis techniques can be found in Stephens et al. (1997). Commonly used risk identification and analysis tools are provided in Table 92.5.

92.3.2 The Identification of Hazards

The specification of a risk scenario starts with the identification of the hazards. A hazard is a state or condition that has the potential to cause loss to something of value. ISO31000:2009 describes the analogous concept of a risk source, defined as an “element which alone or in combination has the intrinsic potential to give rise to risk” (ISO 2009). Prescriptive definitions of hazard can be found in ICAO (2009); DoD (2010a).

92.3.2.1 Primary Hazards of Concern Associated with UAS Operations

A primary hazard is one that has the potential to directly cause harm. Some definitions of primary hazard include the additional condition of *immediately* (Dalamagkidis et al. 2008); however, such definitions preclude primary hazards that have delayed effects or require long-term exposures (e.g., radiation, psychological losses, exposure to carcinogens, or damage to ecosystems). With respect to the operation of UAS in the civil airspace system and over inhabited areas, the primary hazards of concern are well known and common to those for CPA operations. As described

Table 92.5 Some common risk identification and analysis tools

| Description | References |
|---|--|
| <i>Functional hazard analysis</i> is a predictive risk identification technique that attempts to identify and explore the effects of functional failures at different representative levels of a system (aircraft and system levels) | SAE (1996) |
| <i>Failure modes and effects analysis</i> (FMEA) explores how different components and functions can fail (modes) and the potential effects in relation to other components or functions of a system. Failure mode, effects and criticality analysis (FMECA) includes assessments of the likelihood of end consequences | SAE (1996, 2001) and CAA (2010b) |
| <i>Hazard and operability analysis</i> (HAZOP) is a structured and qualitative group brainstorming approach for identifying hazards and their contributing failures | FAA and EURO-CONTROL 2007 and CAA (2010b) |
| <i>Common cause analysis</i> is a technique aimed at identifying risk scenarios in which two or more events could occur as the result of one common event/failure. It combines a number of sub-techniques: zonal analysis, particular risks assessment, and common mode analysis | SAE (1996) and FAA and EURO-CONTROL (2007) |
| <i>Bow-tie analysis</i> primarily used as a risk analysis/modeling tool; a bow-tie analysis combines models (e.g., event tree or fault trees) with consequence modeling tools (e.g., consequence tree) to explore how a particular hazard (the bow) arises and the subsequent manner and types of possible consequential outcomes | FAA and EURO-CONTROL (2007) |
| <i>Event tree analysis</i> used as both a risk identification and an analysis tool; an event tree models sequences of causally related events from an initiating event | CAA (2010b) |
| <i>Fault Tree Analysis</i> is a deductive (top down) graphical risk identification and analysis tool for determining different logic paths in which the top level undesired event could occur | SAE (1996) |
| <i>External events analysis</i> is a risk identification tool focusing on how external/environmental factors/inputs can influence the behavior of the system. It is also useful for the identification of security threats | FAA and EURO-CONTROL (2007) |

in JAA/EUROCONTROL (2004), Clothier and Walker (2006), and Dalamagkidis et al. (2008) and as illustrated in Fig. 92.2 these hazards are the following:

- (A) A collision with a CPA (situated on the ground or in the air) and the potential harm caused to people onboard the CPA (e.g., incident 2 in Table 92.4)
- (B) The controlled or uncontrolled impact with terrain or objects on the terrain (such as people or structures), for example, incidents 5 and 6 in Table 92.4

92.3.2.2 Secondary Hazards of Concern Associated with UAS Operations

Secondary hazards of concern are those that can occur as a result of a primary hazard. Some of the secondary hazards associated with the primary hazard A above, include the potential harm caused to people:

1. On the ground due to falling aircraft or debris from a midair collision (e.g., the falling debris described in incident 2 in Table 92.4)

2. On the ground due to falling aircraft or debris from a near midair collision (e.g., incident 8, Table 92.4, where wake turbulence caused the loss of the UAS)
3. Onboard the CPA due to evasive maneuvers performed in order to avoid a collision with a UAS (while either of the aircraft is in the air or on the ground)

Some of the secondary hazards associated with the primary hazard B above include the potential harm caused to people on the ground due to the following:

1. Release of hazardous materials (e.g., chemical payloads, composite materials, or ordnance) following an impact with terrain or an object on the terrain
2. Progression of fires, the collapse of buildings, motor vehicle accidents, or other hazards arising as a result of the UAS coming to earth (e.g., in incident 3 of Table 92.4 there was the potential for an explosion or fire had the UAS damaged critical components of the oil refinery)

As can be observed in Figs. 92.2 and 92.3, the primary and secondary hazards identified within the UAS risk profile also exist within the CPA risk profile. However, not shown are differences in the failures and conditions contributing to the occurrence of these hazards and in the types and levels of consequence associated with their occurrence.

92.3.3 The Contributing Failures and Conditions

There are a variety of ways in which the hazards illustrated in Fig. 92.2 can eventuate. The specification of a risk scenario includes identifying how a particular hazard can occur. A hazard is typically the result of a series of active failures in combination with latent conditions that involve all components of the system (i.e., the interaction of the components of man, machine, and organization) and the interaction of the system within its operating environment. Some key techniques for identifying these failures and conditions include FMEA, HAZOP, fault tree analysis, human factors studies (discussed below), and anticipatory failure determination.

High-level guidance on common factors contributing to UAS mishaps can be found in studies of existing accident and incident data. For example, some frequent causes of mishaps reported by the U.S. Department of Defense (DoD) are summarized in Table 92.6.

92.3.3.1 Unique Components and Functions

There are some obvious differences in the design and operation of UAS when compared to CPA. For example, a communications link for command and control is a critical component of the safe operation of UAS particularly in the absence of aircraft autonomy (i.e., a remotely piloted aircraft). Other unique components of an UAS include the ground control element, flight termination systems, and devices used in the launch and recovery of the air vehicle. The existence of these components can create unique hazards and contribute toward the occurrence of the

Table 92.6 Percentage of mishaps attributed to different failure mode categories, from OSD (2003)

| Failure mode category | Description | % of total mishaps ^a attributed to category ^b |
|-----------------------|---|---|
| Power/propulsion | Encompasses the engine, fuel supply, transmission, propeller, electrical system, generators, and other related subsystems onboard the aircraft | 37 |
| Flight control | Includes all systems contributing to the aircraft stability and control such as avionics, air data system, servo-actuators, control surfaces/servos, onboard software, navigation, and other related subsystems. Aerodynamic factors are also included in this grouping | 26 |
| Human/ground | Accounts for all failures resulting from human error and maintenance problems with any non-vehicle hardware or software on the ground | 17 |
| Communications | The datalink between the aircraft and the ground | 11 |
| Miscellaneous | Any mission failures not attributable to those previously noted, including airspace issues, operating problems, and other nontechnical factors | 9 |

^aDefined as an accident resulting in significant vehicle damage or total loss of human life, or causing more than \$1,000,000 in damage

^bAveraged over 100,000 flight hours across five different UAS types

primary hazards illustrated in Fig. 92.2. Consideration of such components (and their failures) is not captured in existing CPA risk identification studies.

92.3.3.2 The Importance of a “Systems” Mentality

UAS are more than an aircraft. Consideration of the individual components of the UAS in isolation of the other components of the system and its environment would fail to provide a comprehensive identification of the risks. An emergent property is one which is not determined solely from the properties of the system’s parts but which is additionally determined from the system’s structure and behavior (Thomé 1993). These emergent properties and the boundaries and constraints on them are all potential sources for active failures or latent *accident-producing* conditions. For example, the UAS *system* has the property of line-of-sight (LoS) communication range. LoS range is an emergent property, arising due to the interactions between the system and its environment. Specifically, it is a function of the state of the air vehicle (e.g., antenna attitude), the properties of the communications system (e.g., frequency and minimum permissible signal to noise ratio for a given bit error rate), the ground control system (e.g., geographical position), the mission (e.g., the flight path), and the environment (e.g., weather, terrain, and ambient radio frequency environment). Together, these properties interact to define the maximum LoS range of the system at a given time. Exceeding this range can contribute to the occurrence of a hazard (i.e., a loss of command and control, which for an RPA, could lead to a mishap).

92.3.3.3 The Human Element

Despite the relocation of the pilot, the *human element* still has a significant contribution to the safety of UAS operations. A clear example of this is incident 7 in Table 92.4 (refer to associated accident report). An analysis of U.S. DoD operations recorded over the 10-year period ending in 2003 (Tvaryanas et al. 2005) found that 68.3 % of the 211 mishaps reviewed involved *operations or maintenance organizational, supervisory, or individual human factors*. References (Manning et al. 2004; Williams 2004; McCarley and Wikens 2005; Tvaryanas et al. 2005; Hobbs 2010) provide further analysis and discussion of the contribution of the *human element* to UAS accidents using a variety of modeling frameworks. Common human factors identified in these studies include crew resource management, decision-making, situational awareness, human machine interface design, training, task load, and fatigue. Psychological issues can include the apparent *risk-taking* behavior of UAS operators due to the absence of a *shared fate* between the operator and the UAS; issues of operator trust, awareness, and dependency on automation; issues associated with a handover between remotely located operators; and issues relating to the simultaneous control of multiple UAS. It is important to consider human factors in all aspects of a UAS deployment and not just its launch, operation, and recovery. For example, Hobbs and Stanley (2005) identify the personnel issues of *complacency* and a *model aircraft culture* in the maintenance of UAS; such factors can contribute toward the 8 % of U.S. DoD UAS accidents that were the direct result of maintenance errors (Tvaryanas et al. 2005). For some UAS, much of the maintenance can be performed in the field during an active deployment (e.g., change of payloads, replacement of wings, minor repairs). Maintenance in the field can be subject to additional time pressures (e.g., push for readiness for next deployment), poor working conditions (e.g., exposure to the environment), and the need to make decisions and actions without access to all the necessary information or tools (e.g., arising due to poor logistics and operational planning).

92.3.3.4 The Operation and the Environment

It is important to consider how failures can eventuate through the interaction of the UAS and its operational environment. Many of the hazards arising from the natural environment are common to CPA and are well known, for example, storms and bird strikes (e.g., incident 3 in Table 92.4). However, for UAS, the detection of these conditions can be difficult as the operator is not located onboard the aircraft, and even if it is detected, many UAS do not have the same resilience to them as CPA (e.g., the absence of anti-icing systems or bird strike protection).

A single UAS type can be used for a wide range of applications. The potential failures and conditions need to be investigated for these different operations and environments. For example, the low-altitude operation of UAS in the vicinity of structures creates a number of additional challenges over UAS operations in relatively clear areas. For example, large structures can impede communications, create turbulent environments, and degrade navigation performance through increased multipath and a reduction in the number of visible GPS satellites.

92.3.3.5 Software

Most nonmilitary UAS make use of Commercial-Off-The-Shelf (COTS) consumer-grade software that is often provided without warranty or assurance. Without such assurances, it can be extremely difficult to assess the likelihood of encountering latent errors or undesired behavior. Often, the dependability of software can only be gauged through extensive experience in its use under a variety of conditions. Configuration control is also particularly important for those systems using COTS software. Small bug fixes and *auto updates* to operating systems can introduce new latent conditions and significantly change the stability and behavior of the software system as well as its performance under existing conditions. Software considerations should extend to include any electronic databases (e.g., publicly available digital elevation maps), firmware, operating systems, and applications used during flight or prior to and after flight (e.g., flight planning, software, and documentation control systems). In addressing software-related risks, there are two separate, yet often confused, considerations. Firstly, there are risks associated with the behavior of algorithms and, in the case of UAS, the validity of autonomous behavior. The latter is particularly of concern when the level of autonomy increases (Parasuraman et al. 2000). The second consideration relates to the implementation of the algorithm and is addressed by standards such as DO-178B (RTCA 1992).

92.3.3.6 Security

Security threats are a subcategory of hazards. More specifically, they are hazards that arise, either directly or indirectly, through the intentional disturbance of the safe or normal operational state of the UAS. Most often, these disturbances originate from objects external to the system, which exploit the interfaces between the UAS and its environment (e.g., interference, jamming, or the overriding of control via communications links or physical access to the ground control station (GCS)). The security of the UAS should take into consideration:

- The type of radio control gear, voice, and data links used for communication between all components of the system (including ground personnel and air traffic control)
- Whether the links are vulnerable to intentional or unintentional interference and whether the loss of this link has a safety impact for different phases of the operation
- The type of information conveyed on these links and its criticality to the safety of the operation of the aircraft if corruption, disruption, or spoofing occurs
- Whether the sender or recipient of the information on these links needs to be verified or not (e.g., incident 10 described in Table 92.4)
- The location and physical security of the GCS and any launch, recovery, communications relay, maintenance, and storage sites
- Whether software security, such as firewalls and antivirus programs, is installed and used
- Policies in relation to access to the Internet and the transfer of media via removable storage.

92.3.3.7 The Criticality of Failure Modes

Firstly, flight critical failures are no longer restricted to the aircraft; one must also identify those flight critical failures that exist in the GCS and communications components of the UAS. Secondly, what is considered a catastrophic failure for CPA may not necessarily be catastrophic for a UAS, and vice versa. For CPA, the assignment of criticality to a failure is based on an assumed exposure probability of one (i.e., there is always at least one person onboard; thus, someone is always exposed, see Fig. 92.3). For UAS, the exposure probability is a complex function that depends on where the UAS is operated. In some cases, the exposure probability may approach zero (e.g., those UAS operations restricted to uninhabited areas and in segregated airspace). In such cases, the failure criticality can potentially be assigned to a lower severity category (e.g., major or hazardous), and this assignment should be based on the potential impact of the failure on the ability of the UAS to remain in its predefined operational area. On the other hand, some failures for UAS may have a higher criticality due to the absence of the additional protection provided by a pilot onboard. Thus, adopting existing CPA failure criticality assignments for UAS must be treated with caution.

92.3.4 Assessing the Potential Consequences

The final component of the specification of a risk scenario is the identification of the potential consequential outcomes. Explicitly linked to the concept of hazard are the concepts of loss, harm, or consequence. For example, the definition of hazard provided by ICAO (2009) includes a specification of the types of consequential outcomes to be considered:

Any real or potential condition that can cause injury, illness, or death to personnel; damage to or loss of a system, equipment or property; or damage to the environment. pp. 4–1 (ICAO 2009)

As can be observed in Fig. 92.3, the risks associated with CPA operations include consideration of the potential harm to people onboard the aircraft in addition to those onboard other CPA or on the ground. An analysis of worldwide accidents involving conventionally piloted commercial jet aircraft over the period 2001–2010 reveals that more than 95 % of all fatal injuries were to people onboard an aircraft (Boeing 2011). Therefore, for both of the primary hazards associated with CPA operations, the consequences of principal concern are those to the passengers and crew onboard the aircraft and, secondarily, to the population of people external to the aircraft (e.g., those living in the regions overflowed). For UAS, there are no people onboard the aircraft, and the primary risks are instead to those entities of value considered external to the system. Consequently, the primary types and spectra of consequential outcomes associated with UAS operations are different to those associated with CPA operations.

92.3.4.1 Domains of Consequence

There are a variety of potential consequential outcomes associated with the occurrence of a hazard. For example, MIL-STD-882D (DoD 2010a) defines loss in terms

of damage to people, equipment or property, or the environment. These *types* of loss describe the different domains of consequence. Typically, the primary domain of consequence is that of physical harm to people, with secondary domains being the potential loss registered to equipment and property (inclusive of the air vehicle), the environment, the organization (e.g., financial, reputational, capability, market, or mission losses), clients, the broader industry, and the losses registered to other less tangible values held by society (e.g., culture, trust).

Distinctions are often made between consequences of the same type. For example, the risk management of CPA operations makes a distinction between those operations with fare-paying passengers onboard and those without. Such a distinction is made due to social and psychological factors that influence the general public's perception and acceptance of risk (e.g., the assigned value, dread, fear, control, voluntariness of exposure). For UAS, similar distinctions will need to be made in relation to the primary entities of value at risk on the ground. For example, a distinction is often made between third-party casualties (e.g., a member of the public) and a first-party casualty (e.g., personnel supporting the deployment of the UAS). Similar distinctions are made between damage to property and the damage to hospitals, schools, residential areas, historical or culturally significant sites, etc.

92.3.4.2 The Spectra of Consequences

A qualitative or quantitative spectrum of consequence needs to be defined for each domain of consequence identified. Take, for example, the consequence domain of people. The associated scale of loss could be defined from no injury to multiple fatal injuries. As shown in the studies by Clothier et al. (2010) and Fraser and Donnithorne-Tait (2011), there can be categories of UAS which are unable to cause significant and direct physical harm to other aircraft or people or property on the ground. For these categories of UAS, the losses associated with secondary domains of consequence (e.g., organizational, financial, or environmental) or those losses arising due to the occurrence of secondary hazards (e.g., ensuing bushfires or downstream losses due to damage to critical infrastructure) are likely to be more significant in the evaluation and management of the safety of their operation.

92.3.5 The Set of Scenarios

The outcome of the risk identification process is a set of characterized scenarios. This set is seldom complete as there will always be unknown hazards or failures and conditions that can give rise to existing hazards. It is important that the hazard identification process is periodically reviewed to make use of new knowledge, information, or identification techniques (refer to Sect. 92.7). A hazard log should be maintained to record and track any new scenarios identified during the course of operations and should form a valuable input to any review of the risk assessment. Finally, the endeavor to ensure the set of scenarios is as comprehensive as possible, coupled with the use of conservative assumptions in their

characterization, can lead to the specification of unrealistic scenarios. There are limited resources available to treat the risks associated with the identified scenarios; therefore, it is important that all scenarios be subject to a test of plausibility.

92.4 Risk Analysis

The third step in the SRMP, Fig. 92.1, is an analysis of the risk. Risk analysis describes the process of characterizing the nature and level of the risk for each of the identified risk scenarios. A measure of risk is expressed through the combination of assessments of the consequence and the likelihood of occurrence of the given scenario.

92.4.1 Assessing the Consequence

A qualitative or quantitative table is often used to group and rank the different types and levels of consequence associated with the identified risk scenarios (examples shown in Table 92.7). An assessment of the consequence for a given risk scenario is made by mapping its potential outcomes to one of the consequence levels defined within the table. As there can be more than one consequential outcome associated with the occurrence of a single-risk scenario, a mapping is typically based on the worst possible outcome identified.

Table 92.7 Examples of existing consequence/severity classification schemes

| ICAO SMM (ICAO 2009) | MIL-STD-882D (DoD 2010a) |
|--|--|
| <i>Catastrophic</i> – equipment destroyed; multiple deaths | <i>Catastrophic</i> – could result in one or more of the following: death, permanent total disability, irreversible significant environmental impact, or loss exceeding \$10M |
| <i>Hazardous</i> – a large reduction in safety margins, physical distress, or a workload such that the operators cannot be relied upon to perform their tasks accurately or completely. Serious injury and major equipment damage | <i>Critical</i> – could result in one or more of the following: permanent partial disability, injuries or occupational illness that may result in hospitalization of at least 3 personnel, reversible significant environmental impact, or loss exceeding \$1M but less than \$10M |
| <i>Major</i> – a significant reduction in safety margins, a reduction in the ability of the operators to cope with adverse operating conditions as a result of increase in workload, or as a result of conditions impairing their efficiency. Serious incident and injury to persons | <i>Marginal</i> – could result in one or more of the following: injury or occupational illness resulting in 10 or more lost work days, reversible moderate environmental impact, or loss exceeding \$100K but less than \$1M |
| <i>Minor</i> – Nuisance; operating limitations; use of emergency procedures; minor incident | <i>Negligible</i> – could result in one or more of the following: injury or illness resulting in less than 10 lost work days, minimal environment impact, or loss less than \$100K |
| <i>Negligible</i> – little consequences | |

92.4.2 Likelihood of Occurrence

A range of formal techniques can be used to assess the likelihood of a scenario occurring (e.g., the risk assessment tools described in Table 92.5). Some high-level models characterizing the primary risk scenarios illustrated in Fig. 92.2 have also been proposed, for example (Weibel and Hansman 2004; Clothier et al. 2007; Lum et al. 2011; Lum and Waggoner 2011).

Assessments can draw on a range of information sources including incident and accident data, aircraft activity data, component reliability data, and expert knowledge. Assessment can also use existing models used in other application domains (e.g., space vehicle launch and reentry, motor vehicle accident studies, munitions, debris modeling, generic human injury models, and CPA airspace collision risk models). The output is a qualitative or quantitative assessment of the likelihood of realizing a given risk scenario. Depending on the tools and modeling approach used, this assessment can be used directly in the assessment of the risk or mapped to a likelihood scale or classification scheme (Table 92.8).

92.4.3 Assessing the Risk

A range of qualitative and quantitative scales have been used to describe levels of risk. For example, MIL-STD-882D (DoD 2010a) assesses risk on the qualitative ordinal scale: low, medium, serious, and high. The component measures of consequence (Sect. 92.4.1) and of likelihood (Sect. 92.4.2) then need to be *mapped* to one of these levels of risk. A risk matrix is the most common method for illustrating this mapping, and an example of which is provided in Fig. 92.4. ICAO (2009) also provides an example of a risk matrix.

Table 92.8 Examples of existing likelihood/probability classification schemes

| ICAO SMM (ICAO 2009) | MIL-STD-882D (DoD 2010a) |
|--|--|
| <i>Frequent</i> – likely to occur many times (has occurred frequently) | <i>Frequent</i> – likely to occur often in the life of an item with a probability of occurrence greater than 10^{-1} in that life |
| <i>Probable</i> – likely to occur sometimes (has occurred infrequently) | <i>Probable</i> – will occur several times in the life of an item; with a probability of occurrence less than 10^{-1} but greater than 10^{-2} in that life |
| <i>Remote</i> – unlikely to occur but possible (has occurred rarely) | <i>Occasional</i> – likely to occur sometime in the life of an item; with a probability of occurrence less than 10^2 but greater than 10^3 in that life |
| <i>Improbable</i> – very unlikely to occur (not known to have occurred). | <i>Remote</i> – unlikely but possible to occur in the life of an item; with a probability of occurrence less than 10^3 but greater than 10^6 in that life |
| <i>Extremely improbable</i> – almost inconceivable that the event will occur | <i>Improbable</i> – so unlikely, it can be assumed occurrence may not be experienced in the life of an item; with a probability of occurrence less than 10^6 in that life <i>Eliminated</i> – incapable of occurrence in the life of an item (hazard has been eliminated) |

| | CATASTROPHIC | CRITICAL | MARGINAL | NEGLIGIBLE |
|------------|--------------|----------|----------|------------|
| FREQUENT | HIGH | HIGH | SERIOUS | MEDIUM |
| PROBABLE | HIGH | HIGH | SERIOUS | MEDIUM |
| OCCASIONAL | HIGH | SERIOUS | MEDIUM | LOW |
| REMOTE | SERIOUS | MEDIUM | MEDIUM | LOW |
| IMPROBABLE | MEDIUM | MEDIUM | MEDIUM | LOW |
| ELIMINATED | ELIMINATED | | | |

Fig. 92.4 Example of a risk matrix as per MIL-STD-882D (2010)

92.4.4 Uncertainty

A particular issue in the safety risk management of UAS is managing uncertainty in the risk assessment process. Uncertainty can pervade all stages of the SRMP. Uncertainty influences the level of risk perceived by stakeholders (i.e., the higher the perceived uncertainty the higher the perceived risks) and their preferences for risk treatment (i.e., a preference to treat those risk scenarios with a higher degree of associated uncertainty). Uncertainty arises through a lack of knowledge and information available in the risk assessment process, differences in the level of knowledge held by stakeholders (leading to issues of trust), and a lack of transparency in the SRMP. An effective communication and consultation process (Sect. 92.8) is key to addressing the uncertainty of stakeholders. However, managing the uncertainty in the assessment process is particularly difficult for those UAS that employ COTS equipment with limited or no information on their reliability. A defensible starting position is to attempt to establish the boundaries on the assessment of the risks as opposed to an estimate of the *point value* of the risk. The upper boundary on the risk can be estimated by propagating the assumption that all systems and components *will* fail. An estimate on the lower boundary can be made by adopting a less conservative assumption based on the best available data. As the SRMP is iterative and ongoing, these initial and conservative assumptions can be revised as more experience and data becomes available. An introductory paper on the types of uncertainty and how uncertainty pervades the SRMP can be found in Zio and Pedroni (2012).

92.5 Risk Evaluation

Risk evaluation is the process of comparing the results of the risk analysis with the HLSC to determine whether the risk for a given scenario is tolerable (ISO 2009) or whether further measures need to be undertaken to reduce the risk. There are a range of decision-making frameworks that can be used within the risk evaluation process; these include the as low as reasonably achievable, *globalement au moins Équivalent*, or minimum endogenous mortality frameworks used in the Netherlands, France, and Germany, respectively. Discussion in this chapter is limited to the as low

as Reasonably practicable (ALARP) evaluation framework, which is advocated by ICAO (2009) and has been widely used in the management of a broad range of risks in the UK, the USA, and Australia.

92.5.1 The ALARP Framework

The ALARP framework is intended to represent safety decisions made in everyday life (HSE 1992, 2001b). There are some risks that people choose to ignore and others that they are not prepared to entertain irrespective of the benefits associated with them. In addition, there are those risks people are prepared to take by making a trade-off between the benefits of taking the risks and the precautions required to mitigate them (HSE 2001b). These three types of decision scenarios are the basis for the development of the ALARP framework. Referring to Fig. 92.5, the ALARP framework comprises

A Region of Broadly Unacceptable Risk – Except under extenuating circumstances, risks that fall within this region are generally considered unjustified regardless of the benefits associated with the activity. Such activities would be ruled

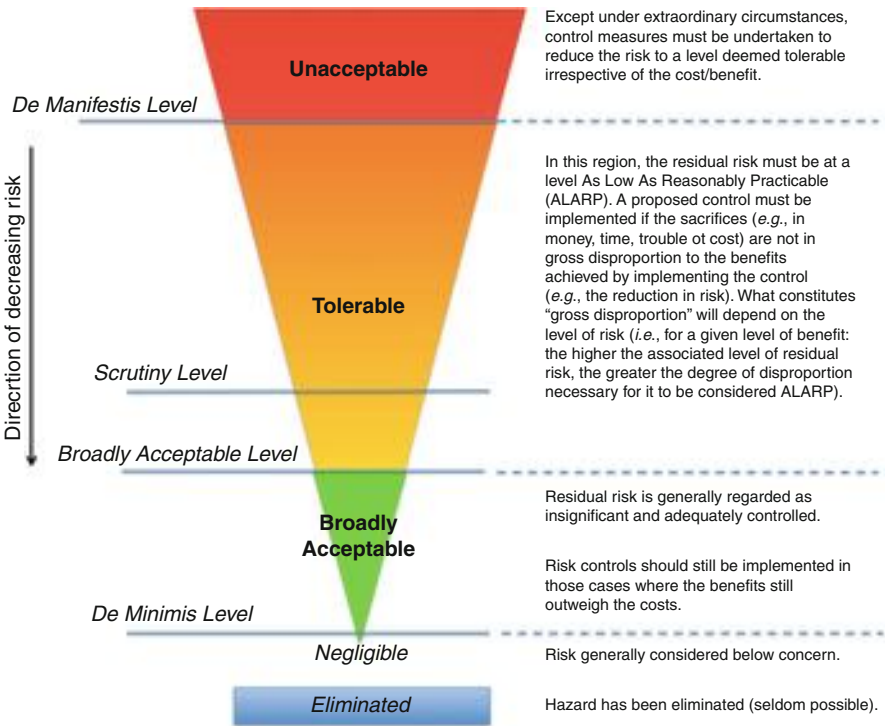

Fig. 92.5 The ALARP risk evaluation framework

out unless further action can be undertaken to reduce the risk (HSE 2001b). This region corresponds with the notion of a *de manifestis* level of risk, which is based on the legal definition of *obvious risk* (RCC 2007). It is defined as the level of risk above which a person of ordinary level of intelligence intuitively recognizes as being inherently unacceptable (Fulton 2002; RCC 2007).

A Region of Tolerability – This region describes those risks which are considered *tolerable*, specifically those situations where there is “...a willingness to live with a risk so as to secure certain benefits and in the confidence that it is being properly controlled. To tolerate a risk means that we do not regard it as negligible or something we might ignore, but rather as something we need to keep under review and reduce still further if and as we can” (HSE 1992). As described in HSE (2001b), risks that fall in the region are considered tolerable if and only if the:

- Risks have been properly assessed (e.g., assessments based on the best available scientific evidence or advice), and the results are used to determine appropriate measures to control the risks.
- Residual risks are not unduly high (e.g., above the *de manifestis* level) and are kept to level as ALARP.
- Risks are periodically reviewed.

A Region of Broadly Acceptable Risk – Risks within this region are “generally regarded as insignificant and adequately controlled” (HSE 2001b). There is no distinct *line* demarcating tolerable risks from broadly acceptable risks; instead, it has been described as the point at which “the risk becomes truly negligible in comparison with other risks that the individual or society runs” (HSE 1992). Obtaining a broadly acceptable level does not mean the pursuit for the reduction of risks to ALARP should be abandoned. As described by the UK Health and Safety Executive (HSE), “duty holders must reduce risks wherever it is reasonably practicable to do so or where the law so requires it” (HSE 2001b).

The Concept of ALARP – A risk is considered ALARP if the cost of any reduction in that risk is in gross disproportion to the benefit obtained from the reduction. Determining that risks have been reduced to a level as ALARP involves an assessment of the risk to be avoided, of the sacrifice or costs (e.g., in money, time, and trouble) involved in taking measures to treat that risk, and a comparison of the two to see if there exists a gross disproportion (HSE 2001a). General discussion on the cost-benefit process that needs to be undertaken and some guidance on the meaning of gross disproportion can be found in references (HSE 2001b,a; CASA 2010; Jones-Lee and Aven 2011).

De Minimis Level – Some specifications of the ALARP framework include a specification of the *de minimis* level of risk. The *de minimis* level stems from the legal principle *de minimis non curat lex* (the law does not concern itself with trifles) (Paté-Cornell 1994; Fulton 2002; RCC 2007). It is often used as a guide for determining when risks have been managed to a level that could be considered below concern.

A Scrutiny Level – Some implementations of the ALARP framework feature a scrutiny line, which is often used to put newly assessed risks in context with risks

that have been tolerated or broadly accepted in the past. Often, the scrutiny level represents the *de facto* risks for a similar activity/industry.

It is important to note that the meaning of ALARP and its implementation in law can change between states (an important consideration when it comes to the risk management of international UAS operations). The description of ALARP provided above is consistent with its implementation in those countries that adopt *common law* (e.g., the UK, the USA, Australia, Canada, New Zealand). Ale (2005) provides an example of some of the issues that can arise due to the application of safety decision-making frameworks such as ALARP within different legal systems.

There are psychological, social, and practical difficulties in the specification and sole use of quantifiable criteria within the ALARP framework. This has led to the use of qualitative frameworks that focus on demonstrating that all *reasonably practicable* measures have been undertaken to reduce a risk as opposed to making quantifiable comparisons of the assessed risks to specifications of the *de manifestis*, *de minimis*, or scrutiny levels. The results from comparisons of assessed risks to HLSC ultimately translate to requirements on design; hence, a quantifiable specification of HLSC within the ALARP framework is most desirable. When introducing a new technology into society one cannot avoid the commonly used *litmus test* of a comparison to similar and existing risks (as often made by the media or by members of the public). In this case, the ELoS HLSC (as described in Sect. 92.2.5) should be represented as scrutiny lines within the ALARP framework. Further research is needed to explore the psychological, social, and practical implications relating to the representation of the quantitative HLSC for UAS in the ALARP framework. There can also be general issues associated with the application of ALARP specifically to new technologies such as UAS, and these are discussed in Melchers (2001).

92.5.2 Evaluating the Risk

The ALARP framework is represented in a risk matrix by assigning the levels of risk, and hence cells of the matrix, to the different regions of the ALARP framework. This assignment is often illustrated through the use of a graduated color scale (e.g., refer to the corresponding colors used in Figs. 92.4 and 92.5). Refer to Figs. 5–4 and 5–5, pp. 5–8/9 of ICAO (2009) for another example of a representation of the ALARP framework within a risk matrix. Each risk scenario can then be mapped to one of the regions within the ALARP framework. Whether or not a particular scenario requires treatment will depend on the ALARP region it is mapped to (as described in Sect. 92.5.1).

92.6 Risk Treatment

For those risk scenarios that are not tolerable, measures need to be undertaken to reduce (mitigate, modify, treat, or control) the residual risk to a level considered as ALARP.

92.6.1 Prioritization of Treatment

The scenarios requiring treatment need to be prioritized due to a practical limit on the resources available to treat the risks. This prioritization is usually based on the level of unmitigated risk, with those scenarios having a higher level of risk given a higher priority for treatment. However, there are other factors that can influence the prioritization of scenarios, for example, the prioritization of scenarios:

- Based on the nature of their associated consequences. For example, the apparent public aversion to accidents with a higher-level consequence, psychological factors (e.g., fear or dread), or those scenarios that have prolonged or sustained consequences
- With a high level of uncertainty.

It is important to note that the treatment of some scenarios may be mandatory irrespective of their risks (e.g., due to environmental protection or workplace health and safety regulations).

92.6.2 Determining Available Mitigation Options

The first step is to determine a list of all possible treatment options. Guidance on potential mitigation strategies can be found in regulatory materials (CASA 2002; FAA 2011b) or by reviewing the safety cases used in the approval of existing operations. In general, risk mitigation strategies reduce the risk through the following:

- A. Removing the hazard altogether
- B. Reducing the likelihood that a hazardous event occurs
- C. Reducing the level of potential consequence associated with the occurrence of an hazardous event
- D. Sharing the retained risk with other organizations
- E. Combinations of the above

92.6.2.1 Risk Mitigation Strategies for Midair Collision

A range of strategies can be used to mitigate the risks associated with the hazard of a midair collision between a UAS and a CPA. Some example strategies are summarized in Table 92.9. The strategies in Table 92.9 are classified based on how the primary reduction in risk is achieved, specifically (1) through elimination of the hazard, (2) through a reduction in the likelihood the hazard occurs, or (3) through a reduction in the consequence given the occurrence of the hazard. Category 2 mitigation strategies are divided into the subcategories of the following:

- A. *See* – strategies that provide the UAS with an awareness of its air traffic environment
- B. *Be seen* – strategies that provide other airspace users with an awareness of the UAS
- C. *Staying away* – UAS operational strategies that reduce the likelihood of encountering other aircraft

Table 92.9 Examples of existing midair collision mitigation strategies

| | | |
|--|---|--|
| (1) <i>Elimination of the hazard</i> | Segregation of UAS from other aircraft (e.g., use of prohibited or restricted airspace); not conducting the operation | |
| (2) <i>Reduction in the likelihood of a hazard occurring</i> | (i) <i>Active</i> | (ii) <i>Passive</i> |
| (A) <i>See</i> | Periodic radio broadcasts; airborne or ground-based systems that employ primary radar (e.g., Fig. 92.6), transponder interrogators, or LIDAR sensors; existing airborne collision avoidance systems (e.g., TCAS-II) | Chase plane; radio listening watch; airborne or ground-based systems that employ electro-optical (Fig. 92.7), infrared, or acoustic sensors; automatic dependent surveillance-broadcast (ADS-B) in; ground-based visual observers; subscription to traffic information feeds |
| (B) <i>Be seen</i> | ADS-B out; transponders; existing ACAS (e.g., TCAS-II) inter-aircraft communication systems (e.g., VHF – Data Link); anticollision strobe lights (Fig. 92.8) | Chase plane; high-visibility paint (Fig. 92.8); establishment and activation of warning or danger areas |
| (C) <i>Staying away</i> | Flying in airspace of known low aircraft activity, over the oceans, above or below international en route airspace; at night, below the CPA minimum safe altitude, outside peak CPA traffic times | |
| (D) <i>Services</i> | Utilization of third-party air traffic services; flying in controlled airspace | |
| (E) <i>Strategic</i> | Survey and crew familiarization with airspace operating environment; crew training in procedures; general awareness (briefing local airspace user groups) | |
| (3) <i>Reduction of the level of potential consequences</i> | Established procedures for responding to an emergency; frangible aircraft; not flying in areas where there are aircraft with a high consequence value (e.g., commercial passenger aircraft) | |

- D. *Services* – third-party air traffic separation services that provide situational awareness and separation management services to the UAS and/or other air traffic
- E. *Strategic* – ongoing strategies that improve the effectiveness or proficiency of the UAS crew in managing the risk of midair collisions or build a general awareness of UAS operations

The subcategories of A and B comprise technological and operational strategies that help to provide an *alerted see-and-avoid* environment and can be further

categorized based on whether the additional situational awareness is achieved through active transmission or not. Some mitigation strategies can be assigned to more than one category, and it is important to note that some of the proposed mitigation technologies are concepts still under development; their suitability as effective mitigation strategies has yet to be determined.

92.6.2.2 Risk Mitigation Strategies for an Impact with Terrain

A range of strategies can be used to mitigate the risks associated with the hazard of a controlled or uncontrolled impact with terrain or objects on the terrain. Some example strategies are summarized in Table 92.10. The example approaches summarized in Table 92.10 are classified based on whether the reduction in risk is achieved through (1) the elimination of the hazard, (2) a reduction in the likelihood the hazard occurs, or (3) a reduction in the consequence given the occurrence of the hazard. Category 2 mitigation strategies are further divided into the subcategories of operational, technological, and strategic. The strategies summarized in Table 92.10 are in addition to those that improve the airworthiness of the system (e.g., the adoption of sound engineering design practices, fault-tolerant design principles, the certification of software to high levels of assurance, the implementation of quality control in manufacturing processes, increasing the depth and frequency of preventative maintenance cycles, completion of pre-flight checks, and procedures and policies for crew management, training and licensing).

92.6.3 The Selection of Mitigation Strategies

ICAO (2009) evaluates mitigation strategies on the basis of their effectiveness (in terms of risk reduction), associated costs and benefits, practicality, whether they create new problems (e.g., introduce new risks), and other factors such as whether they stand up to scrutiny, the acceptability to other stakeholders, whether they are enforceable or durable, and whether the residual risks can be further reduced.

Table 92.10 Example strategies for mitigating the risks of a controlled or uncontrolled impact with terrain or objects on the terrain

| | | |
|--|----------------------|---|
| <i>(1) Elimination of the hazard</i> | | Not conducting the operation |
| <i>(2) Reduction in the likelihood of a hazard occurring</i> | <i>Operational</i> | Isolating UAS operations to designated and controlled ranges where there are no people or property exposed; minimizing/avoiding the overflight of people and property, or limiting operations to areas of low population density; operating over the oceans and away from known fishing areas or shipping lanes; establishing designated recovery or ditching points; flying at night when people are more likely to be sheltered; ability to operate under more than one mode of operation (e.g., autonomous or manual remote operation) |
| | <i>Technological</i> | Automated recovery systems capable of flying to preprogrammed recovery sites; emergency forced landing systems (e.g., Mejias et al. 2009); failure warning systems (e.g., icing or fuel warnings, breach of operational boundaries); controlled ditching in preprogrammed areas; containment systems (e.g., automated <i>fencing</i> , parachute, ditching, or explosive termination systems) |
| | <i>Strategic</i> | survey and crew familiarization with operating environment; crew training in failure and emergency procedures; general awareness (briefing local population) |
| <i>(3) Reduction of the level of potential consequences</i> | | Sheltering of people or assets; frangible aircraft; energy dissipating flight profiles (manual or pre-programmed); air bags; parachute systems; avoiding areas with the potential for consequences of <i>high value</i> (e.g., areas with hospitals, schools, or areas of high population density); personal protective equipment (e.g., helmet and eye protection – for micro/small UAS operations); established emergency procedures; emergency response equipment (e.g., first aid, environmental spill kits, fire fighting, and personnel protective equipment for post accident cleanup) |

92.6.3.1 Effectiveness and the General Hierarchy of Mitigation Strategies

The effectiveness of a mitigation strategy is measured in terms of the magnitude of the reduction in risk achieved. The most effective strategy is to eliminate the hazard, followed by those strategies that reduce the severity of the hazard or the likelihood of its occurrence. The third most effective strategies are those that employ engineering controls preventing the mishap from occurring, followed by warning devices, and procedures and training (DoD 2010a).

Effectiveness of Midair Collision Avoidance Mitigation Strategies

The most effective strategy is to segregate UAS from other airspace users; however, due to issues of practicality and cost, this is not always a viable treatment option. Those safety cases that are primarily based on the situational awareness of other airspace users (e.g., *be seen*, Table 92.9) or strategies that reduce the level of consequence given the occurrence of a mishap are the least effective and, on their

own, are not likely to provide an acceptable safety case. Reducing exposure (e.g., *staying away*, Table 92.9) in combination with other *see* and *be seen* mitigation strategies is likely to provide the most effective approach for managing the risk of a midair collision. In assessing the effectiveness of the different strategies, consideration should be given to the following:

- Types of airspace users that are likely to be encountered and their:
 - Resilience to damage due to a collision with the particular type of UAS (e.g., bird strike protection of transport category aircraft)
 - *Observability* to the different sensing or awareness approaches that could be used (e.g., radar cross-sectional area)
 - Equipage (e.g., whether they have radios or transponders onboard)
 - Ability to detect the UAS
 - Ability to maneuver
 - Typical operating speeds (e.g., determination of closing speeds and time to react)
 - Conditions of right of way
- Operating conditions (e.g., instrument meteorological conditions vs. visual meteorological conditions) or the operational profile flown (e.g., variation in radar clutter performance with altitude)
- Geographical volumes over which protection or awareness needs to be provided
- Temporal changes (e.g., use of strobes during the day vs. at night) and the duration of activity (e.g., effectiveness of ground observers for extended missions)

Effectiveness of Mitigation Strategies for Managing the Risks to People and Property on the Ground

The most effective mitigation strategies for mitigating the risks to people and property on the ground are those that reduce the following:

- Probability of a flight critical failure or human error occurring (e.g., through fault-tolerant design, maintenance, crew resource management, and training)
- Exposure of people and property to the hazard. Specifically the *operational* mitigations in Table 92.10 that restrict UAS operations to uninhabited areas or avoid/minimize the overflight of densely populated regions, critical infrastructure or culturally sensitive sites

Automated emergency flight termination systems and recovery systems are effective but not for all failure modes (e.g., typically only those for failure modes where there is still a degree of control over the flight path of the UA). Least effective are those strategies that rely solely on the general public being sheltered, wearing personal protective equipment, or emergency equipment and procedures employed following a mishap.

Effectiveness of CPA Mitigations

It is important to note that a risk control strategy that is effective for CPA may not be effective for UAS. For example, a number of studies have been conducted to evaluate the effectiveness of ACAS as a means for self-separation, collision

avoidance, or situational awareness for UAS (FAA 2011a). These studies identified a number of technical and operational issues, which have a significant impact on the effectiveness of ACAS as a midair collision avoidance system for UAS.

Evaluating Layers of Mitigations

Seldom will a single mitigation strategy be sufficient for a risk to be considered tolerable. In evaluating the cumulative effectiveness of multiple mitigation strategies, it is important to consider the potential for one strategy to degrade the effectiveness of another, thus forcing a reevaluation of the residual risks. The selection of strategies should ensure coverage of the complete spectrum of risk scenarios (e.g., implementing strategies that are only effective under visual meteorological conditions) and how the mitigation strategies, in isolation and in combination, can be overcome or can fail. The selection of strategies should try to ensure that these failure modes are not common to all of the strategies adopted.

92.6.3.2 Practicality

The practicable feasibility of mitigation strategies needs to be considered in relation to the physical and performance limitations of the system. For example, there are fundamental limits in relation to the maximum takeoff weight, payload volume, and power available to support mitigation systems onboard an unmanned aircraft. Similarly, there are fundamental limits in relation to the maneuverability, speed, range, endurance, glide performance, or ceiling of the UAS.

92.6.3.3 The Costs and Benefits Associated with Treatment Options

Costs should be considered in relation to a broad range of stakeholder groups (e.g., existing airspace users, air service providers, NAAs, the UAS industry, and ultimately, the general public) and include the indirect costs beyond those immediately associated with the occurrence of an accident (e.g., beyond the compensation for loss of life, the damage to property, and fines). Take for example, the mitigation strategies of (a) the use of redundant flight critical systems and (b) the equipage of a collision avoidance system. These mitigation options can result in increased:

- *Platform costs* due to the direct added cost of the collision avoidance system or the use of duplicate subsystems and the increased costs incurred in the engineering design, manufacture, and quality control processes
- *Operational costs* due to additional personnel training (e.g., in the operation of the collision avoidance system)
- *Through-life costs* due to additional maintenance
- *Mission costs* due to reductions in the following:
 - Performance of the system (e.g., the extra weight and drag and its impact on endurance, range, speed, or ceiling)
 - Ability for the UAS to support payloads (e.g., less weight, volume, and power available for payloads)
 - Subsequent ability of the UAS to meet mission objectives

- *Market cost* due to a reduction in the number of serviceable clients
- *Reduction in benefits* with respect to foregone downstream benefits to end users and the broader society

As well as costs, there can be indirect benefits associated with the implementation of mitigation strategies. For example, improving the overall reliability of the UAS can lead to the benefits of a lower platform attrition rate, a reduction in insurance premiums, an increase in availability, and an increase in customer trust and in turn repeat business. These costs and benefits, along with the direct benefit of a reduction in the risks, need to be factored into the determination of ALARP.

92.6.3.4 Other Factors

Mitigation strategies for UAS should be assessed to determine whether they introduce new risks and whether these introduced risks warrant treatment or whether they outweigh the benefits of the employing the mitigation strategy altogether (e.g., explosive flight termination systems). The selection of mitigation options can also be guided by secondary objectives, values, and constraints held by different stakeholder groups. For example, the FAA (2011b) explicitly preclude treatment options that reduce the operational freedoms of other airspace users (e.g., the designation of airspace specifically for use by UAS). Another example is the military preference for passive midair collision avoidance systems due to the requirement to reduce the observability of military UAS operations. External constraints can include applicable standards and regulations (e.g., existing aviation safety, environmental protection, or occupational health and safety regulations) or constraints imposed by insurance providers.

92.6.4 Summary

The selection of mitigation options for UAS is a complex decision-making process. Mitigation options must be evaluated in terms of their effectiveness, costs, benefits, practicalities, and other factors to determine whether their implementation is reasonably practicable or not. This decision process is guided by the ratio of the costs and benefits associated with pursuing the different options for mitigation. A risk is considered ALARP if this ratio is in *gross disproportion*, a concept which is subjective and variable. Finally, a determination of ALARP does not make a risk tolerable. For every scenario, a decision must be made by the organization as to whether it is willing to retain the residual risk in return for the benefits of the operation. Authorization should be obtained at two stages in the treatment process: (1) at the point of approving the selection of mitigation strategies and the decision to retain residual risks and (2) to verify that strategies have been implemented as described. Typically, the delegation of authority is dependent on the level of residual risk that is being retained.

Currently, operational mitigation strategies (e.g., restrictions on the flight of UAS over populous areas) are central to obtaining operational approvals. Miti-

gation technologies like sense-and-avoid and automated emergency landing systems, are currently under development and showing much promise. These mitigation technologies will reduce the need for restrictions on UAS operations and will be key to the uptake of UAS in a greater number of civil applications. These technologies also have the potential to greatly improve the safety of CPA operations.

92.7 Monitor and Review

Risk is dynamic. Key to maintaining and improving the SRMP is a process to monitor and review the SRMP in response to changes in the risk. Risks evolve with changes in the organization, technology, and operations performed and in the natural, social, regulatory, and political environments. Further, there can be opportunities to improve the safety risk management of existing activities if new information, assessment tools, or treatment options become available.

92.7.1 The Importance of Accident and Incident Recording

One of the primary triggers for an ad hoc review of the safety risk management of an activity is the occurrence of an accident or incident. Accident and incident data are a valuable source of information that can be used to identify new risk scenarios and update risk assessments. Most importantly, an analysis of accidents and incidents provides organizations with the opportunity to evaluate the effectiveness of their mitigation strategies and to put in place new measures to further reduce the risks.

The definition of accidents and incidents and the conditions for their reporting depend on the particular state in which the accident occurs. The National Transportation Safety Board (NTSB) in the USA defines an unmanned aircraft accident as the following:

“an occurrence associated with the operation of any public or civil unmanned aircraft system that takes place between the time that the system is activated with the purpose of flight and the time that the system is deactivated at the conclusion of its mission, in which: (1) Any person suffers death or serious injury; or (2) The aircraft has a maximum gross take-off weight of 300 pounds or greater and sustains substantial damage.” p. 600, 49 CFR §830.2 (GPO 2010)

Mandatory reporting of accidents involving UAS in the USA only formally came into force in October 2010 [amendments to title 49 CFR 830 (GPO 2010)]. FAA accident and incident reporting requirements were in force prior to this date and were mandated under the conditions of a certificate of waiver or authorization (FAA 2011b). Annex 13 to the Chicago Convention was amended in November 2010 to include the investigation of accidents and serious incidents involving international civil UAS operations but only for those UAS with design and/or operational approval (ICAO 2011).

92.7.2 Triggers for Review

The occurrence of an accident or incident as a trigger for a review is a reactive approach to safety management. A proactive strategy does not wait for an accident or incident to occur in order to trigger a review of the SRMP. Reviews can be periodic or triggered by certain conditions (e.g., a change in operations, operating environment, regulations, applications, operational types, business activity). Identified risks need to be continually reviewed to ensure that the level of risk has not changed, that mitigations are still effective, that stakeholder expectations are still being satisfied, to determine if new options for risk mitigation are available, or to determine whether there is new information or tools available that can be used to improve the assessment of the risks. Reporting mechanisms should be established that allow the organization to identify and track emerging risks.

92.7.3 Tracking Safety Performance

Measuring and tracking the safety performance of an activity or organization is part of the overarching SMS or SPP established by the organization or NAA, respectively. In most cases, accidents are extremely rare events, and hence, a proactive safety performance management strategy is needed. Such a strategy attempts to estimate the safety performance through the use of a variety of safety performance indicators or measures of lead indicator events (e.g., recording and tracking the number of breaches in policies or procedures, issues detected as part of the preflight inspection of an aircraft, as opposed to counts of accidents).

92.8 Communication and Consultation

The risk communication and consultation process is described as the “continual and iterative processes that an organization conducts to provide, share or obtain information and to engage in dialogue with stakeholders regarding the management of risk” (ISO 2009). Communication and consultation is key to avoiding potential conflict in the safety decision-making process, for ensuring that stakeholder concerns are being addressed, and for reducing uncertainty in the decisions and outcomes. This process is undertaken at all stages of the SRMP. Key to addressing issues of trust and uncertainty is ensuring transparency in the SRMP to the different stakeholders. Both the outcomes from the SRMP and the SRMP itself need to be communicated to stakeholders. It is also important to note that the different stakeholders will have different information needs. The right information needs to be communicated to the right stakeholder and in a method and manner that is acceptable and comprehensible to them. Finally, communication and consultation is a bidirectional process. Eliciting domain knowledge from stakeholders can

significantly improve the SRMP by reducing uncertainty and ensuring a more comprehensive management of the risks. Expert domain knowledge can be used at all stages in the SRMP (i.e., risk identification, analysis, evaluation, and treatment).

92.9 Conclusion

This chapter has highlighted many of the unique issues and challenges associated with the application of the safety risk management process to UAS. These issues and challenges can be technical, operational, economic, political, and social in nature and can influence all facets of the safety risk management process. Some sections of this chapter pose more questions than they do answers, highlighting that there is still much to be learned. The area of greatest need is in developing an understanding of the broader perceptions, beliefs, and expectations of society and how these factors influence decisions in relation to the safety of UAS operations. The challenges and issues discussed in this chapter are, in general, not unique to UAS. Challenges of a similar nature will need to be addressed in the safety risk management of other emerging aviation sectors such as reusable space launch vehicles, personal air vehicles, and hypersonic aircraft. It is hoped that the general processes developed and the lessons learned in the safety risk management of UAS will help to pave the way for these and other emerging and highly beneficial aviation sectors.

While this chapter has highlighted many issues, it is important to note that UAS are being safely operated in civil airspace today. In Australia, an approval to operate is obtained through the presentation of a suitable safety case to CASA, a safety case underpinned by a safety risk management process. Addressing the issues identified in this chapter will be pivotal to reducing the uncertainty in these safety cases, for ensuring consistency in the regulation of the industry, and for supporting the definition of more prescriptive safety regulations.

Acknowledgments The authors would like to thank Dr Neale Fulton, adjunct professor at Queensland University of Technology, Mr. Brendan Williams and Dr Michael Wilson from Boeing Research & Technology, Australia, Mr. Jim Coyne and Mr. Phil Presgrave from the Civil Aviation Safety Authority, and Mr. Kim Jones for their valuable comments and additions to this chapter.

Abstract

This chapter described the certification of (small) unmanned aircraft systems (UAS). It focuses on the certification process, the requirements for the safe design of a UAS, and the organizational requirements for the company designing the UAS.

R. van de Leijgraaf

Civil Aviation Authorities – The Netherlands, Airworthiness Inspectorate, Hoofddorp,
The Netherlands

93.1 Introduction

Aviation authorities worldwide consider an unmanned aircraft (UA) an aircraft as defined by the International Civil Aviation Organization (ICAO). Since these authorities all have signed the ICAO convention, the fundamental standards and recommended practices for the integration of UAS into the airspace will be developed by ICAO. When considering the certification of small UAS, the standards are given in Annex 8 (Airworthiness) of the ICAO Chicago Convention.

ICAO has acknowledged the rapid growing market for UAS and has established in 2008 a study group to address this issue. At the moment, this UAS study group is evaluating all ICAO annexes and is preparing recommended changes to these annexes to accommodate UAS in the ICAO standards. The study group published ICAO UAS Circular 328 on unmanned aircraft systems (UAS), providing guiding information on how UAS can be introduced in the ICAO annexes to facilitate a safe introduction of UAS in the airspace worldwide. As a next step, the study group is developing detailed proposals for changes to the annexes. These changes will be written as guidance material to possible changes in the annexes. This will result in the ICAO UAS Manual, which is planned to be presented at an ICAO UAS Conference in fall 2014.

When the manual is published, it will be up to the various ICAO panels to develop the adaptations to the annexes, based on the guidance material provided by the study group. Experts from the UAS study group will most likely be involved in the work to be performed by the panels.

Autonomous UAS are not considered at the moment by ICAO in the update of the annexes. Only UAS where the remote pilot is capable of interfering with the flight path of the aircraft are considered in the ICAO Circular. Such a system, considered a subset of UAS, is defined as remotely piloted aircraft system (RPAS) by ICAO. In this chapter, the official ICAO terms and definitions, as given in Circular 328, will be used.

This chapter will only focus on the initial airworthiness of the RPAS, i.e., the certification. Continuing airworthiness, which is equally part of airworthiness, will be touched upon lightly and only in relation to the initial certification. Furthermore, this chapter will not address the issues of safety oversight of the whole airworthiness process by the national aviation authorities. When examples of the current aircraft certification practice are given, they will be primarily given in the European context. The same examples are equally valid for the American practice, the only difference is the terminology used by the European Aviation Safety Agency (EASA) and the U.S. Federal Aviation Authority (FAA).

Although ICAO is only responsible for the standards and recommended practices for international operations and operations over the high seas, its standards are usually adopted by states for their national aviation regulations. Therefore, the process and safety standards described in this chapter are applicable to international and national operations of RPAS.

93.2 Aeronautical Products

The whole concept of airworthiness is primarily aimed at developing a safe aircraft to allow safe flight operations. One would expect the topic of airworthiness only dealing with the aircraft, but within Annex 8, ICAO currently recognizes three products that need to have an airworthiness approval:

1. Aircraft
2. Engines
3. Propellers

Each product can go through the certification process as described in the next paragraph and have its design approved. When the design approval is granted, the product will have a type certificate (TC). By themselves the engine and propeller will of course not be able to fly, they still need to be integrated with the aircraft. The advantage of evaluating the engines and the propellers separate from the aircraft design is twofold:

First, it allows the manufacturer of the engines or propellers to design products that can be used on more than one aircraft design (General Electric engines that can be installed on both Airbus and Boeing aircraft, for instance).

Second, it allows the aircraft designer to be involved only with the certification of the integration of the engine and/or propeller into his aircraft, not with the actual certification of the engine or propeller itself. This seriously reduces the effort needed by the aircraft designer to go through the certification process with the aircraft design.

When studying the impact of the introduction of RPAS to the ICAO annexes, in preparation for the ICAO UAS Circular, the UAS study group concluded that the remote pilot station (RPS) should be treated as a new aeronautical product within Annex 8. Therefore, the study group will be proposing to introduce the remote pilot station (RPS) as an additional airworthiness product within Annex 8. This will allow manufacturers of RPS optimal flexibility in developing and providing their product for various RPAS designers. It will also more easily allow for the use of multiple RPS during one specific flight with an RPAS. Think about the possible operation of a long-haul flight with an RPAS and a cruise pilot using satellite communication during the cruise phase with one specific RPS and harbor pilot(s) using a different RPS and direct radio communication during take-off and landing. For small UAS, this operational concept of using multiple RPS during a flight will not be very likely. In that case, the RPS could be certificated as part of the RPAS directly, not through a separate design approval.

93.3 Certification Process

As defined in Annex 8 of the ICAO Convention, an aircraft can only be certificated by the aviation authorities of the country where the principle place of business of

the designer of the aircraft is located. In ICAO terms, the country performing the certification is the state of design. Other national aviation authorities can either fully accept the certification by the state of design, or they can do an additional investigation into the safe design of the aircraft. This additional investigation is called a “validation.” Countries that can act as a state of design usually have bilateral agreements with other countries about the certification and validation process and acceptance of certificates. In general, authorities avoid duplicating tests, so when a validation process is performed, this process focuses on the known differences in safety requirements between the state of design and the validating authority. In Europe, a regional safety oversight organization (RSOO) has been created, which has taken over most of the aviation safety responsibilities from the participating European countries. This organization is called the European Aviation Safety Agency, EASA. When in this chapter a reference is made to a country, EASA can be seen as the equal organization for the national aviation authority for the participating European countries. For instance, EASA is responsible, in the state of design role, for certification activities of Airbus and Fokker aircraft. EASA will also do the European validation process for aircraft designed in, e.g., the USA or Brazil.

In the EASA Basic Regulation (<http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CONSLEG:2008R0216:20091214:EN:PDF>), the responsibilities of the agency regarding UAS are clearly limited. Unmanned aircraft with an operating mass of no more than 150 kg are not the responsibility of EASA, but the responsibility of the individual states.

Certification authorities around the world use a similar process when addressing the certification of an aircraft. This process is described in this paragraph for an aircraft, but as indicated in the introduction of this chapter, RPAS are considered aircraft and are treated in a similar way.

93.3.1 Process Description

A certification project for an aircraft is always started with an official application for certification by the organization responsible for the aircraft design. The organization requesting the certification is commonly referred to as the “applicant.” When the application is accepted by the aviation authority, the certification project will start. This project is normally started with a kickoff meeting where the designer of the aircraft presents the design to the complete team of specialists that have been assigned to the certification team by the authority.

The certification project follows four different phases:

1. *Establishing the Certification Basis* In this phase, the safety requirements against which the safe design of the aircraft must be proven will be defined for the project. These requirements are referred to as the “certification basis.” Normally, the designer of the aircraft is responsible for providing a first draft of this certification basis. During and after the presentation of this first draft, the discussion and interaction with the authority certification team takes place, leading to a mutually agreed and mutually accepted certification basis for the

whole of the project. The basic safety requirements for a certification project are the latest version of requirements from the state of design (usually referred to as Certification Specification (CS) by EASA and Federal Aviation Regulation (FAR) by the FAA) applicable at the moment the application for certification has been received by the authority. A certification project usually lasts several years, and it is considered unfair to the applicant to add updated requirements to the certification basis over the years, due to the further development of the safety requirements. Of course, when both the applicant and the authority agree, newer version of the requirements can be made applicable to the project.

When all safety requirements are agreed between the applicant and the certifying authority, this phase is closed.

2. *Defining the Means of Compliance* Once the safety requirements are established, the applicant and the authority have to reach agreement on how the applicant will show that his design of the aircraft is meeting these requirements. There is a variety of methods available, from expert judgment, through theoretical analysis, down to flight testing. Not only the methods of showing compliance with the requirements are agreed in this phase. The involvement of the authorities in the various compliance finding tasks will also be agreed. In general, complete test plans, documents to be delivered, etc., will be agreed between applicant and authority.

At the end of this phase, there is agreement between applicant and the certifying authority about which tests are required and which reports will have to be delivered by the applicant. Furthermore, there will be agreement about the level of involvement of the authorities in the compliance finding, e.g., which reports need to be accepted and approved by the authorities, which tests will be witnessed by the authorities, and what will be left to the responsibility of the applicant, without any authority involvement.

This phase closes when there is mutual agreement on all mentioned points.

3. *Compliance Finding* In this phase, all activities agreed between applicant and authority in the previous phase will be performed. Design documents will be developed, tests will be performed, and manuals will be written. Where needed, authority will witness testing or approve reports, as agreed in the previous phase. For all certification projects, this phase takes the most time and is the most expensive phase for the applicant.

When all the compliance finding activities have been performed and accepted by the authority, the applicant is ready for the final phase.

4. *Delivering the Type Certificate* At the end of the third phase, there is full agreement between the authority and the applicant about the safe design of the aircraft. Now the applicant can provide a statement of compliance to the authority, to indicate that all safety requirements have been met, all necessary tests have been done, and everything is to full satisfaction of the authorities. When this statement of compliance is provided, the authority then can provide the type certificate to the applicant, indicating that the aircraft is designed in accordance with the applicable safety requirements and that the aircraft can now be built and operated safely.

Although these four phases are given in sequential order, in practice these phases are not clearly separated in time. For some parts, the whole process can be straightforward, and then the process can be done in these clear steps. Other parts require extensive discussions between applicant and authority, and in this case, the process can easily jump back and forth between the various phases. The only certainty in the whole process is that the first three phases have to be fully completed before phase 4 can happen. This last phase is usually the shortest phase of the four.

A more complete description of the certification process can be found in the EASA Type Certification Procedure (<http://www.easa.europa.eu/certification/docs/internal-working-procedures/PR.TC.00001-002%20Type%20certification.pdf>).

93.3.2 Procedure to Deal with Novel Design Features

As indicated, phase 1 concerns the definition of the certification basis. Normally a standard set of safety requirements is selected as the basis. But rulemaking normally does not develop as quickly as the technical advancements in aviation. This means that in most aircraft designs, there are new features that have not yet been covered by safety regulation. A clear example of this was the first fly by wire aircraft.

Within the certification process, there are means of dealing with these novel design features. When such a new design feature is identified, the authority can develop some project-specific requirements, tailored to the specifics of the design. In EASA projects, these specific requirements are captured in so-called certification review items or CRIs, and in FAA projects, they are captured in issue papers or IPs. Normally, both the technical requirements and the accepted means of compliance against these requirements are captured in these documents. In general the novel design features are captured in the first phase, but occasionally, some features are only identified in a later stage of the design. So up to very late in the project, these CRIs or IPs can be developed.

93.3.3 Certification and Validation Projects

In large certification projects, the certification project (performed by the aviation authority of the state of design of the aircraft) and the validation project (performed by any other aviation authority) run in parallel. This saves the applicant valuable time and money and allows operation of the aircraft in all countries where the design has been approved.

For example, consider an Embraer aircraft design. The state of design in this case is Brazil. But Embraer would like to allow operation of their aircraft not only in Brazil, but worldwide. In order to enable these worldwide operations, Embraer needs approval from all other aviation authorities of countries that have signed the ICAO Convention. Luckily, most countries in the world accept either an American (FAA) or European (EASA) approval. That means that additional to the Brazilian approval, Embraer is looking for EASA and FAA approvals as well. So in that case,

there are three projects running in parallel. First, there is the certification project performed by the Brazilian authorities (Agência Nacional de Aviação Civil, ANAC), and the other two projects are validation projects with an FAA validation team and an EASA validation team.

93.4 Certification Safety Requirements

In this paragraph, the major forms of safety requirements will be described.

93.4.1 Certification Specifications

For all RPAS, the certification safety requirements still need to be developed and accepted by national authorities. In its policy on UAS certification (E.Y013-01, August 25, 2009, http://easa.europa.eu/certification/docs/policy-statements/E.Y013-01_%20UAS_%20Policy.pdf), EASA UAS policy described the methodology to develop such requirements. First, it needs to be determined which category of manned aircraft is most applicable to the remotely piloted aircraft system that will be certificated. When this is done, the associated safety requirement for manned aircraft is selected. Subsequently, this requirement needs to be adapted to be applicable to the RPAS.

For small UAS, the following two certification specifications from EASA are most appropriate:

- EASA CS-VLA for airplanes (<http://easa.europa.eu/agency-measures/docs/certification-specifications/CS-VLA/CS-VLA%20%20Amdt%201%20combined.pdf>)
- EASA CS-VLR for rotorcraft (http://easa.europa.eu/agency-measures/docs/certification-specifications/CS-VLR/MERGED_v2.pdf)

At the moment, there are a few (unofficial) certification specifications available. Firstly, the NATO FINAS group has provided a specification based on CS/FAR 23, primarily used for military purposes and not applicable to small RPAS. Secondly, there is a final draft version available of the CS-LURS (Certification Specification Light Unmanned Rotorcraft System, adapted from CS-VLR), which the JARUS group (Joint Authorities for Rulemaking on Unmanned Systems) has developed. This last group is a voluntary group of national aviation authorities, together with EASA and EUROCONTROL, that works on drafting UAS regulation.

To give an example of the sort of topics that are covered in certification specifications, the various subparts that together form the CS-LURS set of requirements are given below:

Book A:

Subpart A: General

Dealing with general requirements like applicability.

Subpart B: Flight

Dealing with flight envelope, weight, performance issues, and flight characteristics.

Subpart C: Strength requirements

Dealing with loads on the aircraft, structural, and mechanical safety and fatigue.

Subpart D: Design and construction

Dealing with materials, rotor design, (hydro-) mechanical flight control design, landing gear, fire protection, lighting protection, and construction of the airframe.

Subpart E: Powerplant

Dealing with the engine installation, rotor drive system, fuel systems, batteries for electric engines, oil system, and exhaust system.

Subpart F: Equipment

Dealing with primarily electrical, electronical and computer systems, system safety, system installation, and the airborne part of the command and control link.

Subpart G: Operating limitations and information

Dealing with all sorts of operational issues.

Subpart H: (reserved for Detect and Avoid)

Subpart I: Control station

Dealing with the remote pilot station.

Appendix A: Instructions for continued airworthiness

Appendix B: Engines

Appendix C: Test procedure for self-extinguishing materials

Book B: Acceptable means of compliance

Providing clarification of the regulations in Book A and by the authorities accepted means of showing compliance against the regulations.

93.4.2 European Technical Standard Orders (ETSO)

Technical Standard Orders (TSO) are a well-known mechanism from the manned aviation regulations to allow system manufacturers to develop approved systems irrespective of the aircraft in which it will be installed.

During the certification process, the designer of the aircraft is responsible for the total certification effort. That does not only mean that he is responsible for the fuselage, engines, wings, etc., but also for the systems that are installed in the aircraft. The designer is really acting as the system integrator of the total system that will become the aircraft.

When it comes to certification of the electrical or avionics systems onboard the aircraft, there are two ways of getting an approval. The first possibility is that the full system functionality and integration with the other onboard systems is done during the certification of the whole aircraft. The second possibility is to have the system functionality approved prior to the aircraft certification and focus on the certification of the integration with the other onboard systems during the aircraft certification. This second method provides some benefits to the system manufacturers that build these electrical or avionics systems. This described methodology is equally applicable to aircraft seats, for instance. But this is considered out of scope for UAS in this paragraph.

The system that is used for this specific functional approval is the European Technical Standard Order (ETSO, in the USA it is referred to as a Technical Standard Order or TSO). The certifying authority can establish specific functional requirements for equipment. Then, in a separate process, the manufacturer of the system can obtain approval for the functionality of the system. This approach has two distinct advantages:

1. The manufacturer of the system is able to provide his systems to different aircraft manufacturers.
2. The aircraft designer does not have to consider the functional approval of the system, only the integration of the system in the total aircraft system.

Some typical examples of these sorts of systems are VHF radios, navigation receivers, transponders, etc.

Normally, the authorities are not defining the functional requirements for the system themselves, but they work closely together with the manufacturing industry to define some acceptable functional standards. Within aviation, these standards are developed in two standardization bodies: EUROCAE (European Organisation for Civil Aviation Equipment) and RTCA (Radio Technical Commission for Aeronautics). EUROCAE is primarily European, while RTCA is primarily American. In most cases, these two bodies work together to develop a worldwide functional standard for equipment. The process by which these standards are developed is the following; the governing body of either EUROCAE or RTCA identifies the need for a new standard and drafts terms of reference for a working group (WG, EUROCAE) or special committee (SC, RTCA) to establish these new standards. Then a working group or special committee is created (most of the times these groups work together, as said earlier), and participation from members of EUROCAE or RTCA is sought. The participants are primarily from industry, but aviation authorities participate in these groups as well. Within this group, a functional standard is developed, based on consensus with all participants in the group.

When such a group has finalized its work and either EUROCAE or RTCA have published the industry functional standard, the aviation authorities adopt this standard by referring to that standard in a (E)TSO. Once the (E)TSO is published, the equipment manufacturer can apply for approval with the aviation authority. The largest part of the approval process for an (E)TSO is to show compliance with the industry standard that has been published by EUROCAE or RTCA (or both).

After obtaining this approval, the manufacturer is able to provide his equipment to an aircraft designer who is looking for that specific functionality in his aircraft design. During the certification process of the aircraft, the aircraft designer does not have to show that the system that is installed in his aircraft meets the functional requirements for that system. He can provide the (E)TSO approval of the system to the certifying authority and that is the required proof that the system meets the requirements. The aircraft designer, however, is still responsible for proving that the integration of that equipment with the other systems onboard the aircraft is still in accordance with the safety requirements for the aircraft design.

The approval for the equipment against the functional requirements requires a lot of functional testing and significant environmental testing. With this testing done at the equipment level and granting a more generic functional approval of the equipment, both the equipment manufacturer and the aircraft designer save significantly in cost and time for the certification of aircraft.

93.5 Relation Between Safety Requirements and RPAS Components

In this paragraph, the various systems that together form the RPAS will be addressed. It will look at how to relate the safety requirements given in the previous paragraph with these various parts.

93.5.1 Remotely Piloted Aircraft (RPA)

When converting a manned certification safety requirement for an RPAS, there are a few issues that need to be considered. First is the obvious issues that are directly related to not having a person onboard. This includes requirements on onboard chairs, seat belts, emergency oxygen, etc. But there also are less obvious issues that need to be considered. In general, a small UAS is a much more complex aircraft than the equivalent category of manned aircraft, especially from a systems perspective. This means that additional requirements are necessary to cover these design features, primarily the requirements in Subpart F of the various certification requirements.

Another area that usually needs additional requirements is the power plant installation section (Subpart E). Electrically driven engines and dual turbine engine installations, these kinds of design features are not covered by the equivalent manned aircraft safety requirements. Therefore, the subparts of the requirements that address these issues need special attention and most probably need a partial rewrite of the whole section.

One final topic that needs to be mentioned is the emergency control and failure warning systems. There is nobody onboard to perform a number of emergency recovery actions that are implicit in the manned aircraft safety requirements. These requirements need careful rethinking and an adaptation that allows the pilot in the remote pilot station to still be informed about possible system failures and perform some emergency control if that is required.

From the given table of contents of CS-LURS, Subparts A–G are covering the RPA requirements.

93.5.2 Remote Pilot Station (RPS)

This is a new system component of the RPAS that has no equivalent in the manned aviation regulations. In the ICAO concept as described in the UAS Circular,

the remote pilot station (RPS) will be a separate aeronautical product. This will mean that once the ICAO annexes have been adapted accordingly, there will be a separate certification safety requirement document for the RPS. At the moment, the safety requirements for the RPS are still part of the safety requirements document for the RPA. In current safety requirements documents, there is a specific subpart (Subpart I) dedicated to the RPS requirements.

Establishing the requirements for the RPS is not a matter of simply copying the requirements related to the cockpit design from manned aviation to the RPS. Of course, all human machine interfaces are part of the RPS and have a prominent place in the RPS requirements. But most of these interfaces are part of systems that have components both in the RPA and the RPS. In such a situation, it is necessary to develop a consistent strategy for dividing the requirements between the subparts for RPA and RPS. It should be avoided to duplicate requirements between the RPA and RPS. In the JARUS team that worked on the CS-LURS, the philosophy was used to include the requirements systems that had components in both the RPA and RPS part into the RPA part of the document. The requirements that refer to the RPS only are then collected in the subpart for the RPS.

From the given table of contents of CS-LURS, Subparts A and I are covering the RPS requirements.

93.5.3 Command, Control, and Communication System

The command, control, and communication (C3) system will not be certificated separately. When a radio line of sight system will be used, the airborne part and the ground-based part of the C3 system will be certificated as part of the RPA or RPS, respectively. For the safety requirements, this means that the requirements for the C3 components will be contained in the respective subparts of the certification specification. This is identical to how radio communication systems in manned aviation are currently certificated.

When a beyond radio line of sight system, e.g., satellite communication, will be used, the current proposal in the ICAO circular is to work with a certificated communication provider that is under safety oversight of the aviation authorities. It is considered impossible to certificate a satellite communication system as a fully integrated part of the RPAS. In this case, the performance requirements for the C3 system and the interfaces between RPA, RPS, and C3 system will be defined and the components of the RPA and RPS that will interface with the communication system will be included in the safety requirements of the respective subsystems.

For small UAS, in most RPAS designs, a radio line of sight system will be used, so the first approach to certificating the system, as described above, will be applicable.

From the given table of contents of CS-LURS, Subparts A, F, and I are covering the command and control requirements.

93.5.4 Other Systems

There will be very specific subsystems being designed as part of an RPAS. The first two systems that immediately come to mind are a launching and recovery system and a flight termination system. These systems are usually unknown in the manned aviation system, so specific safety requirements and associated system standards need to be developed for these. At the moment, the CS-LURS does contain some requirements on the flight termination system. Over time, the detailed safety requirements will be introduced in the certification specification. Until the time that these requirements are part of the official specifications, the authorities will be able to deal with these subsystems by introducing dedicated requirements for a certification project and document these requirements in a certification review item (EASA system) or in an issue paper (FAA system).

93.5.5 Detect and Avoid

One of the specific subsystems that are foreseen to be used in RPAS is the detect and avoid system (DAA). This system will be required to replace the collision avoidance capability that is provided by the onboard pilot in manned aviation. Another chapter in this book is fully dedicated to the DAA system, so this paragraph will only focus on the certification aspects of it. From a certification perspective, there are two issues to address.

First the functionality of the system needs to be defined. This is usually done by asking standardization organizations like EUROCAE and RTCA to define standards for the system. The aviation authorities can then accept these standards and make them part of the safety requirements by including the standard from EUROCAE and/or RTCA in a (European) Technical Standard Order ((E)TSO), which is explained in more detail in the previous paragraph. Additional to this equipment approval, some functional requirements can also be included in the certification specification.

Secondly, specific safety requirements for the system need to be developed, in line with the current practice of assuring system safety in the manned certification standards.

Various rulemaking bodies around the world are currently working together to develop both of these standards. At the time of writing of this chapter, there was no definitive regulation for this system available yet. In practice this will mean that operations of RPAS on a regular basis will be limited to visual line of sight, unless an authority has given a specific approval to a certain operational scenario to allow operations beyond visual line of sight.

From the given table of contents of CS-LURS, Subparts A and H are covering the DAA requirements.

93.5.6 Concluding Remarks

The whole area of safety requirements for small UAS is undergoing significant development at the moment. This paragraph therefore cannot address these requirements too specifically, because without a doubt these would have changed when this book is published. Therefore, the framework for certification has been given. The issues that are currently being addressed are also provided. Together this should allow understanding of the requirements once they are published by the aviation authorities.

Apart from the specifics of CS-LURS, this chapter is equally applicable to other certification specifications, ranging from airplanes (small and large) and helicopters (small and large).

93.6 Certification Organizational Requirements

Not everybody is allowed to design an aircraft, according to the aviation regulations. Before being granted this right, an organization needs to prove that it is capable of designing a safe aircraft. This whole process is referred to as Design Organisation Authorisation (DOA) approval. In the EASA Airworthiness Regulation (EASA Part 21, <http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CONSLEG:2003R1702:20091228:EN:PDF>), the whole process of acquiring and maintaining a DOA approval is given in Subpart J.

The DOA approval process is not about demonstrating the technical ability to design an aircraft but is about the organizational capabilities to design in a structured and (safety) controlled manner. These organizational capabilities include a quality assurance system, an independent validation system to do a check on the technical design, training of relevant personnel, delegation of responsibilities within the organization, etc. So the process is aimed at assuring that the organization that is designing the aircraft is capable of:

- Designing in accordance with the QA system
- Providing an independent validation check
- Training the personnel timely and adequately
- Working in accordance with procedures that assure the quality of the work
- Appropriately delegating responsibilities within the organization

The philosophy behind the DOA approval is that the authorities can partly rely on the internal design organization procedures when certifying the aircraft. During the “defining the means of compliance” phase of the certification project, the authorities will normally agree with the applicant about which specific parts of the compliance finding can be delegated to the applicant, i.e., which reports will only be checked and validated by the applicant and which tests will be independently witnessed by the applicant only. In this case, the validation organization within the

applicants' organization can be considered to act on behalf of the authorities. That is one of the reasons why the independence of the validation team within the design organization is considered of prime importance.

93.7 Final Remarks

As said at the introduction of this chapter, UAS are aircraft. Therefore, UAS will need to fit into the currently existing aviation system, both from an airworthiness and from an operational perspective. But the introduction of UAS into civil airspace is slowly changing the way aviation regulators are thinking about airworthiness and safe operations. In manned aviation, that aircraft is the core element where everything needs to be integrated. The aircraft in itself is the end product and provides the platform where everything (fuselage, equipment, engines, etc.) are integrated. With the introduction of RPAS, the aircraft is "just" the airborne component of the total system. This means that the whole approval system and the associated safety oversight system by the national aviation authorities can no longer be aircraft centered but should be system centered. When you consider the aircraft in manned aviation as the core element where the whole system is integrated, this system-centered approach for RPAS is no different to what the authorities are used to from manned aviation. The only difference is that the system in the case of the RPAS is more than the aircraft, while in manned aviation, the system is the aircraft. In the future, this new thinking will be finding its way into ICAO Annex 8. But the fundamentals of the safety approach by ICAO, an approved design and safety oversight by countries, will not be changed.

This chapter has focused on the airworthiness issues only. Although the chapter is written with small UAS in mind, the processes and practices given in this chapter are, in general, equally valid for larger UAS. Only the specific requirements and examples given herein are tailored toward small UAS. The certification process and the layout of the certification specification is identical for larger UAS.

The authorities are looking for the differentiation between large UAS and small UAS by downscaling the requirements to an appropriate level. It is widely understood that a Global Hawk should be certificated against different requirements than a 2 kg octocopter UAS. But the whole system and process of approval should be identical.

One of the issues that the authorities are facing to deal with at the moment is that there is no manned equivalent for the certification specification for small UAS, certainly for those well below 25 kg. This leads to the following more fundamental question: To what level do the requirements for larger UAS need to be downgraded to provide safe UASs that are still economically viable? A follow-on question to this is as follows: What sort of categorization scheme can be used to classify these small UASs? Industry and authorities are currently addressing these issues.

Abstract

To make a safe transition of UAS into the National Airspace System, new regulations must be developed by the Federal Aviation Administration. The technologies employed by UAS are in many circumstances fundamentally different

than those of traditional manned aircraft. The regulations written to support the airworthiness certification, operations, maintenance, etc. of manned aircraft often do not apply as written without interpretation, revision, and/or deletion. This chapter provides the necessary details on how to conduct a technology survey and regulatory gap analysis of UAS technology subsystems. Four past studies performed by Embry-Riddle Aeronautical University for the FAA's William J. Hughes Technology Center are discussed. These studies address UAS propulsion systems, sense-and-avoid technologies and procedures, command control and communication, and emergency recovery and flight termination systems. Each study will be discussed in this chapter, and a recommended process for future studies is provided.

94.1 Introduction

To safely transition unmanned aircraft systems (UAS) into the National Airspace System (NAS), new regulations must be developed by the Federal Aviation Administration (FAA) as will other international civil air authorities (CAAs) for their respective airspaces. There are many subtle and fundamental differences between technologies used for UAS versus traditionally manned aircraft. Before new regulations or policies can be written to support unmanned aviation, regulatory issues must be articulated.

Beginning in 2006, researchers at Embry-Riddle Aeronautical University (ERAU) began collaboration with the FAA William J. Hughes Technology Center to identify technology-based gaps within the FAA's current regulatory framework. The first study surveyed UAS propulsion technologies. Follow-on research included a regulatory gap analysis of UAS propulsion performed in 2007–2008. Three additional technology survey and gap analysis studies followed for UAS sense-and-avoid (SAA) technologies; command, control, and communication (C3) technologies; and emergency recovery and flight termination (ERFT) technologies and procedures.

The purpose of each technology survey was to articulate representative technologies and frameworks being used in current and near-future UAS. The regulatory gap analysis focuses on the alignment of the technology with existing regulations. It should allow the target audience to clearly identify and articulate where revisions or reinterpretations are required. This chapter begins with an overview of technology surveys, gap analyses, and relevant types of FAA documents. Next, the above-mentioned studies are presented as separate case studies. This chapter concludes with the authors' recommended best practices for future studies.

94.2 Background

UAS represent a near-disruptive technology for the current NAS in the United States of America and in the corresponding airspace systems of nations worldwide. While total displacement of aircraft with an onboard pilot from the NAS seems extremely unlikely at any near-future time, the introduction of remotely piloted

aircraft having varying degrees of onboard autonomy has been beyond the current regulatory framework for aircraft design and manufacture, for flight activities, and for on-ground operations and maintenance.

The introduction of disruptive or near-disruptive technologies on markets has been studied regarding technologies such as the Internet, wireless telephony, and mobile electronics. Less effort has been dedicated to the impact of these technologies in industries such as aviation and aerospace where the primary motivation for existing regulations stems from public safety, both of air passengers and of those on the ground.

Current federal air regulations (FARs) did not anticipate operation of controlled unmanned aircraft in civil airspace. There is no specific part or definition under applicable law related to unmanned aircraft. The absence of absolute legal guidance with respect to the jurisdiction of UAV regulation, the definition of UAV, and the integration of UAVs in the national airspace prevents the optimum use of UAVs for the public benefit. Yet, given the risks of a ground impact or mid-air collision with other aircraft, the need for regulatory certainty respecting UAVs is an imminent issue deserving the attention of regulators, manufacturers, and operators alike (Ravich 2009).

To better articulate issues related to UAS technologies, the FAA Office of Aviation Research and Development funded a number of technology surveys and regulatory gap analyses, including the following UAS aspects: propulsion, C3, SAA, and ERFT. Before presenting the content of these studies, the following section shall address the higher level concepts of what a “technology study” or a “gap analysis” is, in the context of the introduction of disruptive technology in a regulatory context (such as the introduction of UAS into the NAS).

94.2.1 Technology Surveys

A technology survey for any disruptive or near-disruptive suite of technologies is a summary of current and near-future technologies having the disruptive impact.

One approach to articulate the elements of a set of technologies, such as those that could serve as propulsion systems for a remotely piloted aircraft, would begin with a catalog of the different aircraft and their propulsion systems. Listings of UAS in service and development are published regularly (AIAA 2011). While such tables are rich with aircraft dimensions, weight, operating regimes, flight durations, etc., they consistently fail to include specific details for the technologies in use. Due to proprietary interests of the developers and manufacturers, details ranging from the displacement volumes of internal combustion engines to the name of a vendor that developed a particular ballistic recovery system are rarely published; developers and manufacturers are understandably reticent to supply such information outside of a nondisclosure agreement.

The lack of such details turns out to not prevent an effective technology survey. From a regulatory point of view, what matters in such a survey is not the collection of details across some number of disruptive technology exemplars, but the underlying technologies those details represent. It is more important to articulate the families

of technologies in use than to exhaustively enumerate each unique case. The technology survey must comprise a complete articulation of the classes which the particular technology might take, but only that list of classes. Specification of that list of classes becomes part of the technology survey itself, based on an initial review of the forms of the technology in use in the disruptive technology.

The results of the technology survey are usually presented in tabular form, with that data kept as a spreadsheet or database while the survey is performed. The table is populated with rows, each of which collects the attributes of the representative elements of each class in the technology in the columns of the table. While a single representative element is conceptually sufficient to articulate the collection of technologies, the table usually contains multiple representatives for each technology. A complete articulation of every last instance and representative element of the technologies is not required for a successful survey.

A technology survey articulates current *and near-future* technologies through a collective set of representative examples. Given the snail's pace of changes to aviation regulations, the technology survey needs to capture technologies on the horizon that could have an impact within the next 5 or 10 years, even if they are not currently in production use.

A second, and possibly more important, artifact of the technology survey is a conceptual framing of the technologies to be used in future works, such as regulatory gap analyses. The conceptual framework can range from formal modeling of the underlying technologies to an abstract capturing of those technologies' salient aspects and operations. The model/framework creates the context for conduct of the regulatory gap analysis.

94.2.2 FAA Documents

In addition to the regulations, there are a variety of FAA documents that must be produced and/or revised to accommodate UAS-NAS integration. This section defines some common documents related to airworthiness, certification, and FAA policy. A *technical standard order (TSO)* defines the minimum operations performance standards and minimum aviation system performance standards for an aircraft system or subsystem. A component authorized for production under a TSO is identified as compliant with that TSO. The FAA can utilize *advisory circulars (ACs)* to share information with the aviation community. ACs have varied audiences including engineers, pilots, operators, etc. ACs can be used as a means of presenting critical design requirements so that aircraft meet sufficient airworthiness standards. It should be noted that these documents are not law. Lastly, *guidance material* is published by the FAA to the community. One example is the FAA UAS Interim Guidance Document 08-01 (Federal Aviation Administration 2008). Another example is the Aeronautical Information Manual (AIM), which defines pilot procedures in the NAS (Federal Aviation Administration 2012a). Guidance materials are not regulatory or as official as an advisory circular but are used to convey FAA policy, procedures, etc. to the aviation community.

94.2.3 Regulatory Gap Analyses

The FAA is chartered through the same piece of statute law chartering the entire Department of Transportation, Title 49 of the United States Code (USC). The FAA authorized in 49 USC §44701 to regulate aircraft and their usage within the framework of Federal administrative law. Regulations issued by the FAA comprise Chap. I (Parts 1–199) of Title 14 of the Code of Federal Regulations (CFR). These are divided into several subchapters relating to definitions, rule making, aircraft, airmen, airspace, air traffic and general operating rules, air carriers and operational, schools, airports, navigation facilities, and the FAA itself. It should be noted that 14 CFR Parts 1–199 are still known to many in the aviation world as “the FARs,” where “FAR” stands for “Federal Aviation Regulation;” in Federal speak, “FAR” has since been superseded to mean “Federal Acquisitions Rules.”

The meaning of a regulatory gap varies according to which chapters of Title 14 CFR one is considering. For example, aircraft are only allowed to fly in the NAS when the aircraft has been issued a type certificate (TC) for its design (or a Supplemental Type Certificate (STC)). The issuance of such a TC or STC follows a prescribed set of activities in which the aircraft designer articulates which elements of Title 14 CFR apply to the design at hand and then demonstrates through testing, analysis, and formalized processes that the design complies with the specifications and regulations of the articulated elements.

When an aircraft design employs a novel technology, it is unlikely that there is an existing regulation applicable to the technology. The designer can qualify the use of the technology toward certification through either special conditions (SC) or equivalent level of safety (ELOS) findings. A third option, exemption, exists, but applies more often to exemptions from specified procedures than from specified requirements. In either case, the aircraft designer articulates in an issue paper the features of the new technology and how its inclusion in the aircraft design satisfies the thrust, in general SC or in particular ELOS, of the regulations; FAA engineers respond to the issue paper, and the officers responsible for certification take the designers’ and the FAA engineers’ analysis into account in deciding whether to issue a TC.

For aircraft, then, a regulatory gap exists when certification of an airframe employing a technology would require either a SC or ELOS finding to use that technology. The result of the gap analysis is a collection of annotated regulations. The annotations consist of declarations as to whether the regulation:

- Applies (as is)
- Applies with interpretation
- Applies with revision
- Does not apply

From previous literature, it was found that several approaches to presenting regulatory gaps exist (Kirk et al. 2007; Frater et al. 2006). Kirk et al. (2007) provide an examination of Federal aviation laws, regulations, and guidance materials for applicability to UAS in general. Frater et al. (2006) present a different style of regulatory gap, focused upon nanotechnology, in which the results are presented

in a tabular form where related aspects of existing legislation and regulations are summarized, the gap or potential gap due to novel technology presented, and further comments or annotations are appended (see Annex 5 of Frater et al. 2006). ERAU's approach is much closer to the former following a process by which the collection of rule applicability results was looked at from both global (all rules together) and local (one rule at a time) to produce text describing the regulatory gaps.

94.3 Case Study #1: Propulsion Technologies for UAS

94.3.1 Technology Survey

The goal of the UAS propulsion technology survey, Griffis et al. (2007), was to examine existing and novel propulsion systems for UAS such as reciprocating piston engines (RP), wankel rotary engines (RO), propeller drive systems (PR), gas turbine propulsion systems (GT), rocket-powered means of propulsion (RK), electric motor-based propulsion system (EM), battery-based propulsion system (BB), fuel cell-powered propulsion system (FC), solar/photovoltaic-powered systems (PH), and ultracapacitor-based energy storage (UC).

A conceptual framework was derived as shown in Fig. 94.1. This framework guided the study of each technology area to maintain internal consistency. The elements of this framework are defined as follows:

Energy source (ES). Propulsion requires expenditure of energy, and the ES is the origin of that energy. ES is intended to be a generic label for things like the following examples: gasoline, diesel fuel, lithium hydride, liquid hydrogen, solar energy, etc.

Energy transformer (ET). An ET converts the potential energy within the ES into a means for producing work, heat, or electrical current.

Power plant (PP). A PP is any aspect that harnesses the product of the ET into motion. For example, a motor that spins a shaft as a result of a supplied electric current classifies as a PP in this context.

Propulsion effector (PE). A PE is the interface between the motion generated and the impulse exerted to move the vehicle; it is what will give the effect of propulsion.

Fig. 94.1 Technology survey framework for UAS propulsion systems

Control effector (CE). A CE is whatever is in place to give the effect of control to the propulsion means in a way that serves the purpose of controlling propulsion generation for the vehicle. CE is intended to be a generic label for things that perform control on propulsion such as a full authority digital engine control (FADEC), throttle control, fuel mixture control, and current regulator.

The conceptual framework is representative of the state of propulsion systems. For example, consider the following utilization of the framework. A UAS employing an avgas-fueled RP would have petroleum distillates for its ES, combustion as its ET, the piston/crankshaft as its PP, a PR as its PE, and control of the flow of fuel, air, and electricity as its CE. It should be noted that in some cases single physical units can assume the role of two or more conceptual elements. For example, the thermodynamics of a GT can be considered an ET, PP, and PE simultaneously.

Reciprocating Piston Engines Reciprocating piston systems vary in size, geometry, and configuration. Often an engine is classified by how many cylinders it contains, how much total volume is displaced within its cylinders, or the configuration of those cylinders. They all contain some variation of the same basic parts, and there is a common principle behind how work is generated from stored energy of the fuel consumed as presented in Table 94.1. Representative examples of RP-based UAS are presented in Table 94.2.

Table 94.1 Conceptual decomposition of a reciprocating piston engine

| Conceptual unit | Description |
|----------------------------|--|
| <i>Energy source</i> | Petroleum distillates |
| <i>Energy transformer</i> | Heat production and expanding volumes resulting from contained combustion of petroleum distillates |
| <i>Power plant</i> | Piston motion resulting from expanding volumes, which in turn rotate the crankshaft |
| <i>Propulsion effector</i> | Propeller or fan unit driven directly or indirectly (geared) by the crankshaft |
| <i>Control effector</i> | Throttle, regulation of fuel flow |

Table 94.2 Representative cases of UAS using reciprocating piston engines (Office of the Secretary of Defense 2005; Parsch 2006; RCV Engines, Ltd 2006)

| Aircraft | Manufacturer | Subclass |
|----------------|------------------|---|
| MQ-1B Predator | General Atomics | 4-stroke |
| RQ-2B Pioneer | Pioneer UAV | 2-cylinder, 2-stroke |
| RQ-5A Hunter | Northrop Grumman | 4-stroke, heavy fuel |
| ScanEagle A | Insitu | 1-cylinder, 2-stroke (heavy fuel variant available) |
| T-Hawk | Honeywell | Heavy fuel engine |

Wankel Rotary Engine Wankel rotary engines use the combustion of petroleum-based fuel, and the desired output is the rotation of a power shaft that drives the rest of the system. They differ from conventional reciprocating engines in that their volume displacement and associated internal motion are rotational, as opposed to back and forth. An internal triangular core, shaped as a “Reuleaux” triangle, divides a chamber with an epitrochoid-shaped stator into three expansion areas (AREN 2006). A conceptual breakdown of the this propulsion technology is shown in Table 94.3. Examples of RO-based UAS are presented in Table 94.4.

Propeller-Based Systems A large body of knowledge exists for propellers, which is outside the scope of this document. However, as they are an important instance of commonly utilized propulsion effector, they deserve mention. Most reciprocating piston and rotary engines use propellers as their propulsion effectors, and many smaller UAS use electric motors to drive a propeller.

Gas Turbine Engines A gas turbine engine is an internal combustion engine operating on a highly dynamic process, processing air and fuel to yield high-velocity thrust. A gas turbine engine comes in various forms including turbine engine, turbofan engine, and turboprop engine. A conceptual decomposition representative of all three gas turbine approaches is presented in Table 94.5, and examples of its use in UAS are presented in Table 94.6.

Rocket Propulsion A rocket is propelled by a chemical reaction that generates extreme pressure gradients and high-velocity particles that exit a nozzle. The resulting momentum exchange provides impulse over some duration, accelerating the rocket’s mass (Brian 2007). Propulsion derived exclusively from rocket power tends to be used in applications where the asset is not expected to return home.

Table 94.3 Conceptual decomposition of a Wankel rotary engine

| Conceptual unit | Description |
|----------------------------|--|
| <i>Energy source</i> | Petroleum distillates internal energy relative to oxidation products |
| <i>Energy transformer</i> | Heat production and expanding volumes resulting from contained combustion of petroleum distillates |
| <i>Power plant</i> | Reuleaux triangular rotor motion within an epitrochoid stator turning the eccentric shaft |
| <i>Propulsion effector</i> | Propeller or fan unit driven directly or indirectly (geared) by eccentric shaft |
| <i>Control effector</i> | FADEC, carburetor, fuel/air flow control |

However, takeoff assist can utilize rocket-based propulsion (Office of the Secretary of Defense 2005). Table 94.7 shows the conceptual decomposition of rocket propulsion, and Table 94.8 presents some examples of its use for UAS.

Electric Motors For electrically based propulsion systems, electric motors are used as the power plant because they can easily couple with propellers as the propulsion effector; all that is needed is a continuous source of electricity. The rotational speed of a DC motor is proportional to the voltage applied to it, and the torque is

Table 94.9 Conceptual decomposition of electric motor-based propulsion

| Conceptual unit | Description |
|----------------------------|--|
| <i>Energy source</i> | Unspecified |

proportional to the current (Hall et al. 2003). A conceptual breakdown of propulsion using electric motors is provided below in Table 94.9.

Batteries For UAS applications, rechargeable batteries are preferred and therefore the focus of discussion. Lithium batteries tend to be lighter and possess higher energy density (Reid et al. 2004). Table 94.10 presents the conceptual decomposition of UAS propulsion using electric motors driven by batteries, and Table 94.11 provides representative examples of UAS using batteries. Unfortunately, manufacturers do not frequently offer the details on what particular chemistry of battery is used.

Fuel Cells Instead of consuming oxygen in the direct combustion of fuel, a fuel cell consumes oxygen (or some other environmentally provided reactant) to

Table 94.12 Conceptual decomposition of a fuel cell based propulsion system

| Conceptual unit | Description |
|----------------------------|--|
| <i>Energy source</i> | Molecular hydrogen internal energy relative to water |
| <i>Energy transformer</i> | PEMFC creating a power source through ionization and electrochemical oxidation of molecular hydrogen |
| <i>Power plant</i> | Electrically driven motor |
| <i>Propulsion effector</i> | Propeller or fan unit driven directly or indirectly (geared) by motor shaft |
| <i>Control effector</i> | Hydrogen flow regulators, voltage/current boost regulators, analog/digital feedback control loops |

| <i>Energy transformer</i> | Superpositioned power-generating photovoltaic cells stimulated by the photoelectric effect |
| <i>Power plant</i> | Electrically driven motor |
| <i>Propulsion effector</i> | Propeller or fan unit driven directly or indirectly (geared) by motor shaft |
| <i>Control effector</i> | Voltage/current regulators, analog/digital feedback control loops |

generate electrical power via an electrochemical process. There are a wide variety of fuel cells, including proton exchange membrane fuel cells, phosphoric acid fuel cells, molten carbon fuel cells, solid oxide fuel cells, methanol fuel cells, and alkaline fuel cells (Theiss and Thomas 2000; National Fuel Cell Council 2006). Table 94.12 presents the conceptual decomposition of fuel cell-based propulsion, and Table 94.13 presents two representative cases of fuel cells used in unmanned aircraft.

Photovoltaics Photovoltaic technology obtains usable energy from sunlight. Being effectively cost free and inexhaustible, solar power is attractive for long-endurance systems. Unfortunately, due to weather or daily sunlight availability, UAS operations can be limited unless there is some means of energy storage. A conceptual framework for photovoltaic-based propulsion is shown in Table 94.14 with examples of its usage in Table 94.15.

Table 94.15 Representative cases of UAS using photovoltaics (AC Propulsion 2005; AIAA 2005)

| Aircraft | Manufacturer | Subclass |

| SoLong | AC Propulsion | Solar cells on wings |
| Helios | AeroVironment | Solar cells on wings |

Table 94.16 Conceptual decomposition of an ultracapacitor-powered propulsion system

| Conceptual unit | Description |
|----------------------------|---|
| <i>Energy source</i> | Electrostatic potential within capacitor plates, charged by external source |
| <i>Energy transformer</i> | Application of external load, liberating potential energy in the form of electric current |
| <i>Power plant</i> | Electrically driven DC motor |
| <i>Propulsion effector</i> | Propeller or fan unit driven directly or indirectly (geared) by motor shaft |
| <i>Control effector</i> | Voltage/current regulators, analog/digital feedback control loops |

Ultracapacitors An ultracapacitor is a specialized modern capacitor that has an unusually high energy density when compared to common capacitors (Electricity Storage Association 2007). Ultracapacitors are a potential stored energy source for a UAS propulsion system using electric motors. Ultracapacitors can retain much greater energies than standard capacitors for a comparable geometry. While there are no existing applications of ultracapacitors in existing UAS, their use in automotive applications provides a natural transition point into aerospace applications. A conceptual breakdown of propulsion using this technology is shown in Table 94.16.

94.3.2 Regulatory Gap Analysis

Following the technology survey, follow-on research was funded to perform a regulatory gap analysis. The analysis examined Title 14 CFR Part 27 Subpart E, Airworthiness Standards: Normal, Utility, Acrobatic, and Commuter Category Airplanes Power Plans; Title 14 CFR Part 33, Airworthiness Standards: Aircraft Engines; and Title 14 CFR Part 35, Airworthiness Standards: Propellers.

94.3.2.1 Regulatory Gap Analysis Process and Tools

The regulatory gap analysis was performed in two parts. The first part was a local assessment of the regulations to determine where regulatory gaps exist. The second part was a global assessment. The global assessment yields information on the state of the regulations based upon the results of the local assessment.

The local assessment was performed using a spreadsheet to capture a section-by-section analysis of the regulations.

Each row represents a specific section of the regulation part being examined. The section is analyzed based upon its degree of applicability for each conceptual technology and conceptual decomposition framework element. The dimensions of applicability were identified as applies (APP), applies with interpretation (AWI), applies with revision (AWR), or does not apply (DNA). For this study, these terms are defined as follows:

APP The regulatory guideline, as it stands, makes sense for the corresponding technology identified in the spreadsheet.

AWI Understanding the intent of each regulatory guideline, it can be interpreted to cover other areas or technologies that are not explicitly mentioned or addressed, for example, regulations that cover RP technology and also AWI to RO technology.

AWR Employed prudently. Suggests that the regulatory guideline is fine as it stands except with a minor amendment.

DNA The regulation does not apply to any of the propulsion technologies or conceptual aspects of a UAS propulsion system.

94.3.2.2 Results

Upon completion of the local analysis using the spreadsheets, global analysis was performed to derive the final results and recommendations of the study. First, the “fundamental gaps” are identified, which include any fundamental technological differences between the propulsion technologies for UAS versus manned aircraft. Next, the “open set” gaps are identified where regulatory gaps exist because of safety concerns for technologies that fall outside of the existing regulatory framework.

The Fundamental Gap The fundamental gap between the existing regulations and UAS propulsion technologies results from a greater diversity in the types of ET and PP that can be utilized for a UAS. Existing regulations focus upon one of two types of systems, GT and RP. As a result, some regulations simply do not apply to alternative propulsion systems, and in other cases new regulations are required to address the safety concerns of the new technology. A fundamental gap exists in regulation of systems that depend exclusively on EM for propulsion and that there exists no specific regulation addressing the kinds of power supplies that would be driving these propulsion systems. UAS (excluding optionally piloted vehicles) do not need to be concerned with the power requirements to propel the weight of both the pilot and the onboard support and control interfaces, thereby further reducing the electrical carrying requirements of an electrical power source. Technologies such as FC, modernized batteries, UC, and PH have the ability to supply sufficient electricity to provide sufficient endurance for a UAS and must now be considered by regulators.

The regulatory guidelines for thermodynamically driven engines address a set of associated high-level concerns related to the lubrication of moving parts, heat transfer, fuel delivery, air supply, fuel storage, etc. The GT and RP approaches to propulsion both carry flammable liquid petroleum distillates that burn hot with oxygen and have reactants that need to be expelled. These fundamental issues

(among many others) are addressed in the regulatory guidelines in a manner that assures that any implementation of these approaches will be airworthy and have an associated reliability for a given specified period of time. For an electric engine, many of these factors do not apply with the same literal interpretation. Some issues still need to be addressed such as ensuring that the motors remain sufficiently cool and the moving parts remain lubricated. However, a new set of concerns are introduced with the concept of an exclusively EM. Many of the restrictions and regulations in place for guaranteeing the safety of GT and RP in some cases do not make sense and are insufficient when dealing with an EM.

The Open Set Gap From the fundamental gap and the technology survey, it is evident that there exist technologies that exist outside of the regulations. Incremental adjustments to the regulations can be made to accommodate these changes. As new technologies emerge, this could result in regulators continually attempting to patch the regulations rather than create a new mechanism for addressing these new and emergent technologies. In order to close the coverage of the open set gap, the study concluded that the concepts of catch-all regulations should be embraced and extended. This can include extending concepts of abstract regulation, in similar approaches to the conceptual framework. Ideas like those in Parts 23 and 25 Sects. 1301 and 1309 can be complemented with regulation of generic propulsion systems, regulating only the conceptual components, their abstract interfaces, and the conceptualized interactions that each component would have between its interface and another conceptual component interface.

94.4 Case Study #2: Sense-and-Avoid Technologies for UAS

94.4.1 Technology Survey

The sense-and-avoid (SAA) technology survey is guided by a representative framework for sense-and-avoid technologies for UAS. Figure 94.2 graphically depicts this framework. Three major categories of technologies relevant to the topic of SAA for UAS are sense, avoid, and be seen. Each will be discussed in this section.

94.4.1.1 Sense

The first category of SAA technology is *sense*. These technologies allow the UAS to detect other traffic and local terrain features. It is subdivided into airborne sensing and ground-based sensing.

Airborne: Cooperative Cooperative technologies require other NAS users to be equipped with specialized communication equipment, such as a working transponder, such that they can be seen by other aircraft.

Traffic alert and collision avoidance system (TCAS) is a technology used in manned aviation to improve pilot situation awareness to mitigate midair collisions. TCAS I and TCAS II provide traffic advisories to the pilot in the event that

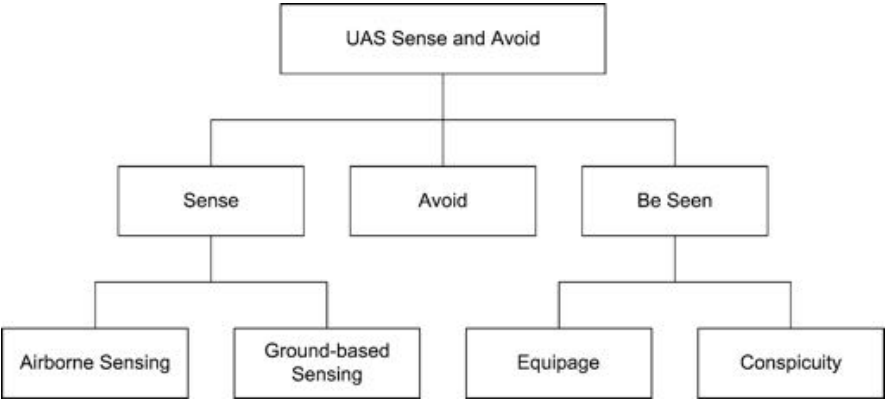

Fig. 94.2 Technology survey framework for UAS sense-and-avoid technologies

there is a risk of collision given the current flight path and oncoming traffic. TCAS II also provides collision avoidance directives to the pilot (Federal Aviation Administration 2012b). A recent FAA study examined TCAS for UAS (Federal Aviation Administration 2011). It concluded that TCAS could be a viable tool to aid situational awareness to the UAS operator/pilot but stated that the technology was never approved as a sole means of replacing the pilot’s role to see and confirm the presence of other air traffic.

Automatic dependent surveillance-broadcast (ADS-B) can also provide an airborne sensing capability to improve situational awareness of local air traffic. Equipped aircraft broadcast their current position and some additional state data via data link. The broadcast message can be received by suitably equipped aircraft. For manned aviation, the aircraft positions received can be displayed in real time to the pilot to enhance local situational awareness. Air traffic controllers can also receive this information via ground-based transceivers (Federal Aviation Administration 2007).

There are two types of ADS-B technology currently in use. Universal Access Transceiver (UAT) technology at 978MHz is most commonly used by general aviation aircraft. The second type utilizes a 1,090MHz Extended Squitter (ES) Mode-S transponder and is most commonly applied to transport category aircraft (Federal Aviation Administration 2007). The MITRE Corporation has produced prototype UAT units for UAS operations including one that is transmit only and another that is capable of both sending and receiving ADS-B messages (Strain et al. 2007).

Airborne: Noncooperative, Active Active non cooperative systems scan ahead of the aircraft to identify local traffic and/or collision threats by emitting and then receiving some form of sound or energy. The technologies vary in size and configuration for airborne sensing of local air traffic and/or terrain features.

Radar can be equipped onboard a UAS for airborne sensing of other aircraft. Smaller non-cooperative radar systems have been employed in robotics applications in the past such as millimeter wave (MMW) radar. *Laser* systems such as LIDAR or laser range finders emit laser light, which is reflected off of the surface of a target. Depending upon the scanning technique, sampling resolution, etc., it is possible to analyze the shape of the target. The system can also track a target over successive scans allowing for a determination of range, bearing, speed, and trajectory. The sensors can be robust enough to support operation in conditions of low human visibility such as fog or smoke. *Sonar* systems utilize the emission of acoustic pulses. The time of flight from transmission to the reception of the reflection is used to determine the approximate range to the target. Due to the limited resolution and range, sonar at this time is not likely a viable option for airborne active sensing.

Airborne: Noncooperative, Passive Passive noncooperative systems do not emit sound or energy in order to detect a target. These sensors often cannot yield as robust of a data set as active sensors including safety critical data such as bearing, range, velocity, or trajectory of the target. *Electro-optical (EO)* cameras convert visible spectrum light into electronic signals and analyze the changes in data. EO cameras can be used with image processing algorithms to detect and analyze visible targets. Video or still images can also be rebroadcast to ground-based operators. Motion detection algorithms (Hottman et al. 2007) can be used to detect potential targets and track features of its motion by using multiple cameras. *Infrared* cameras are similar to EO but capture light frequencies within some subset of the infrared spectrum. These cameras and their processors can produce images for human operators as either black-hot objects or white-hot objects (i.e., with black-hot, the darker a pixel is within the image, the hotter it was perceived by the camera, and vice versa for white-hot). These images can also be examined by computer vision algorithms to do automatic target detection and tracking. One advantage of infrared is that it can operate in conditions where the visual spectrum is occluded such as fog and smoke (Access 5 2004). An *acoustic* system utilizes an array of microphones and processors to analyze the sounds within the airspace around the aircraft and can be capable of detecting and tracking local air traffic (Hottman et al. 2007). The viability of this approach is debated. For instance, a NASA Access 5 study indicates concern about the high signal-to-noise ratio (Access 5 2004). However, SARA Inc. has developed a prototype system utilizing a windscreen to dampen the noise from wind and aircraft vibration (SARA, Inc. 2008).

Ground-based: Cooperative *Traffic information system-broadcast (TIS-B)* is similar to ADS-B. Suitably equipped aircraft or ground stations can receive information regarding local air traffic. TIS-B uses ground-based radar to detect local air traffic. This information is then transmitted via uplink to aircraft equipped with an ADS-B receiver. The ground-based radars can detect non-ADS-B-equipped aircraft so long as they have a Mode-S or Mode-C transponder (Access 5 2004).

Air traffic control (ATC) radar-based separation is another approach that can be taken to aid the sensing of aircraft. Primary radar can be used to detect cooperative and noncooperative aircraft within a limited range. Secondary radar could be used to detect transponder equipped, cooperative aircraft.

Ground-based: Noncooperative *Ground-based radar* separation can be supported for noncooperative aircraft as well as cooperative aircraft. To detect a noncooperative aircraft, primary surveillance radar would be required. Such radar provides limited range and can have difficulty discriminating between local aircraft and other airborne phenomena such as birds.

Spotters can provide noncooperative ground-based sensing of local air traffic so long as the UAS is operating within their visual line of sight. The observer must be able to identify the aircraft and local air traffic. It is the spotter's duty to notify the pilot in command (PIC) if any perceived right-of-way issues exist with local air traffic. A pilot in command (PIC) is the UAS pilot/operator that has legal authority over the flight. Their responsibility from a regulatory point of view is analogous to the pilot in command of a manned flight. It is also common to have airborne spotters that observe the UAS and its local air traffic from a chase aircraft.

94.4.1.2 Avoid

The second category of SAA technology is *avoid*. Collision avoidance can be addressed through one of two primary mechanisms. First, the system can be diverted by a remote operator. Second, the aircraft could choose to autonomously avoid the collision using its autopilot. There can also be a blending of these two approaches. Aircraft autonomy is addressed further in Sect. 94.5.

94.4.1.3 Be Seen

The third category of SAA technology is *be seen*. This represents the ability for the aircraft to be seen by other aircraft both cooperative and noncooperative and ATC. This is divided into UAS equipage for being seen and UAS conspicuity.

Aircraft Equipage *ADS-B* can be equipped on UAS. The MITRE Corporation has developed the UAT Beacon Radio transmit-only and transceiver ADS-B (UBR-TX and UBR-TVR) prototypes for general aviation and UAS operations (Strain et al. 2007). This equipage would allow the UAS to be visible to ATC and suitably equipped local air traffic. *Transponder*-equipped UAS will also be visible to others whenever operating in range of a primary or secondary radar site. Lastly, *TCAS*-equipped UAS could be detected by other TCAS-equipped aircraft so that they could receive collision warnings and/or deviation instructions should a collision risk exist.

Aircraft Conspicuity An RTCA SC-203 report, DO-304 (RTCA SC-2003 2007), states the concept and need for conspicuity quote well:

Conspicuity: Many UA are small and made of materials that provide minimal radar cross sections. Aircraft that are difficult to see by human sight or by systems (e.g., radar or optical) can increase risks of collisions. These could be mitigated by paint schemes, lights or radar reflectors to enhance visibility, but these measures must be appropriate to the flight environment.

In addition to the techniques discussed in the definition above, procedural changes made by the UAS operator can also impact the ability of others to detect the UAS (Hottman et al. 2007).

94.4.2 Regulatory Gap Analysis

The regulatory gap analysis for SAA is divided into two areas of focus. First, FAA Title 14 CFR Part 91 is reviewed to identify regulations related to the PICs role to see and avoid other aircraft. Next, while not law, the AIM (Federal Aviation Administration 2012a) is examined because it provides guidance to pilots regarding their role to see and avoid other aircraft.

94.4.2.1 FAA Title 14 CFR Part 91

Title 14 CFR §91.111: Operating Near Other Aircraft This regulation covers restrictions forbidding the operator to control his/her aircraft in close proximity to other aircraft. The regulation states that operations near another aircraft cannot be made if a collision hazard exists. For manned aviation, this is an instruction to provide adequate self-separation to mitigate risk of collision. For an unmanned aircraft, this regulation points out the necessity of a separation mechanism. The sensing mechanism must have sufficient accuracy and resolution such that the operator and/or vehicle autonomy can determine both the location of the aircraft and the location of the other aircraft. The pilot in command and/or the autonomy must be capable of responding appropriately when a minimum distance of separation is violated. Qualitative and quantitative requirements for avionic components will be necessary to ensure that a sufficient level of safety is maintained.

Title 14 CFR §91.113: Right-of-Way Rules: Except Water Operations This regulation covers the necessary vigilance required by the system (operator and/or autonomy) to see and avoid other aircraft. It also identifies the right-of-way requirements concerning a variety of airborne platforms, as well as the right-of-way requirements among similar aircraft in various situations. The regulation also discusses right of way for landing aircraft. Similar to 91.111, there is a necessity of the sensing technology to determine when the UAS is operating at the same or a sufficiently close altitude to another aircraft and that the two aircraft are converging. There is currently no special rules for UAS. As regulators and engineers evaluate the safety case for passing operations, it is possible that such rules and priorities must be identified.

A potential gap exists with respect to UAS operating around aircraft performing landing operations. A landing aircraft is said to have the right of way. If two aircraft are landing, the lower aircraft has the right of way. This would require that the

aircraft be capable of not only sensing the other aircraft but also deriving its intent to land. Similarly, the regulation also gives right of way to aircraft in distress, which can likely be difficult to identify when the pilot is physically decoupled from the aircraft.

Title 14 CFR §91.115: Right-of-Way Rules: Water Operations This regulation covers right of way similar to 91.113 but includes water operation with interaction can include non-aircraft vessels. This includes head-on, crossing, and overtaking conditions with other vessels. This specifically must be addressed for UAS designed for water operations. Visual observation can be more difficult with water operations. Identifying surface vehicle capabilities and intent can also be more difficult for a UA and/or its operator.

94.4.2.2 Aeronautical Information Manual

Essential to the scope of this project, the AIM identifies the process of fulfilling the see-and-avoid requirements. It also provides a detailed synopsis of how ground operations should be performed. For ERAU's analysis of the AIM, excerpts were extracted that were deemed applicable to see and avoid processes of manned aircraft that would need to be replaced by SAA capabilities of UAS.

AIM §4-4-14: Visual Separation This section discusses visual separation as a mechanism for ensuring safe operation in the terminal area and en route. This includes visual observation provided by ATC in the tower within the terminal area. It also includes active scanning of the airspace around the aircraft to ensure separation. In most flight situations, scanning the sky is a necessary component of flight safety, and it is mentioned in AIM §8-1-6(c)(1) that spotting potential threats increases directly with the amount of time the operator spends scanning the skies. A SAA system would more than provide constant scanning. Unlike the human eye scanning at 10° per second limited by several blind spots in the aircraft, a SAA system may be less limited with regard to the distance, speed, and directions of sensing.

AIM §4-4-15: Use of Clearing Procedures This section discusses clearing procedures used to maintain visual awareness of the airspace around the aircraft. It defines expectations for pre-takeoff, climbs and descents, straight and level, traffic patterns at VOR sites, training operations, etc. It also distinguishes between low-wing and high-wing aircraft. UAS operations also require a clearing of the airspace to maintain assurance of safe separation with other aircraft. However, depending upon the see-and-avoid systems onboard, the need for actual clearing procedures may be reduced or eliminated given the scanning and/or field-of-view capabilities of the sensor(s).

AIM §5-5-8: See and Avoid This section simply restates that under permitting meteorological conditions the pilot has the responsibility to see and avoid other aircraft. The controller can provide local air traffic information as workload permits.

The controller can also issue safety alerts if other unsafe situations are observed. This relates directly to the sections of Part 91 discussed above.

AIM §8-1-6: Vision in Flight This section of the AIM discusses effective use of vision given various levels of illumination as well as techniques that can be employed to scan the sky. It also identifies some quantitative data that can be useful in determining human capabilities for aircraft detection. Some of these details can be relevant to UAS when dealing with ground observers. Other aspects may not be applicable as scanning techniques and the impact of illumination may have little or no impact on particular sensors.

AIM §8-1-8: Judgment Aspects of Collision Avoidance This section of the AIM provides guidance on handling unique collision avoidance situations. It describes determining relative altitude based upon the location of another aircraft with respect to the observer's determination of the horizon. This holds some relevance to visual sensors such as EO or IR cameras. However, some UAS sensors may not be capable of utilizing this technique or have better alternative results for altitude approximation. Visual observers on the ground would be unable to apply this technique.

The section also describes addressing multiple threats simultaneously. This calls on observation of the other aircraft as the pilot performs the avoidance maneuver to ensure that a secondary collision threat does not result. This can be challenging depending upon the SAA technology and the lack of situational awareness for the PIC. Some situations in which visual limitations exist are also discussed. For instance, poor windshield conditions are considered (which could be similar to a fouled sensor on a UAS), which would need to be replaced and/or repaired prior to flight. Similarly, smoke, haze, dust, etc. can reduce visual acuity for manned aircraft visual separation but may or may not have an impact for UAS operators depending upon the sensing techniques employed.

94.5 Case Study #3: Command, Control, and Communication Technologies for UAS

94.5.1 Technology Survey

UAS C3 for this study is defined as:

Command: Aspects related to ensuring the aircraft's progress toward completion of its mission including, but not exclusive to, flight automation, remote piloting, link loss (LL) procedures, situational awareness, flight ATC coordination, etc.

Control: Aspects related specifically to flight control including control surfaces, fly-by-wire(less) systems, and aspects involving flight control at the GCS including cockpit indicators and aircraft controls (yoke, pedals, throttle levers, joystick, touch screens, etc.)

Communication: Aspects of wired and wireless communication necessary to ensure safe operation of the aircraft and communication with ATC regardless of the UA's proximity to the GCS.

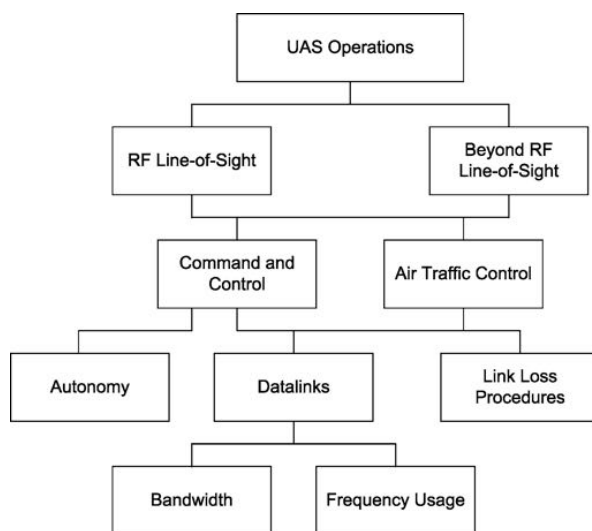

Use of the C3 acronym is not without issue. C3 as originally used by the U.S. Department of Defense (DOD) had “command” meaning ordering tactical elements to carry out some particular mission or goal, “control” as execution of that mission by means of verification of progress and correction toward the goal(s), and “communication” referring to communication between the command and control elements (United States Naval Academy 2008). The Radio Technical Commission for Aeronautics, Inc. (RTCA) Special Committee 203 (SC-203) has condensed this acronym to control and communication (C2), eliminating command. “Control” under their definition combines all aspects of the system necessary to direct the aircraft's execution of its mission; “communication” refers to both ATC communication and communication between the control station, the aircraft, and flight observers (air or ground based). Such a grouping is problematic, in that there are numerous regulations focusing upon control-related aspects, including those related to control surfaces, cockpit layout, pilot flight control requirements, and adequate redundancy.

A technology survey was performed on C3 technologies for current and near-future UAS. A web search yielded a summary of the UAS. From this list, representative aircraft with low, medium, and high endurance, operating within both RF line of site (LOS) and RF beyond line of site (BLOS), was selected. For each, a deeper search was performed to locate data sheets and other information. These data were compiled, and a hierarchical model was produced based on the key variation points among representative systems. Using this model and the data collected, the technology survey section was generated and organized. In this report, the terms LOS and BLOS will refer to line-of-sight capabilities of RF signal propagation. Any cases of visual line of site will be explicitly stated as such.

The C3 framework is shown in Fig. 94.3, organizing surveyed technologies into categories. UAS operations utilize LOS and/or BLOS communications. Under each, technical issues are divided into two categories, C2 and ATC. For C2, the survey explored technologies and issues necessary to safely support flight operations of the UAS from a remote pilot and/or control point of view. For ATC, technologies and issues on the interaction of the aircraft or PIC with ATC were explored. Various data links were examined including their frequencies and data rates. LL procedures are enumerated. For C2 only, the issue of autonomy, remote pilot versus autopilot, is examined.

It is important to note that most BLOS-capable UAS incorporate some LOS technologies. LOS operation may be divided between three classes of UA: low endurance, medium endurance, and high endurance. Low endurance operates almost entirely within LOS. Examples included Advance Ceramic Research's (ACR) Manta B (Advance Ceramic Research 2008), ACR's Silver Fox (Advance Ceramic Research 2008), Meridian (Hale et al. 2007), AeroVironment's (AV) Raven (AeroVironment 2008), and AV's Dragon Eye (AeroVironment 2008). Medium- and high-endurance classes operate in both LOS and BLOS conditions. Medium-endurance examples include Insitu's ScanEagle (Insitu 2008), Insitu's Georanger

Fig. 94.3 UAS C3 hierarchical system model

(Insitu 2008), and AAI Corp.'s Shadow (AAI Corp. 2008). Examples of high endurance include General Atomics' (GA) Predator (General Atomics Aeronautical Systems, Inc. 2008), GA's Mariner (General Atomics Aeronautical Systems, Inc. 2008), Northrup Grumman's (NG) Global Hawk (Northrop Grumman 2008), NG's BAMS (Northrop Grumman 2008), and AV's Global Observer (AeroVironment 2008). Table 94.17 lists some examples of LOS C3 technologies.

BLOS UAS cover primarily high-endurance UAS. Table 94.18 lists some examples of BLOS C3 technologies aboard UAS.

C2 Data Links LOS C2 data links use spectrum from VHF (30–300 MHz) to microwave C band (4–8 GHz) (Neale and Schultz 2007). The most common LOS data link employed for UAS is C band, using 3.7–4.2 GHz for downlink and 5.9–6.4 for uplink. C Band is strategically chosen its frequency less affected by extreme weather.

Some small UA like ScanEagle and Georanger, Meridian, Shadow, Dragon, and Raven use UHF (300 MHz–3 GHz) for LOS C2. It is not uncommon for these aircraft to utilize 72 MHz handheld remote control similar or identical to those used by hobbyists. Some experimental UAS use IEEE 802.11 for C2 link (Brown et al. 2006; Frew et al. 2008), allowing ad hoc networks between UAS. Their range is LOS and directional antennas may be required to ensure signal strength to maintain connectivity.

For BLOS, low Earth orbiting (LEO) and geostationary Earth orbiting (GEO) satellites represent two extremes for satellite communication (SATCOM). LEO satellites operate around 400 km (250 miles). GEO satellites operate around 35,800 km (22,200 miles). Because they are closer to the Earth's surface, LEO satellites can transmit equivalent bit-error-rate messages with lower power.

Table 94.17 Line-of-sight communication for a sample of surveyed unmanned aircraft

| Aircraft | Manufacturer | LOS communication | Characteristics |
|-------------|---|--|---|
| Predator | General Atomics Aeronautical Systems | C band | Wingspan 20.1 m Length 10.9 m Payload 385.5 kg Max altitude 15,240 m Max endurance: 30 h |
| Global Hawk | Northrop Grumman Integrated Systems | CDL (137 Mbps, 274 Mbps); UHF SATCOM | Wingspan 39.9 m Length 14.6 m Payload 1,360.7 kg Max altitude 18,288 m Max endurance 36 h |
| ScanEagle | Insitu Group | 900 MHz of spread spectrum frequency hopping; UHF command/telemetry | Wingspan 3.1 m Length 1.2 m Payload 6.0 kg Max altitude 4,998 m Max endurance 20 h |
| Meridian | University of Kansas | 72 MHz Futaba radio 2.4 GHz microband radio | Wingspan 8 m Length 5.1 m Payload 54.4 kg Max altitude 4,572 m Max endurance 9 h |
| Desert Hawk | Lockheed Martin | Military 15 km data link | Wingspan 1.4 m Length 0.9 m Payload 3.1 kg Max altitude 152 m Max endurance 1 h |
| Dragon Eye | AeroVironment | Military 10 km data link @ 9600 baud | Wingspan 1.2 m Length 0.9 m Payload 2.3 kg Max altitude 152 m Max endurance 1 h |
| Manta B | Advance Ceramic Research | Military band/ISM band radio modem; 24–32 km radio | Wingspan 2.7 m Length 1.9 m Payload 6.8 kg Max altitude 4,876 m Max endurance 6 h |

Since they are not stationary relative to the Earth's surface and narrower field of view, LEO satellite constellations require a larger number of satellites to achieve the same coverage as GEOs. In Peters and Farrell (2003), a constellation of 80 LEO satellites was compared with a six-satellite GEO constellation with equivalent coverage area using Ka band. The LEO constellation outperformed the GEO constellation with reduced latency, lower path losses, and reduced launch cost. A LEO satellite constellation has higher operational costs. Examples of widely used LEO constellations include Iridium (2008) and Globalstar (2008). For both cases,

Table 94.18 BLOS communication for a sample of surveyed unmanned aircraft

| Aircraft | Manufacturer | BLOS communication | Characteristics |
|-------------|---|---|-----------------------|

when the UA moves from one satellite's coverage area to another, service may be temporarily disrupted as communications are handed off.

BLOS C2 data links range from UHF (300 MHz–3 GHz) to Ku band (12–18 GHz) via SATCOM (Neale and Schultz 2007). Ku band is used by high-endurance UAS like Global Hawk, BAMS, and Predator and its derivatives. INMARSAT SATCOM data links, with a frequency range from 1,626.5 to 1,660.5 MHz for uplink and 1,525–1,559 MHz for downlink (INMARSAT 2008), are used by some high-endurance UAS including BAMS, Mariner, and Global

Hawk. L band iridium data links range from 390 MHz to 1.55 GHz (Iridium 2008) and are used by smaller, low- or medium-endurance research UAS such as Georanger and Meridian.

Certain military UAS use Common Data Link (CDL) or Tactical CDL. CDL is a jam-resistant spread spectrum digital link incorporating multiple microwave bands (Global Security 2008). CDL is mostly used for BLOS operations; it can be used for LOS operations to ensure continuously safe and seamless communication when deployed in hostile territory. Data sheets for larger military UAS (e.g., Predator-B, Global Hawk) show identical specifications to CDL without explicitly stating the technology is in use.

Flight Control Technologies and Operation Low-endurance UAS often uses LOS remote control (R/C) for at least part of the flight. For takeoff/landing, an R/C pilot controls the aircraft. Once airborne, the pilot can fly the aircraft manually or allow the autopilot to perform waypoint navigation along a flight path. Representative examples include Manta B, Meridian, Raven A and B, Dragon Eye, Silver Fox, and Shadow. High-endurance UAS often use autopilot for all LOS (and BLOS) flight operations. The flight plan is programmed into the autopilot. Once the mission begins, the aircraft will autonomously takeoff and follow the predefined path. The pilot remains out of the C2 loop but monitors the flight operations and, if need be, interrupts the autopilot and takes over piloting duties. Representative examples include Predator, Mariner, ScanEagle, Georanger, Global Hawk, and BAMS.

For BLOS operations, remote piloting becomes less feasible with SATCOM due to its latency. Most long-endurance BLOS UAS employ autopilots and a pilot on the loop (able to intervene if necessary). The flight plan is programmed in the autopilot via the GCS GUI.

C2 Link Loss Procedures In the original study performed by ERAU, lost link (LL) procedures were addressed as part of the C3 study. One year later, the ERFT study revisited this topic in greater detail. For the sake of conciseness and to avoid redundancy, this topic with respect to C2 will be further addressed within the ERFT case study later in this chapter.

ATC Communication, Coordination, and Lost Link For ATC LL, the objective is to reestablish voice communications between the GCS and the ATC authority. For LL with ATC for LOS operation, a land-based phone line is the only option currently used. Some UA are equipped with multiple VHF transceivers that could be used to establish a ground control to ATC voice communication link using the UA as an intermediary.

BLOS UAS PIC-ATC communications can utilize the UA as a communication relay. The PIC contacts the ATC facility local to the UA via VHF radio onboard the aircraft. For BLOS operations, reestablishing a connection after LL requires redundant voice communication systems onboard. For the Altair LL, the FAA and ATC were provided with detailed flight plans, making sure that the ATC knew

the aircraft's location. Additionally, the missions were planned meticulously with respect to ATC coordination, such that all potential ATC facilities are notified. The mode of notification was not explicitly disclosed (Ambrosia et al. 2007).

Using a UA as a voice relay with ATC has technical issues such as handoff. For manned aircraft, as it transitions from one ATC cell to another, the onboard pilot dials the VHF radio to the appropriate ATC channel as instructed through the handoff procedure. For several existing COAs and aircraft, the aircraft performs a rapid ascent to an altitude above controlled airspace (i.e., above 60,000 ft) and maintains this altitude for the duration of the flight. As a result, interaction along a flight path involving multiple ATC facilities is not common, and proper procedures to handle operations within controlled airspace have not been formally developed. For UAS to operate within ATC-controlled airspace in the NAS BLOS, further protocols must be established regarding the handling of the handoffs and setting of the new frequencies of the aircraft's ground-to-ATC relay. Another potential issue of using UAS as a relay is the spectrum availability to handle additional voice channels (25 kHz bandwidth) to support each UA (Heppe, personal communications, Insitu, Inc., 2008). A proposed alternative is to utilize ground-based telecommunications networks to connect the PIC at the GCS to the ATC facility under which the UA is operating.

94.5.2 Regulatory Gap Analysis

The C3 gap analysis examined 14 CFR Parts 21, 23, 25, 27, and 91 and the AIM. Each section was labeled *does not apply*, *applied as is*, *applies with interpretation*, or *applies with revision* with respect to the categories command, control, and communication. Fundamental gaps were identified as well as gaps associated with particular technologies and/or regulations. Related gaps were grouped as appropriate. Additional regulatory concerns not fitting into the above categories were also identified.

The regulatory gap analysis was performed iteratively. First, each section of the parts was classified using the four labels above for command, control, and communication. During the second pass, the reviewer annotated sections that were labeled as applicable with interpretation or revision. Third, the annotations were organized and merged to produce the regulatory gap analysis report.

94.5.2.1 Fundamental Gaps

Fundamental gaps were defined as issues with the existing regulatory framework resulting in widespread regulatory gaps from the fundamental difference between UAS C3 versus manned aviation C3 and their operating/flight procedures. The most fundamental gap is that UAS are comprised of two physically separate subsystems, the UA and the GCS at which the PIC is located, connected via data links. Secondly, ATC-PIC voice must now be reconsidered. Numerous gaps result from communication being decoupled for UAS. Under some instances, reinterpretation is required such as 14 CFR §§21.{3, 16, 19, 33, 35, 37, 45, 127, 305, 605, and 609}

and 23.1309. It was concluded that UAS should be certified as a whole, and any deviations from current TSOs as regulated in 14 CFR §21.609 should be acceptable only by demonstrating an ELOS for the entire system.

The second fundamental gap is the definition, roles, and responsibilities of the PIC. Because the PIC is no longer onboard the aircraft, regulations and procedures defined with this expectation must be reviewed and reinterpreted to address this change.

The decoupling of the pilot's flight control interfaces and the aircraft control system (autopilot, surfaces, etc.), and the required data link to support this wireless interaction, results in the next fundamental gap. Revisions would be required in 14 CFR §§23.{175, 177, 1329}, 25.{175, 177, 253, 331, 1303, 1329}, and 27.143 to ensure that the failure of certain data links will not result in a system failure. Regulations that previously described the redundancies needed between for flight controls and control surfaces may now be reinterpreted as applying to the data link.

94.5.2.2 Command

In industry and the military, UAS pilots have not necessarily been licensed pilots. 14 CFR §§21.37 and 21.31(b) call for the pilot to be licensed and medically certified in order to assume command of the aircraft. It must be decided whether UAS PICs require the same medical and training standards as licensed pilots. Training can be developed to certify licensed UAS operators, requiring at minimum pilot ground school. Flight instruction regulations are defined in 14 CFR §91.109. For a typical training flight, an instructor pilot sits in the aircraft's copilot position, having complete authority to take command of the aircraft at any time. UAS instructor pilots must similarly be able to override a UAS trainee, requiring GCS with a redundant set of flight controls offering the instructor pilot the same ability to immediately subsume the trainee pilot's commands.

Under 14 CFR §91.7, the PIC of an aircraft has the responsibility to perform the safety-critical preflight check of the aircraft prior to departure. This is suitable for UAS operations in which the takeoff and landing occur at the same site as the UAS PIC. If the takeoff and/or landing site is decoupled from the PIC, an approved designee must be permitted to assume this duty.

FAA UAS Interim Guidelines 08-01 require use of a ground- or chase aircraft-based observer to achieve SAA. Use of an observer produces gaps regarding AIM procedures and guidance. AIM §§4.4.1 and 4.4.12 define guidance stating that the PIC has overall authority regarding the safety of the aircraft regardless of any order issued by ATC. If the observers have greater situational awareness than the PIC, the chain of command in choosing how to respond to a safety-critical situation must be reconsidered. AIM §§4.4.14 and 5.5.1 both discuss the authority of ATC to command the aircraft in visual flight rules (VFR). It can be asked, should similar authority be given to the observer when, regarding vertical clearance, the surveillance capabilities of ATC within the terminal area are vastly superior to those of a ground observer? It may be necessary to set limits upon when a PIC has authority to accept or reject ATC orders and guidance from observers.

The need for pilot situational awareness and the ability to react quickly to adverse conditions conflicts with the physical decoupling of pilot and aircraft in UAS. 14 CFR §§25.253 and 23/25.671 discuss design of the flight control system to provide timely information to the pilot and to handle the commands in the event of a critical warning or sudden loss of control. UAS data link latency increases the time it takes for the pilot to become aware of an adverse situation and react. Maintaining an ELOS under these conditions is challenging. AIM §3.4.6 defines alert areas (e.g., areas of a heavy volume of training flights), and AIM §3.5.4 defines parachute jump areas. Higher situation awareness is also necessary when operating under special use airspace. UAS should be prohibited from both of these environments unless suitable SAA technology is approved. A remote pilot lacks the necessary situation awareness and the reaction time necessary to avoid a potential collision.

AIM §§4.1.19 and 4.4.14 define conditions in which the pilot would have to switch transponder or radio frequencies during transitions from various modes of flight. Current radios and transponders are equipped with knobs that must be turned to change frequencies. Approved alternative mechanisms must be developed to allow this transition to be triggered remotely or automatically.

94.5.2.3 Control

14 CFR §25.397 discusses mechanical loads placed upon the cockpit controls such as stick and wheel controls. Since the cockpit controls are decoupled from the control surfaces, this regulation is no longer applicable. Other mechanical requirements such as those in 14 CFR §§23.395 and 23.405 are no longer necessary as the aircraft is clearly in a fly-by-wire(less) control mode.

The requirement of status indicators to aid the pilots' situational awareness must also be reconsidered. 14 CFR §§25.1303, 23/25.1309, and 91.205 as well as AIM §1.1.19 define the indicators required for the pilot. Under the UAS paradigm, the indicator status information must be transmitted to the GCS and then displayed on the GCS flight control displays.

14 CFR §§23/25.1329 require the capability of the system to avoid becoming stuck in a hard-over. In the event of a GCS or data link failure, the aircraft's autopilot and control system should have sufficient intelligence to detect faults and prevent improper configurations from occurring.

14 CFR §23.679 discusses the need for lockouts of controls, while the aircraft is grounded to prevent accidental bumping of controls, but the lockout must be disabled and cannot be set during flight. For UAS, it may be necessary to include such mechanisms while in flight as well. Consider the need for a UAS operator (other than a PIC) to leave a position temporarily. It may be beneficial to enable a lockout mechanism given the lack of situational awareness to ensure the aircraft is not accidentally controlled by a 3rd party.

94.5.2.4 Communications

Regulatory gaps can be divided into communication segments. GCS-UA communication will focus upon the command data link. GCS-ATC will focus upon

ATC to remote pilot interactions, which may rely upon the UAS as part of the communication link.

GCS-UA Communications 14 CFR §25.143 requires the aircraft to be safely controllable and maneuverable during all phases of flight. The higher latency associated with BLOS operations adds challenges to meeting this regulation with an ELOS. Latency also impacts the remote pilot's use of SAA tools as TCAS and ADS-B, as well as a number of other data services provided by ATC must be rebroadcast from the UA to the remote pilot. The transmission of real-time state data for visual indicators specified in 14 CFR §§23.207, 25.1303, 25.1309, and 91.205 is similarly affected by latency.

There is also a need to address link loss detection and recovery, which is currently not regulated. 14 CFR §23.685 discusses the aircraft's mechanical design to preventing mechanical jamming throughout the aircraft's various linkages as essential to control systems. Loss of data link due to RF range or jamming (malicious or otherwise) represents a different but analogous type of jamming associated with controls. 14 CFR §91.511 requires aircraft to be equipped with sufficiently redundant communication systems for flight over bodies of water exceeding 30 min duration or 100 nautical miles extent. UAS component redundancy can be weight, cost, power, and space prohibitive.

GCS-ATC Communications The technology survey identified techniques to handle communication between the remote pilot located at the GCS and the controlling ATC facility. The major difference is that pilot communication does not originate from the aircraft, but the GCS. 14 CFR §91.185 requires procedures for handling a LL between a pilot and ATC. This regulation may be interpreted as requiring UAS to use a terrestrial telecommunications link from the GCS to the ATC in case the GCS-ATC radio link is lost.

AIM §4.1.15 discusses safety alert messages that require an immediate response by the pilot to avoid eminent damage to the aircraft and/or others; AIM §4.4.10 defines messages in which the word IMMEDIATELY may be added in order to inflect the urgency of the controller's command. As latency may make "immediate" infeasible, "immediate" may need to be replaced with a quantifiable time limit for the pilot to take action. AIM §5.3.1 defines en route procedures for pilots, and AIM §5.3.1.2 defines the controller pilot data link as a supplemental means of providing en route commands from the controller to the pilot. To ensure these en route directives are met, the UA must be equipped with a controller pilot data link, relaying that data back to the PIC at the GCS. Current guidelines do not require this capability and must be revised.

94.5.2.5 Other C3 Gaps

FAA TSOs (Federal Aviation Administration 2012c) are an additional source of regulatory gaps. For the TSO gap analysis, there is less concern regarding whether or not the performance standards are applicable with interpretation versus revision

as new TSOs may be issued with less effort than a change to the FARs. TSO-C9c: Automatic Pilots (Federal Aviation Administration 2012e) defines the requirements for automatic pilots, which must be approved for use in civil aircraft. This TSO is written toward an autopilot on a manned aircraft in which a pilot is in immediate control of the aircraft. The TSO references SAE Aeronautical Standards AS-402A (SAE International 2001). A detailed analysis of AS-402A yielded the following gaps. TSO-C9c §4.2.3 calls for “a controller, if present, it shall operate in the plane and with the sense of direction of motion of the aircraft. The control sensing shall be plainly identified on or adjacent to each control.” This requirement can be reinterpreted toward the requirements of the ground control station.

TSO-C9c §§4.3.1 and 4.3.2 call for “a means by which the pilot can be made cognizant of the condition, including control behavior” and “the direction and relative magnitude of the primary pitch servo present and other two axes.” This requirement may be re-interpreted toward the requirements of the ground control station. It must also be considered that any feedback of information to the GCS controls and indicators from the UA will be susceptible to latency.

TSO-C9c §4.4.1 calls for “corrective control to be: (a) Pitch $\pm 50^\circ$ (b) Roll $\pm 75^\circ$ (c) Yaw $\pm 20^\circ$.” Since the PIC is no longer in immediate control of the aircraft, the corrective controls about these three axes may require greater limitations of corrective controls, while the autopilot is engaged.

TSO-C9c §4.5.1 calls for “a system interlock to prevent the automatic pilot engagement until it has reached a fully operable condition.” For aircraft that handle autonomous takeoff and landing, this requirement is no longer relevant. However, for aircraft in which the PIC may manually remote control the aircraft, this requirement must be reinterpreted toward a requirement for the GCS.

TSO-C52b: Flight Director Equipment (Federal Aviation Administration 2012d) establishes minimum performance standards referencing SAE AS-8008 (SAE International 1984). The regulatory gaps identified are similar if not identical to that of TSO-C9c. TSO-C52b §3.6 calls for identical corrective control capabilities for the pilot, while the autopilot is engaged as TSO-C9c §4.1.1. Likewise, TSO-C52b §3.8 calls for the same lockout mechanism as defined by TSO-C9c §4.5.1. The recommendations for interpretation remain the same for each.

94.6 Case Study #4: Emergency Recovery and Flight Termination Systems for UAS

94.6.1 Technology Survey

To maintain a sufficient level of safety, UAS are equipped with systems to detect faults and failures of onboard components, including electromechanical systems (e.g., control-surface actuators) and avionics systems (e.g., data links, actuator controllers, and sensors). In emergency recovery (ER), the aircraft determines that a fault has occurred, recovering from it while maintaining safe flight. Link loss (LL) procedures, addressing and rectifying failure of command and control data links, are

a subset of ER. UAS experiencing LL or GPS loss may leave a predefined area for operation, the bounding box (BB), and need to be brought down. Flight termination (FT) technologies and procedure end the UA flight while minimizing the risk to the public and property. A flight termination system (FTS) is an onboard system that executes a flight termination, which may be remotely triggered via an independent communications channel by the PIC or automatically performed by the UA on the basis of aircraft conditions.

Information was gathered for UAS systems and related technologies related to emergency recovery, link loss, and flight termination. Data sheets and other materials were collected on a number of UAS and UAS subsystems. A questionnaire was developed and distributed to UAS researchers and industry workers, but very few vendors replied, and fewer were willing to provide data. After conversations with individuals in academia and industry, it was determined that the questions were too concerned with proprietary information and had the potential to expose issues manufacturers may not want made public, including experimental flight test results.

Figure 94.4 presents the developed ERFT conceptual framework. From left to right, the criticality of a vehicle loss and ramifications of such a loss increase. When criticality is low, health-based recovery systems diagnose and correct the problem, and the vehicle continues onward. With greater criticality, mission-level contingency systems handle an emergency recovery, often accompanied by termination of the aircraft’s mission. The final and most extreme response is flight termination. In addition to this framework above, UAS pilot procedures differ from those for manned aircraft with the difference in some cases tied to the technology being used, but in others coming from fundamental differences between UAS and manned aircraft, and their operations.

Table 94.19 summarizes the ERFT capabilities of several surveyed autopilots for small UAS (Vaglienti et al. 2008; Procerus Technologies 2008a; MicroPilot Inc. 2005). Table 94.20 presents the ERFT capabilities of several of the surveyed aircraft (Heppe, personal communications, Insitu, inc., 2008; McDuffy, personal communications, Insitu inc., 2008; Butler and Loney 1995; Flightglobal 2009b; Winstead 2008; Flightglobal 2009d; Flightglobal 2009a; Donaldson and Lake 2007).

Health-Based Recovery Health-based recovery systems handle less extreme aircraft system faults and failures in which the aircraft’s mission continues by adjusting the vehicular attributes. Redundancy is the more common framework for

Fig. 94.4 A framework for guidance of ERFT technology survey

Table 94.19 Autopilot ERFT capabilities

| Autopilot | Contingency-based recovery | Flight termination |
|------------------------|--------------------------------------|--|
| Cloudcap Piccolo | Return to waypoint | Mission selectable from close throttle, aerodynamic termination, and/or deploy parachute |
| Procerus Kestrel | Shallow bank until restored | Aerodynamic termination |
| Micropilot MP-2028g | Mission selectable (see next column) | Mission selectable from fly to climb, descend, roll, eject chute, etc. |

Table 94.20 Known ERFT capabilities for surveyed aircraft

| Aircraft | Manufacturer | Contingency-based recovery | Flight termination |
|-------------|--------------------------------|---|--|
| ScanEagle | Insitu, Inc. | Loiter at point for lost link | Aerodynamic termination if departs mission area |
| Predator | General Atomics | Return home for lost link | Optional parachute for early models |
| Global Hawk | Northrop Grumman | Contingency flight paths for various emergency/ contingency modes | Terminate with extreme prejudice |
| Polecat | Lockheed Martin | Unknown | Terminate with extreme prejudice |
| X-48B | Boeing and Cranfield Aerospace | Unknown | Parachute, airbags, and spin parachute (for stall testing) |
| Arrow | Jordon Military | Unknown | Parachute and flotation device |

health-based recovery, while fault detection, identification, and recovery (FDIR) is a recent approach to health-based recovery. With sufficient redundancy, when a component becomes non-functional, it is possible for the control system to transition to a backup system and continue nominal operation. A European UAS research commission recently funded the development of a medium-altitude UA equipped with a redundant engine (Flightglobal 2009c). Redundancy is common in civil and military aviation, with dual or triple redundant systems used for safety-critical hydraulic, electrical, and computational components within aircraft.

For fault detection, residuals representing the error between the expected and actual responses of the aircraft’s systems are calculated. Fault identification analyzes the residuals to identify the cause of the problem. Fault recovery adjusts the control system dynamically, reducing the impact of the failure and restoring nominal operation. If the recovery system is unable to perform such a restoration, then a

mission contingency plan or a flight termination system may be activated (Rotstein et al. 2006; Atkins 2004; Heredia et al. 2004).

Mission Contingency Recovery In mission contingency recovery, the aircraft deviates from its current mission to one of several possible emergency-recovery modes, altering its flight path to mitigate risk due to the failure and/or allow safe recovery of the aircraft. As an example, the Global Hawk UAS possesses a sophisticated contingency management system (CMS) with recovery modes including link loss recovery, return-to-base command, abort landing command, and land now command (Winstead 2008). For each of these, the CMS redirects the aircraft to a flight path appropriate for the current mode, requiring all points along the mission route to have contingency routes that branch off for each contingency mode. Along a contingency route, additional contingency routes can be branched off should additional failures occur. Figure 94.5 presents a primary flight path and a number of contingency branches for Global Hawk. In this figure, only three abstract contingency modes, C1, C2, and C3, are considered. Such an elaborate contingency plan allows ATC along the mission and contingency paths to be aware of the aircraft's potential presence and the circumstances for that presence.

As it is unsafe to operate a UAS when the control data link between the aircraft and the ground control operator is down, lost link procedures are considered contingency-based recovery. The survey revealed that the most common LL procedure is for the aircraft to fly to a predefined location, where it can either loiter until the link is restored, autonomously land, or be remotely piloted via secondary data link (Walker 1997; McMinn and Jackson 2002; National Transportation Safety

Fig. 94.5 Contingency routes for Global Hawk (Winstead 2008)

Board 2008; Ro et al. 2007). The BAT III LL procedure is a simple return home functionality, flying directly to the last known location of the GCS (Ro et al. 2007). Within sufficient range of the GCS, a remote pilot controls the aircraft to land. NASA and Boeing's PhantomWorks X-36 follows a similar method of returning to base and loitering (Walker 1997), but rather than return to base directly, the aircraft follows a predefined return path. Researchers at NASA Dryden are developing a path-planning algorithm for return-to-base and LL operations ensuring that the UA stays within its authorized flight zone (McMinn and Jackson 2002). LL procedures for BLOS operation in either medium-endurance or high-endurance UA are nearly identical to LOS operations. Altair flew in NAS for Western States Fire Imaging Mission. During one of its missions, the UA had a modem malfunction, resulting in BLOS Ku band C2 LL. The aircraft switched to C band and flew to a predetermined loiter point until the link was reestablished (Ambrosia et al. 2007).

For small UAS, commercial autopilots have contingency management features for link loss. The Piccolo Autopilot (Vaglienti et al. 2008) supports a lost communication timeout in seconds. If after that specified time a message from the GCS has not been received, the aircraft flies to a LL waypoint. The Procerus Kestrel lost link procedure returns the aircraft either to base or an alternate "rally point" (Procerus Technologies 2008b). Micropilot's various autopilots allow users to define the response to the lost link procedure and the criteria for diagnosing the lost link (Micropilot 2008). Its LL procedure supports the return to any waypoint or alternatively to trigger a FTS.

Flight Termination A FTS brings an aircraft down expeditiously while maintaining an appropriate level of safety to public and property. Given sufficient redundancy, a FTS may not be necessary, but two motivating factors for having such a system include insufficient redundancy, often the case for smaller UAS, and the FTS being mandated per conditions of the restricted airspace in which the aircraft is flying (i.e., range safety).

One approach is to aerodynamically terminate a flight by setting the aircraft's control surfaces to a state resulting in the vehicle crashing into the ground or a body of water in a semi-controlled manner. One form of aerodynamic termination is to perform a slow downward spiral, allowing some aircraft damage to be mitigated by a slow descent and the aircraft's final position to be controlled. This mechanism is ideal under airspace violation events, as it prevents deeper intrusion into an unauthorized airspace. This technique is used by the Insitu ScanEagle (McDuffy, personal communications, Insitu inc., 2008) and is also provided as a feature by the Piccolo (Vaglienti et al. 2008), Micropilot autopilots (Micropilot 2008), and the Kestrel autopilots (Procerus Technologies 2008b). In glide-path descents, the aircraft glides from its current altitude to a landing site without engine power. Under a glide-path termination, a suitable landing site may be designated by the UA PIC (Atkins 2004) or autonomously (Atkins 2004; Fitzgerald et al. 2005). Glide-path descents for high-altitude UAS allow the aircraft to terminate in a region in which the risk can be mitigated, as the aircraft can glide out over the ocean or an unoccupied area before impacting with the surface.

Several ballistic recovery systems are available to handle flight termination of an unmanned aircraft. Parachutes have a history of use in manned aircraft, and some technical standard orders exist (Federal Aviation Administration 2009c). Autopilots such as the Piccolo (Vaglianti et al. 2008) and Kestrel (Procerus Technologies 2008b) allow parachute deployment to be part of the FTS if the target aircraft is appropriately equipped. While not a standard feature, parachutes have been installed on the Predator UAS (Butler and Loney 1995), and a number of other UAS are parachute equipped (Flightglobal 2009c; Donaldson and Lake 2007; Procerus Technologies 2008b; Micropilot 2008; Vaglianti et al. 2008). Parafoil parachutes provide additional loft permitting greater control for the aircraft such that it is possible to achieve a glide-path approach (Fitzgerald et al. 2005). This is used on the BAE SkyEye and the IAI I-View (Donaldson and Lake 2007). Some aircraft such as the X-48B also include spin parachutes, which aid in recovery of an aircraft caught in a spin. Airbags or flotation devices may accompany parachute-based FTS. The X-48b is equipped with airbags to reduce the forces at impact (Flightglobal 2009a). The Jordon Arrow is equipped with a foam body in order to remain buoyant if the aircraft is terminated in the water (Donaldson and Lake 2007).

94.6.2 Regulatory Gap Analysis

This section presents the process and results of the ERFT regulatory gap analysis. Title 14 CFR Parts 23, 25, 27, 29, and 91 were reviewed as well as guidance materials, including the Aeronautical Information Manual (AIM) (Federal Aviation Administration 2012a), Airplane Flying Handbook (AFH) (Federal Aviation Administration 2009a), and Helicopter Flying Handbook (Federal Aviation Administration 2009b). Regulatory gaps were organized based upon aspects of pilot/crew procedures, health-based recovery, contingency-based recovery, and flight termination. Both fundamental gaps, regulatory gaps that exist because of the difference between technologies when regulations were written and UAS technologies utilized, as well as open-set gaps, gaps due to UAS technologies that have no analogue with currently regulated technologies, are identified.

The gap analysis was performed by an iterative process. The regulatory and guidance materials to be considered were determined and collected, followed by an initial review employing coarse filtering to identify ERFT-relevant sections of those materials. Rubrics were developed for each of the four aspects to determine the level of applicability of each section, introducing greater transparency and consistency in identifying gaps. The rubrics provided aspect-specific criteria to facilitate consistent classification of the section as applying as is, applying with interpretation, applying with revision, or not applying. Their length precludes their being included here; for the full text of the rubrics, see Stansbury et al. (2009a). A representative example of a rubric is shown in Table 94.21 for assessment of regulations/procedures related to pilot procedures. Using the rubrics, team members analyzed the identified sections, adding annotations to justify each classification. Chapter 16 of AFH was analyzed through a less-formal procedure by deriving the implications of manned emergency

Table 94.21 Rubric for assessing regulations related to pilot procedures

| | |
|-----------------------------|---|
| Does not apply | Regulation or guidance material does not discuss procedures relevant to the emergency recovery/contingency procedures to mitigate risk |
| Applies as is | Regulation or guidance material discusses procedures relevant to the emergency recovery/contingency procedures to mitigate risk. Given current language, applicable as is need for interpretation or revision for UAS paradigm |
| Applies with interpretation | Regulation or guidance material discusses procedures relevant to the emergency recovery/contingency procedures to mitigate risk. Parts of the language of the regulation require interpretation toward equivalent operations for unmanned aircraft |
| Applies with revision | Regulation or guidance material discusses procedures relevant to the emergency recovery/contingency procedures to mitigate risk. Regulation defines procedures of the pilot for safe operation within NAS that are unachievable for UAS given the language as it is written |

procedures for UAS. The results of the several analyses, including the annotations, were discussed to determine a consensus as to the level of applicability of each section. The discussion below focuses upon regulations that required revision or interpretation. Fundamental gaps and open set gaps were also identified. The result of the gap analysis follows.

Pilot and Crew Procedure Gaps Title 14 CFR §91 and the AIM were examined regarding pilot and crew procedures. The AFH was also examined as it indicates expectations of the PIC of a manned aircraft in an emergency. Pilot and crew procedures defined within 14 CFR Part 91 assume the pilot, crew, and passengers are onboard the aircraft. While the pilot of a UAS may no longer be onboard the aircraft, it is possible for a remotely piloted or autonomous aircraft to carry passengers or crew in the not too distant future. These regulations cannot simply be dismissed for “unmanned” aircraft, but rather must be interpreted or revised to be appropriate for cases in which pilots, crew, and/or passengers are or are not onboard. Examples of these regulatory gap include 14 CFR §§91.509, 91.511, and 91.513, which define survival equipment for emergency evacuation for overwater flights, and 14 CFR §91.501, which requires any crewmember onboard the aircraft to be familiar with the emergency equipment and emergency procedures onboard the aircraft before flight. This regulation is also written with the assumption of the PIC being onboard the aircraft and must be reinterpreted.

Procedures for normal flight operations impacted because the pilot is not aboard the aircraft include operations where a pilot would diagnose or respond to an emergency situation that could be handled through health-based recovery, contingency-based recovery system, or flight termination. An example is AIM §§5-4-11, 5-4-14, and 5-4-16, defining arrival procedures, including instrument approaches and simultaneous landing approaches. Under these conditions requiring fast reaction times, the need to abort a landing or deviate from an arrival path could be better handled through contingency-based recovery, which can both restore safety and send a notification to ATC. Similar issues of deviation and notification of ATC exist in AIM §§6-1-1, 6-1-2, and 6-2-1, which define emergency procedures, and AIM §7-1-14, which defines weather avoidance assistance procedures. Other procedure-related guidance includes AIM §6-2-5, which defines requirements for use of the onboard emergency locator during emergencies such as ditching, which under the UAS paradigm ought to be activated by the flight termination system; AIM §6-3-3, which defines procedures for selecting a suitable glide path to ditch the aircraft, which under the UAS paradigm could be performed by the PIC, FT system, or both; and AIM §6-4-2, which defines procedures for a pilot handling the loss of a communication link with ATC. The health-based recovery should be responsible for diagnosing the issue and switching to a redundant communication system if available; if communication is not restored, the contingency management is better capable of handling the procedures for transponder settings to alert ATC of the issue and performing appropriate LL procedure.

Throughout the regulations and the AIM, the pilot is assumed to be capable of issuing a distress call and/or rapidly communicating any sudden deviations with ATC. Given the significant changes to the communication paradigm between pilot, aircraft, and ATC, these procedures need to be revised or significantly reinterpreted. Guidance materials falling under this gap include AIM §5-3-1, which is written assuming traditional communication paradigms for manned aircraft, instead of the aircraft acting as a relay; AIM §§6-1-1, 6-1-2, and 6-2-1, which discuss the ability to deviate from standard procedures in an emergency; AIM §6-3-1, which discusses distress communications where the PIC must provide immediate notification and response to notifications dependent upon the condition and the directives of ATC, with “immediate” being made difficult because of latency; and AIM §6-3-2, which discusses request for emergency assistance when flying under distress.

Additional pilot- and crew-related gaps from Title 14 CFR and AIM include 14 CFR §91.609, which establishes the requirement for flight data recorders and cockpit voice recorders in transport category aircraft; AIM §1-1-19, which assumes that onboard global position system (GPS) would be identical to the currently technical standard order (TSO)-defined units featuring a graphical display for the pilot. Under the UAS paradigm, the GPS can likely be different from these TSOed GPS units and thus may require entirely different procedures for addressing a minor or major GPS failure. Aspects of chapter 16 of the AFH suggest that a new approach will be required regarding emergency situations in UAS. In a traditionally piloted aircraft, the pilot uses visual means to best determine the location in event of an unplanned landing. UAS require either dedicated space in which to fly or technology

to implement determination of the location for a flight-termination event. There is currently no performance specification for such a technological solution. Also, the necessity and means of informing other aircraft in the event the UAS engages in ERFT procedures should be specified. Finally, in the event of a ground-based or airborne observer, procedures should be specified to handle loss of visual contact with the UA, whether due to IMC or some other situation.

Health-based Recovery Gaps For health-based recovery systems, the gap analysis focused upon regulations for equipment that identified potential risks and mitigated them through corrective measures that did not alter the aircraft's current flight plan. Similar to the procedural gaps, the physical disconnect of the pilot from the aircraft lead to situations in which the regulation must be interpreted or revised toward the use of a health-based recovery system to address the situation. 14 CFR §§23/25/27/29.672 mandate that an indicator light notify the pilot if there is a loss in stability control. Under the UAS paradigm, due to data link latency, an indicator light may not be sufficient for notifying the pilot of this situation. The regulation also calls for the aircraft's control to be recoverable by the pilot. However, a health-based recovery system could be capable of dynamically reacting to the fault and recovering stability control. If such a system were onboard the aircraft, it would be necessary that it be demonstrated to provide an ELOS, and the regulation must be reinterpreted to consider such an alternative.

Engine fire suppression systems as mandated by 14 CFR §§23/25.1195 can be considered a health-based recovery system currently onboard some manned aircraft. This regulation requires revision for a number of reasons. The propulsion system of a UAS may not be based upon the use of an internal combustion (e.g., fuel cell, electric motors), which would likely not need a fire suppression system. Based upon the size of an aircraft, requiring such a system may produce a significant burden. For instance, a small hand-launched UAS could likely be incapable of handling such a system and remain airworthy.

Health-based systems may be capable of handling a variety of different failures either by initiating the appropriate transition to a redundant system or by diagnosing and recovering the failure directly. As a result, regulations such as 14 CFR §§27.695 and 29.695, which discuss recovery from power and control failures, ought to be reinterpreted to consider the health-based recovery system operating in place of the pilot in command. Similarly, health-based recovery may be capable of providing the "immediate" response to some emergency situations defined in the AIM such as AIM §5-4-11.

In AIM §§1-1-1, 1-1-12, and 1-1-20, it is assumed that minor failures of navigation aids may be detected by the pilot in command and the pilot can then act appropriately to maintain safe flight. Under the UAS ERFT framework, a health-based recovery system could both detect and recover from a minor fault without having a significant impact on flight. Voice communication loss and recovery is discussed in AIM §6-4-1. A health-based recovery system could be utilized in place of pilot procedures to autonomously change to a redundant communication link.

Contingency-Based Recovery Gaps Because contingency-based recovery results in the UAS deliberately changing course to recover from some emergency condition, the procedural guidelines as defined in the AIM may require some re-interpretation because of the physical separation from the UAS with its contingency-based recovery system and the pilot in command. For instance, AIM §4-3-5 defines the necessity to quickly notify ATC in the event of a land abort. Since such a deviation may be executed by the contingency-based recovery system, the system must either alert ATC directly or communicate the event to the PIC who then notifies ATC resulting in added delay. This gap exists for a number of sections of the AIM including AIM §§4-3-5, 4-4-1, and 5-5-2.

Lost link procedures also generate a number of gaps. Current regulations do not address the command data link, but do address the voice communication channel. Recovery procedures for voice communication loss are defined in AIM §§6-4-1 and 6-4-2. The latter requires the pilot to notify ATC via a change in transponder setting. If the aircraft is used as a communication relay and the loss of communication with ATC occurs as a result in the link from GCS to UA failing, the pilot would be unable to command such setting change. Diagnosis and recovery of communication failures, however, could be handled entirely without the PIC actions as part of a predefined set of lost link procedures onboard the aircraft. It may be useful to define separate transponder alert settings for voice and data communication losses, respectively.

A number of other contingency situations occur in which the contingency-based recovery system would override the actions specified in the AIM. Specific examples include AIM §§1-1-1, 1-1-12, and 1-1-20 for corrective measures in the event of a navigation aide failure; AIM §7-1-14 for utilizing weather avoidance assistance; etc.

Flight Termination Gaps The examination of regulations and procedures related to flight termination focused upon those that addressed the ditching or emergency landing of an aircraft. One major gap that exists with respect to FT is the structural and restraint requirements for passengers and crew onboard aircraft. For UAS, it might be assumed that no pilot is onboard; however, in the future unpowered aircraft may still be used for passenger or cargo transport. In the case in which the intended design and use of the aircraft would not support any humans onboard, these safety regulations would not be applicable. If the intent is for passengers or crew, it should be possible to mandate only those safety elements necessary to support that use. Impacted regulations include 14 CFR §§23/25/27/29.561, 23/25/27/29.562, 23/25/29.803, 23/27/29.805, 23/25/27/29.807, 25/29.809, 25.810, 23/25/29.811, 23/25/29.812, and 23/25/29.813. Similarly, emergency/survival equipment and crew training on procedures to utilize this equipment are mandated in 14 CFR §91.501, 91.509, 91.511, and 91.513.

14 CFR §91.609 establishes the requirement for flight data recorders and cockpit voice recorders in transport category aircraft. This regulation provides no exemption for aircraft without a pilot in the cockpit, such as an unmanned transport-category aircraft. While a voice recorder could be useful to record communication between

ATC and the GCS-based operators, the wording of this requirement will likely require revision for it to fit correctly. 14 CFR §§25.1457, 27.1457, and 29.1457 also address cockpit voice recorders, though it provides the requirements of the device, rather than the requirement to have the device.

The AIM and chapter 16 of the AFH define procedures for the pilot if the aircraft must be ditched. AIM §6-2-5 defines the requirements for triggering the emergency locator upon ditching the aircraft. AIM §6-3-3 discusses the procedures for finding a suitable crash glide path to ditch the aircraft in water. In all of these cases, it may be possible to automate these tasks as part of the onboard flight termination system.

Fundamental Gaps During the gap analysis, fundamental gaps were identifiable because a significant number of regulations were identified as having gaps and the justifications for these gaps were very similar. The physical decoupling of the PIC from the aircraft qualifies as one of the largest fundamental gaps as it results in the largest number of regulatory gaps related to procedures and airworthiness regulations. For instance, any procedure requiring an immediate response must be reevaluated as “immediate” may no longer be achievable as currently understood due to latency and a lack of situational awareness.

A number of regulations and procedures are written regarding the safety of passengers and crew onboard the aircraft; however, one of the fundamental differences between UAS and manned aircraft is that a UAS can be constructed for operation solely without passengers or crew. All existing relevant regulations must be reinterpreted, revised, or eliminated from applicability for UAS. The GCS generates an additional fundamental gap as existing regulations for cockpit layout and equipment must be reinterpreted and/or revised in order to support aircraft control remotely. It may be necessary to revise existing regulations as some traditional cockpit controls have been eliminated in place of a mouse and keyboard being used to define waypoints and the autopilot controlling flight surfaces.

Under the AFH and HFH, procedures existed for the pilot to down the aircraft. A fundamental gap exists in regard to how procedures are written for UAS regarding emergency flight termination. A flight termination system such as a parachute is available to UAS, which is rarely seen or used by manned aircraft. The kinetic energy of a UAS can be dramatically different than a manned aircraft such that terrain considered previously unsuitable for an emergency landing may be adequate.

Open Set Gaps Several pieces of aircraft equipment must be evaluated to determine what regulations must be defined for their usage within an unmanned aircraft, as they are not typically found within a manned aircraft, including command data link; ATC/GCS voice link; GCS components; situational awareness sensors such as any onboard cameras, radars, and auditory sensors; health-based recovery system; contingency management system; and flight termination system (explosives or ballistic recovery system).

The PIC can only communicate with the aircraft via a command data link at the GCS. An open set gap exists because manned aircraft are not equipped with data

links for this purpose, and no existing regulations exist for the command data link as part of 14 CFR. Regulations must exist to define performance, link loss procedures, data frequencies, message sets, etc. In the event of a mishap, UAS technology must be equipped with a contingency management system capable of identifying the failure and then executing one of several possible predefined actions. A number of possible approaches are available. The open set gap occurs because nowhere in the current regulatory framework is such a system mandated nor its minimum performance requirements defined. Additional open set gaps exist for the roles of the UAS flight crew. Ground observer qualifications including training, health, visual acuity, etc. are not currently defined as part of the regulations.

94.7 Conclusion

This chapter has discussed the role of technology surveys and regulatory gap analyses in supporting the FAA and policy makers in understanding how the current regulatory environment must adapt to accept the near-disruptive technology of UAS. Earlier in the report, the concepts of the technology survey and regulatory gap analysis were presented, but without any specific best practices.

Each case study summarized published research conducted by the ERAU team over the course of several years. The first two studies involved propulsion systems for UAS (Griffis et al. 2008; Griffis and Wilson 2009). Next, C3 (Stansbury et al. 2008, 2009d) and SAA (Reynolds and Wilson 2008a, b) were studied. Finally, given the lessons learned from the previous studies, the ERFT study (Stansbury et al. 2009a, b, c) tried to pool together the best practices from the previous studies in order to produce a less subjective analysis of the regulations. It is recommended that the reader seek out these papers for further information and more detailed versions of their respective technology surveys and gap analyses.

This chapter concludes with the authors attempt to convey some recommended practices for conducting technology surveys and regulatory gap analyses. This shall hopefully allow those in the UAS community seeking to analyze other technology areas to start with a solid iterative foundation for conducting their studies.

94.7.1 Guidance on Performing a UAS Technology Survey

An iterative process is recommended for conducting a technology survey for a UAS. First, a web search will provide a summary of the market for a specific UAS technology. The preliminary results will likely be a list of UAS utilizing the technology, manufacturers of that technology, some major categories of the technology, and some high-level information on how the technology is applied to UAS. Second, given these preliminary results, a second survey of literature (both online and print published) should be conducted to derive a deeper understanding of the technology (i.e., specific data sheets, user manuals, guidance materials). The resulting data should be compiled. Third, a framework should be derived for

conceptually representing the technology, its subcategories, and its relationship to UAS. This model is used to help define the key points of variation among representative systems. Lastly, utilizing this model, a final technology survey is conducted in which collected references and additional research results are applied to the model to clearly articulate the representative cases of the various technologies as applied to the context of UAS.

94.7.2 Guidance on Performing a Regulatory Gap Analysis

The gap analysis proceeds in steps. The first step is to review Title 14 of the Code of Federal Regulations to determine putative applicability of the regulation to the particular technology at hand. Putative applicability is determined by as inclusive of an applicability criterion as possible: if the regulation could be construed through even a generous interpretation to apply to the technology, it is included in the putative list.

The second step is to develop rubrics which classify the regulation applied to the technology as one of applies, applies with interpretation, applies with revision, and does not apply. A rubric is developed for each element of the conceptual model or framework for the technologies under review. The language of the rubric should be such that a reasonably well-informed individual using the rubric should come to similar conclusions as to whether any given regulation applies to the technology at hand.

The third step is to apply the appropriate rubric of step two to each of the regulations in 14 CFR 1–199. Multiple individuals should perform step three, such that their results can be compared. Differing results should be discussed until agreement is reached as to the proper classification. Annotations should be provided to identify the rationale for the classifications made whenever necessary.

The fourth and final step is to compare the results of step three with the putative list from step one. Disagreements between the step three list and the putative list should be re-examined to ensure that the classification is appropriate.

Abstract

Unmanned aerial systems (UASs) have rapidly grown into a significant application for civilian operations. However, regulations and guidelines have lagged, leading to uncertainty for domestic development. Within the USA, there has been significant pressure to develop the regulations to utilize UASs within the National Airspace System (NAS), but there remains a significant amount of discussion on UAS operation and its subsequent safe integration. The purpose of this chapter is to discuss the challenges of UAS integration into the NAS for a class of small UASs for personal remote sensing (PRS). This approach is centered on the three pillared foundation for NAS integration presented by the U.S. Department of Defense (DOD) Unmanned Aircraft System Airspace Integration Plan and focuses on the specific challenges that are unique to the PRS UAS platform. This chapter presents a concept of operations for these unmanned aircrafts (UAs) along with an application scenario example and concludes with a discussion of the future use of UASs in the NAS and how it is achievable through adequate regulations and standards.

95.1 Introduction

Civilian and commercial unmanned aerial systems (UASs) regulations have remained largely underdeveloped, despite the anticipated growth of the UAS industry in the aerospace industry (Hill 2012). In the USA in particular, while regulations and standards have been developed for military applications, there has been little progress for domestic UASs to achieve access and integration in the U.S. National Airspace System (NAS) (Kaliardos and Lyall 2013). Within the U.S., exploratory reports such as the Small Unmanned Aircraft System Aviation Rule Committee (SUAS ARC) Comprehensive Set of Recommendations for sUAS Regulatory Development, the Interim Operational Approval Guidance Policy 08-01, and the Department of Defense (DOD) Unmanned Aircraft System Airspace Integration Plan have been released over the past decade attempting to address these issues, but many restrictions and uncertainties still exist, especially for civilian operations (Barnhart et al. 2012; Stark et al. 2012a). Compounding the issue is that to many people, unmanned aircrafts (UAs) are an unknown danger, their misperception due to the high profile of military UASs (Barnhart et al. 2012). While the dangers of a UAS should not be understated, these systems have the potential to be a valuable tool for a wide range of domestic applications. In particular, small UASs are expected to achieve a significant growth over the next decade as their potentials are fully realized.

Typically, UASs have been designed with the intent of completing missions deemed as the “three D’s”: dull, dirty, or dangerous. In these missions, UAs are utilized as a replacement for manned aircrafts in an effort to make these missions safer (DOD 2011). While this effort has been effective for military applications, the concept that UASs are to be a replacement for manned aircraft is a constraint towards the development of domestic uses of UASs.

Fig. 95.1 UAS prototypes (Utah Water Research Lab)

While many people view the primary application for UASs as espionage and warfare, they have a significant potential as a remote sensing platform. Small unmanned aerial systems (SUASs) can be effectively utilized as remote sensing platforms down to a personal level (Chen et al. 2011). While it is unlikely that everyone will own a UAS in the future, many people can utilize a method for data collection. In this capacity, a personal remote sensing (PRS) UAS can be defined as a class of unique application-based small unmanned aerial systems for specific data collection and remote sensing applications, either for scientific or commercial applications (Chao and Chen 2012). An example of a successful application can be found in the AggieAir Flying Circus, a remote sensing service operation that specializes in high-resolution, multispectral aerial imagery for a variety of applications (AggieAir Flying Circus 2012). This service center, sponsored by the Utah Water Research Laboratory (UWRL), has had a great deal of success providing its unique capabilities over several sites across the western USA with its fleet of UAS (Fig. 95.1).

Remote sensing operations come from a variety of scenarios. Geo-referenced aerial imagery can be utilized for rangeland management (Bestelmeyer 2006). Landowners can monitor the growth of crops using sophisticated imaging sensors (Hunt et al. 2010; Berni et al. 2009; Jensen et al. 2009). Wildlife researchers could utilize the imagery to the nesting habits of waterfowl (Jones et al. 2009). Scientific thermal imagery can be utilized for a wide variety of agricultural applications (Sheng et al. 2010) as seen in Fig. 95.2 (Chen et al. 2012). When equipped with thermal imagery sensors, UASs may be utilized in fire-fighting applications as well (Ambrosia et al. 2003; Casbeer et al. 2005). Emergency response personnel may use a PRS UAS equipped with thermal imagery to help in search and rescue operations (Rudol and Doherty 2008). Scientific researchers may use a PRS UAS to aid in wetland management (Jensen et al. 2011). These applications are all enabled through the use of UAS in a manner that manned aircraft could not accomplish at a much lower cost and a much safer level.

However, in utilizing these platforms, a variety of challenges are presented. UA can be a great tool, but when used incorrectly or maliciously, they can become

Fig. 95.2 Thermal imagery collected by AggieAir (Chen et al. 2012)

extremely dangerous. Compounding the issue, PRS UAS platforms are often similar in size to typical RC model aircraft. While safety is an important standard for RC model flying (AMA 2011) and are regulated by the Academy of Model Aeronautics (AMA), RC aircrafts are often incorrectly sold as toys in department stores, with little to no awareness of the danger that they could pose. This misconception can affect the mindset of users of the similarly sized PRS UAS, especially for those who started as an RC hobbyist with no familiarity of the AMA or their safety standards. Do-it-yourself hobbyists have flocked towards building their own UASs with no rules or regulations to follow to ensure their safety. Without proper regulations and guidance, this can present a significant threat. A serious discussion on the future of UASs must address several issues, none of which are easily solved.

- Who should be allowed to use UASs and in what capacity?
- What can be done to ensure that UASs are being used properly?
- How can regulations be utilized to promote air safety?
- Standardized training for commercial operations?
- Is strict regulation necessary the proper solution?
- How can PRS UASs be utilized efficiently and cost effectively in the presence of regulation?

Describing and defining a concept of operations is the first step towards addressing these concerns and understanding how UASs can be utilized effectively and safely in the NAS for everyone. The concept of operations described in this chapter (Fig. 95.3) is designed to help promote the utilization of UASs for personal remote sensing in a manner congruent with integration into the NAS and addresses the unique challenges and questions that these platforms present. This preparation is designed around the three foundations for UAS airspace integration: any UAS must be certified as airworthy, flight operations must be in compliance with any regulatory guidelines, and the UAS operators must be certifiably qualified (DOD 2011). With Fig. 95.3 as the big picture in mind, UAS operations in the NAS will become routine in the near future.

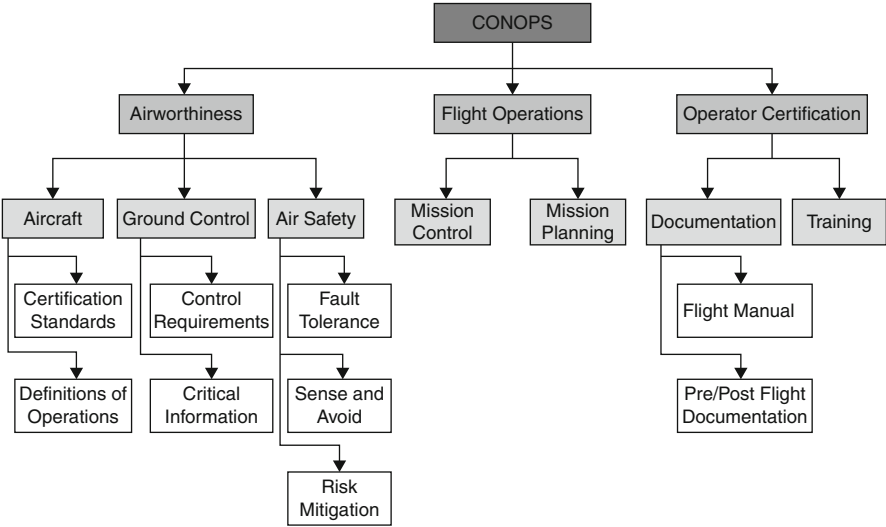

Fig. 95.3 Concept of operations for PRS SUASs (Stark et al. 2012a)

The rest of the chapter is organized as follows. The next section, Airworthiness, discusses the design criteria that are used to demonstrate airworthiness for UAS platforms. The following section, Flight Operations, introduces critical aspects for mission control and planning, with a special emphasis on the acquisition of mission data. An investigation into operator certification is presented in Sect. 95.4 towards a goal of understanding human factors and risk management in UAS systems. In Sect. 95.5, two example application scenarios are briefly examined. The final section concludes with a discussion to provide insight into the questions posed by UAS to NAS integration and comments on the future trends in UAS development for domestic use.

95.2 Airworthiness

Airworthiness is a broad concept that can be defined as containing the necessary criteria for safe and controlled flight (De Florio 2011). It brings together the major components of an airworthy system: proper aircraft standards, ground control criteria, and an emphasis on air safety. In the following section, each of these three aspects is discussed.

95.2.1 Aircraft Standards

Aircraft standards have been utilized to define the necessary requirements to promote an understanding of acceptable means of compliance with air safety requirements. Current regulations are underdeveloped, especially within the USA

While some regulations have been proposed, one area that they are still deficient on is the standards regarding the utilization of autonomous control and its effect on safety standards.

95.2.1.1 Current Regulations

In the USA, the Federal Aviation Authority has yet to release any specific regulations regarding UASs; instead current recommendations point towards the applicable sections of U.S. FAA Federal Aviation Regulations (FAR) 14 CFR Part 23 – Airworthiness Standards: Normal, Utility, Acrobatic, and Commuter Category Airplane (Federal Aviation Authority 2013). While some aspects are applicable, FAR 14 CFR 23 is deficient for many UASs, especially small UASs (SUASs) as defined in Group I (Table 95.1). An international attempt by the NATO Standard Agreement (STANAG) 4671: UAV System Airworthiness Requirement (USAR) was presented in 2010 (STANAG 4671 2010). Based on several existing regulations, including the FAR 14 CFR Part 23 and the European Aviation Safety Agency Certification Specifications – 23 (Normal, Utility, Aerobatic, and Commuter Aeroplanes), STANAG 4671 defines the basis for certification for military UASs. Recently, NATO has begun drafting of STANAG 4703 USAR Light (<150 kg) for defining the airworthiness of smaller UASs, and STANAG 4702 USAR Rotary Wing for airworthiness for rotary-wing UASs.

While the STANAG USAR regulations are focused on military applications, many of the concepts are applicable for PRS UASs. However, the smaller scale,

Table 95.1 UAS groups as classified in Department of Defense (2011)

| UAS groups | Maximum weight (lbs) | Normal operating altitude (ft) | Speed (kts) | Typical operations |
|------------|----------------------|--------------------------------|-------------|--|
| Group 1 | 0–20 | <1,200 AGL | 100 | Small portable systems for short-range surveillance and reconnaissance, within visual range |
| Group 2 | 21–55 | <3,500 AGL | <250 | Small to medium support for intelligence, surveillance, and reconnaissance in unimproved areas |
| Group 3 | <1,320 | <FL 180 | | Medium to long-range endurance for enhanced missions |
| Group 4 | >1,320 | | Any | Large UASs with extended range and endurance for beyond line of sight operations |
| Group 5 | | >FL 180 | | Includes the largest systems for specialized operations |

Table 95.2 Autonomous UAS control levels (Stark et al. 2012a)

| Level | Automation control qualifications |
|---------|--|
| Level 1 | Completely autonomous including autonomous sense and avoid (SAA) |
| Level 2 | Autonomous mission capable; UAS operator required for collision avoidance and mission re-tasking |
| Level 3 | UAS operator specifies desired aircraft attitude; control surface and throttle autonomously controlled |
| Level 4 | Remotely piloted; no augmented control |

lower margins for cost efficiency and mission applications necessitate adjustments, particularly in air safety. These standards would be beneficial in many ways but its effectiveness would be greatest in UASs that are flown regularly. The SUAS ARC, following public opinion, was explicit in exempting recreational use from following airworthiness regulations to provide the greatest latitude for model aircraft operators (SUAS ARC 2009).

For systems that are expected to fly regularly, such those flown by commercial operations, one deficient aspect of the STANAG USAR regulations is the lack of consideration towards the various levels of automation that may be utilized. A PRS UAS may have several levels of autonomous control and may be adjustable in mid-flight (Stark et al. 2012a). Mid-flight adjustments in autonomy are especially useful for mission re-tasking or for emergency contingency actions. Autopilot systems must be expected to act in a deterministic capacity in order for safety protocols or standards to be utilized effectively. A quantification of autonomous control levels is presented in Table 95.2.

95.2.2 Ground Control Station

The GCS plays a critical role in the airworthiness of a UAS. It is composed of two major aspects, the use of the GCS to aid UAS operations and the utilization of a communication standard.

95.2.2.1 Ground Control Station Standards

The GCS provides the UAS operator with a method for communication with the UA. The combination of a GCS and the onboard autopilot must be utilized to fully replace a manned pilot. Where the autopilot is deficient (by design or by automation level), the GCS must be able to provide the operator with sufficient knowledge to make informed and safe actions. Both STANAG 4671 and the SUAS ARC have suggested primary and secondary levels of information requirements. These listings are adequate for many uses, including PRS UASs, though in practice, the data that is presented is less important than how it is presented. Studies of human-automation interaction have utilized metrics such as situational awareness (Drury et al. 2006a,b),

and cognitive load (Ayaz et al. 2010; Bahner et al. 2008) to evaluate their systems (Parasuraman 2010). These metrics can be utilized to great effect in analyzing performance of a single UAS operator controlling multiple aircraft, though this application is currently recommended to be prohibited by SUAS ARC (2009).

95.2.2.2 Communication Standards

The role of communication between the ground and the UA is critical for maintaining safe operations. In typical PRS UAS operations, operations are limited to line of sight (LoS). In addition to safety reasons, this is also a result of utilizing common civilian frequencies. In the USA, unlicensed, industrial, scientific, and medical frequencies are governed by Part 18 of the Federal Communication Commission (FCC). These frequencies include 915 MHz, 2.45 GHz, and 5.8 GHz; the latter two are often significantly crowded with Wi-Fi Internet usage. These commonly used civilian frequencies are susceptible to noise that limits their effectiveness over long ranges. One counter to the overcrowding on these frequencies is to utilize frequency hopping, such as that found in Spektrum 2.4 GHz DSMX RC transmitters and receivers. By changing frequencies in a pre-agreed-upon pattern, a robust link performance can be achieved that limits inadvertent or malicious frequency jamming.

95.2.3 Air Safety

Air safety is a broad term that constitutes a significant portion of defining airworthiness. This can most effectively be accomplished through the use of assessments and risk analysis to address the most difficult aspect of integration of UASs into the NAS. STANAG 4671 proposes a Functional Hazard Assessment (FHA), congruent with existing airworthiness standards for manned aircraft that aims to identify all potential hazards and mitigating actions. In a typical procedure, a preliminary system safety analysis is performed by examining the individual operational phases: planning, staging, launching, flying, and landing. At each phase, the functions of each of the active components are identified and potential fault conditions are listed. Utilizing a common cause analysis metrics, the severity and probability of each of the fault conditions can be quantified (STANAG 4671 2010).

In this section, ideas and procedures are presented to assist in the development of an FHA and methods to improve air safety through fault-tolerant systems, sense-and-avoid systems, and risk mitigation strategies.

95.2.3.1 Fault Tolerance

Fault tolerance in SUASs such as PRS UASs is an important element for air safety. While full-sized aircraft can often utilize several layers of redundancy, smaller aircraft are often limited by cost or weight restrictions. Instead, extra emphasis can be placed on developing fault-tolerant systems in an effort to achieve an acceptable level of safety.

Faults are typically described as abnormal behavior or a complete loss of a component within a flight control system (Ducard 2009). These faults can be separated into two major categories: hardware faults and electronic faults. Hardware faults occur on the aerodynamic and structural components and range from mechanical failures to electromechanical failures, such as control surface ineffectiveness. Electronic faults are typically related to avionics or control systems, such as sensor failures, autopilot failures, or communication failures. It is important to note that not all faults need to be handled singularly by fault tolerance. The more effective strategy is to provide multiple levels of air safety by a combination of fault tolerance and risk mitigation strategies.

95.2.3.2 Sense and Avoid

The most challenging aspect for a UAS to meet is typically referred to as “see and avoid” for traditional manned aircraft. For a UAS, “sense and avoid” is a more appropriate phrase, but the concept remains the same. The ability to sense flight obstacles, including other aircraft and ground hazards, and perform evasive maneuvers is a critical element for UAS integration into the NAS (ASUAPO 2008; SUAS ARC 2009; DOD 2011). Sense-and-avoid systems are typically separated into two categories: airborne Sense and Avoid (ABSAA) and ground-based sense and avoid (GBSAA). In the USA, for both of these types of systems, adequate performance has typically been described as being able to detect a potential collision such that any avoidance maneuver will prevent the aircraft from being less than 500 ft from the object (DOD 2011). This is a significant technical challenge, especially for airborne systems.

However, for PRS UASs, the typical mission is accomplished within direct LoS in remote locations. Protocol for direct LoS operations may include the use of an observer that actively scans for potential hazards (DOD 2011). Unlike larger UA platforms, PRS UAs are typically small, slow but maneuverable aircraft that are capable of effective avoidance maneuvers, especially in the presence of other air traffic. The combination of LoS operations, remote locations, and effective avoidance maneuvers mitigates most other airborne threats and provides a sufficient ability to prevent collisions.

Beyond LoS operations pose a significantly greater challenge for SAA systems. In addition to the distinction between ABSAA and GBSAA, there is a distinction between cooperative and noncooperative SAA technologies. Cooperative SAA such as the traffic collision avoidance System (TCAS) and automatic dependent surveillance -broadcast (ADS-B) rely on the installation of extra equipment on the aircraft that allows for the transmission or broadcast of the UA’s information to other aircraft in the area (Angelov 2012). These technologies have a significant history of success for manned aircraft and are the superior choice for air traffic control. However, their effectiveness is limited to other cooperative aircraft. In the areas that PRS UASs are likely to be conducting missions, such as remote farmland, air traffic is typically not a great threat, but rather ground hazards such as satellite towers or noncooperative air traffic such as ultralight aircraft pose the greatest threat.

Fig. 95.4 AggieAir PRS UA with high-visibility reflective markers

Noncooperative systems, either airborne or ground-borne-based systems, typically rely on sensing technologies such as optical cameras, radar, or laser scanning. These systems have significant technical challenges ahead for their utilization to become common. A recent study of a pilot's ability to detect other air traffic suggests that the minimum resolution for an optical solution is $1,920 \times 1,080$ HD video and is only effective at ranges under 1 mile (Kephart and Braasch 2010). This aspect of SAA systems is an active area of current research (Angelov 2012).

While much work remains to be accomplished regarding SAA technology, more work can be done towards UAS observability. As a typically noncooperative aircraft, a PRS UAS must be designed to ensure an adequate level of observability to ground crew and other aircraft. This includes conforming to a high-visibility high-contrast color scheme as described in other specifications (MIL-STD-2161B 2008). While no standard has been developed specifically for UAS, bright colors such as yellow, orange, and neon green are effective when contrasted with darker blues, blacks, and purples. Illuminating lights such as those suggested in STANAG 4671 are also effective but not sufficient singularly. Reflective markers such as those depicted in Fig. 95.4 can be utilized effectively.

95.2.3.3 Risk Mitigation

Risk mitigation is a broad term that encompasses fail-safe protocols and off-nominal procedures to be performed when appropriate. Many of these protocols are designed to mitigate as much damage as possible in the event of an unforeseen event, considering first the safety of the operators, ground crew, and general public and secondly the recoverability of the UA. An incomplete listing of risk mitigation protocols is listed in Table 95.3.

Table 95.3 Risk mitigation protocols

| Fault | Protocols |
|------------------------------------|---|
| Loss of thrust | UAS operator takes manual control and attempts an emergency landing |
| Loss of GPS | UAS operator takes manual control and attempts an emergency landing |
| Loss of attitude | UAS operator takes manual control and attempts an emergency landing |
| Control surface failure | UAS operator takes manual control and attempts an emergency landing |
| Loss of datalink comm. | Autopilot may enter datalink communication fail-safe and return to a predesignated location, or UAS operator takes manual control and attempts an emergency landing |
| Structural damage | UAS operator takes manual control and attempts an emergency landing |
| Emergency kill situation | UAS operator deactivates all propulsion elements |
| Fail-safe control surface protocol | UAS operator activates control surface lock to place the UAV in a controlled trajectory termination immediately |

95.3 Flight Operations

A PRS UAS is primarily a civilian system. As these systems mature, they will be actively utilized in a large variety of applications. However, unless regulatory standards are fully defined and implemented, they pose significant risk. One of the most important requirements that must be introduced is a clear definition of the flight operations of missions. In this section, the defining characteristics of a flight operation, specifically the operational environment and mission planning, are presented.

95.3.1 Operational Environment

One of the distinct advantages of PRS UAS is the relatively short setup time required to organize for a mission. In an ideal setting, a UAS operator could set up the system, launch and complete a mission, and pack up in a couple of hours. In contrast, a manned aircraft conducting the same mission might require several days of planning and setup. Mission planning for a PRS UAS is still a critical element, ensuring that mission objectives can be accomplished safely.

In many typical PRS UASs, no infrastructure setup is necessary or is sufficiently portable and transportable (Fig. 95.5). This advantage allows missions to be conducted wherever ground access is available, allowing missions to be accomplished without the use of an established airport or runway. Air traffic is typically minimal

Fig. 95.5 Portable UAS launch equipment

and the entire operation can be accomplished within line of sight (LoS), and the terminal area (launch and recovery operations) occupies the same space as the operational area. In addition, most operations can be completely accomplished in low traffic class G airspace (DOD 2011), minimizing potential air traffic situations.

95.3.2 Flight Authorization

Operation of a PRS UAS must also conform to existing regulations on aircrafts. Few options in the USA are currently available for FAA authorization. The most common option is for UAS operators to apply for a Certificate of Waiver or Authorization (COA) that permits the use of a specific or class of UA with clearly defined operations. However, this is currently applicable for UA designated as public aircraft, a designation for aircraft used only for the U.S. Government or U.S. governmental functions such as national defense, law enforcement, search and rescue, and aeronautical, biological, or geological resource management (ASUAPO 2008).

However, there is plenty of confusion of the topic of UAS operation within the U.S. Currently, there are no official FAR that address UAS operations. However, the FAR has published several related documentation, including standards that may eventually become regulatory rules but are currently recommendations. One source of confusion on operating authorization stems from Advisory Circular (AC) 91-57, published in 1981. This circular encouraged voluntary compliance for model aircraft standards presented. Item 3.c is the most commonly referred item on this circular, stating that model aircraft are not to be flown higher than 400 ft. AGL (AC 91-57 1981).

In 2005, the FAA issued the policy statement AFS-400 UAS Policy 05-01 to provide guidance to determine if UAS may be allowed to conduct flight operations in the U.S. NAS (AFS-400 2005). This policy was not designed to be a regulatory,

though it has stood as the first attempt to standardize domestic UAS operations and developed the guidelines used for evaluating each COA application (Barnhart et al. 2012). In regard to the low-flying UAS operations that PRS UAs complete, item 6.13 is significantly applicable. This item lists that any UAs that comply with the guidance in AC 91-57 are considered model aircraft and are not evaluated by the UA criteria described in AFS-400 UAS Policy 05-01 (AFS-400 2005). This however was intended not to sanction civil operations but to continue the nonregulation of model aircraft and recreational use of the NAS (Barnhart et al. 2012).

In 2008, the FAA published the Interim Operational Approval Guidance 08-01 (IOAG 08-01) to replace AFS-400 UAS Policy 05-01. This document provided provisions for civil UAS operation through the use of a Special Airworthiness Certificate in the experimental category as the only certification available to civil operators. This document lists that all applicable regulations of 14 CFR parts 61 and 91 must be observed for UA (ASUPO 2008).

The SUAS ARC published in 2009 provides additional set of recommendations for SUASs (SUAS ARC 2009). This is largely congruent with the specifications described in the IOAG 08-01 with special consideration for the needs of SUAS such as PRS UASs. However, the recommendations listed are not regulatory or standards and are not meant to supersede any previous standards such as IOAG 08-01.

Future documentation and regulations have been promised, but their likely contributions would be similar to the standards and recommendations already in place.

95.3.3 Data Mission Assurance

While many UAS missions are defined by payload implementation, the data acquired is emphasized in a PRS UAS (Coopmans et al. 2012). Calibration, setup, and payload reliability are all aspects that dictate mission parameters. The goal of a PRS UAS is for maximum data quality and this plays a major role in mission design. The mission for a PRS UAS is designed around the data to be sampled rather than when it is convenient to fly. Weather conditions may not always be favorable, placing additional burden on preflight mission risk analyses.

95.4 Operator Certification

The UAS ground crew is a significant aspect of the unmanned aerial system. For UAS integration into the NAS, human factors must be considered (Kaliardos and Lyall 2013). Within the closed-loop UAS system, the decision making and the higher-level control of the system relies on the human element for system resiliency (Stark et al. 2012b). Utilizing the study of human factors in UASs, the human aspects of control, use, and safety operations can be effectively considered during the design of human training, record keeping, and organizational factors that make up the administrative part of a UAS.

95.4.1 Human Factors

A report by the FAA from December 2004 (Williams 2004) indicates the multitude of human factors in several military UASs. In this study, poor training and unfamiliarity of the new technology was described as the major factors in a significant number of UAS incidents. In order to quantify and study the various human factors involved in general aviation accidents, Shappell and Wiegmann presented a comprehensive human factors analysis and classification system (Shappell and Weigmann 2000). In this system, four levels of failure are described: Unsafe acts, preconditions for unsafe acts, unsafe supervision, and organizational influences.

Using HFACS, a similar report on UAS accidents provides a breakdown of the more common human factors for failures (Manning et al. 2004). Organizational influences were present in 14 % of accidents, while decision errors and unsafe supervision problems were present in 11 % of the accidents, respectively. This report also recommends the use of HFACS as a supplement to accident investigations as it provides valuable statistical data on the causes of human errors that help develop training programs. A later report offered similar conclusions (Glussich and Histon 2010), stressing the need for better training strategies as well as the need for more study.

Implementation of the organizational factors plays a significant role in reducing human-related errors (Shappell and Weigmann 2000). Constant repetition of procedures encourages commitment and aid the cognitive load of the humans in the loop, reducing the probability of errors (Bahner et al. 2008).

Utilizing these methods can lead to improving UAS ground crew training (Stark et al. 2012b). While the specific training hours for each skill set depends on the design and complexity of the UAS, the training program can be broken down into five programs: Basic UAS Operator Certification, UAS Aircraft Crew Certification, Mission Certification, Avionic Systems Certification, and Payload System Certification.

95.4.2 Documentation and Logs

An important step for the continued performance of the UAS is proper record keeping. This includes the continued implementation of pre-/postflight inspections, detailed flight logs, and flight reconstruction data collection. This ensures the airworthiness of the aircraft, the continued training of UAS operators, and the reduced human-caused failures.

Preflight analysis documentation and pre-mission documentation account for a high level of documentation but are critical aspects to maintain airworthiness. These documentations include but are not limited to flight-readiness reviews, pre-mission risk analysis, predeparture checklists, preflight checklists, and detailed mission procedures.

A preflight risk analysis is a common part of pre-mission operations. It is a part of military and general aviation procedures and its use for UASs is a natural

progression. This use of quantifiable metrics to analyze fly or no fly conditions removes ambiguity and promotes efficiency and safety (Barnhart et al. 2012).

Like traditional aircraft, the working parts of airframes have maximum flight hours. If these hours are exceeded, failure of these parts is likely. Logging of flight time allows maintenance schedules to be implemented for PRS-level airframes, increasing the safety for everyone in the airspace. RC aircraft typically do not list expected part lifetimes, making it difficult to gauge typical usage life. Thorough testing and verification is recommended for RC aircraft that have been converted towards regular UAS operations. Encouraging operators to log hours is a useful tool to promote a standardized proficiency in the UAS and to verify their experience.

Performance metrics for PRS aircraft designs allow failures to be documented and quantified, allowing designers to improve aircraft designs based on data gathered in the field. Other aircraft subsystems such as payloads, launchers, and ground support equipment can also be addressed in this fashion, enabling a trail of accountability for performance and safety.

95.5 An Application Scenario

There are countless numbers of applications where personal remote sensing enabled by UASs can provide significant benefits over traditional satellite imagery or manned aircraft. While other platforms can be utilized, small UAs can provide high-resolution, multispectral imagery at a higher rate due to their relative low-cost and reduced logistical requirements.

95.5.1 The Riparian Application Scenario

In this application scenario based on ongoing work done by the AggieAir Service Center, multispectral imagery is collected by a PRS UAS for riparian applications (Jensen et al. 2011). The goal of the proposed mission is to provide information that can be utilized to study the fish habitat within the river. Since the river is constantly changing, aerial imagery is to be collected at several times throughout the year. The mapping of the various flow conditions will be utilized to study the health of the river and its effect on the fish habitat. The important aspects of the data collection are that the river channel must be clearly identifiable with accurate georectification to provide sufficient resolution. The quality of the imagery and the timing of the imagery are both equally important for data analysis. Example raw imagery of this type of scenario is depicted in Fig. 95.6.

95.5.2 Mission Preparation

Given the river's remote location, large plots of land are available for launch and landing, as well as any emergency procedures. Neither air traffic nor local population is a major concern. In this particular mission, a target goal is <25 cm

Fig. 95.6 Example raw riparian imagery (a) NIR imagery, (b) RGB imagery

resolution, but the area coverage is large. The target flight altitude is recommended at 1,000 ft. This flight altitude is allowed by the COA issued to the aircraft at this location, but a notice to the air traffic control is issued as well. The preflight simulation estimates the total flight time expected at 30 min, well within the maximum flight time of the aircraft and the allowed flight time at this altitude as listed by the COA. The proposed altitude is within LOS, but binoculars are provided as a precaution. Given the conditions of the aircraft and the mission plan, the pre-mission risk analysis is largely dependent on the atmospheric conditions at the time of the proposed flight. On the day of the proposed flight, the weather conditions are favorable, ensuring that the mission is low risk and would provide the highest quality data conditions.

The flight path for data collection is a critical element. In order to achieve maximum data collection, the UA will follow the path of the river, and then sweep back and forth perpendicular to the river as it returns home. Preflight simulation estimates imagery coverage at 400 %, a sufficient level. Previous flights have indicated that turbulent wind at this altitude negatively effects data collection and thus a higher imagery coverage is necessary to ensure coverage.

In this regard, the understanding of the performance of the payload has affected the mission parameters. The collection of NIR imagery for the accurate mapping of the river necessitates that the mission occurs at the sun's highest apogee to minimize shadows that mask river detection.

95.5.3 Mission Success Metrics

The success metrics of this mission can be defined as the optimality of data collection with respect to flight time and the number of flights necessary to collect adequate information. The quality of the imagery is not known to the ground crew until the end of the mission. If the data is not usable, the mission must be repeated, an inconvenient prospect especially in the presence of time constraints (maximum sun apogee, rapidly changing flow conditions).

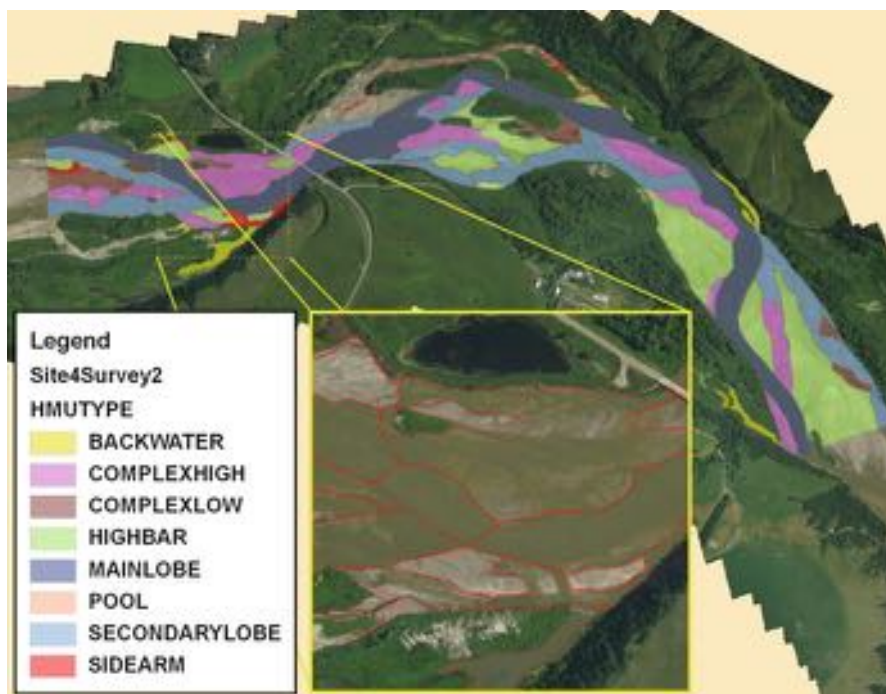

Fig. 95.7 Annotated mosaic a few days after flight with annotation by Rushing Rivers Institute (AggieAir Flying Circus 2012)

An example of the final imagery created through this application is seen in Fig. 95.7. In this image, with final annotations provided by Rushing Rivers Institute, the various flow levels throughout the year are visible in an understandable format that benefits riparian studies.

95.5.4 Applications for Advanced Payload Development or Human-Automation Interaction

Future work of applications of advanced cognitive payloads or human-interface devices can be utilized in several capacities. In future implementations, they may be utilized to improve UAS operation safety or to improve performance by adding additional autonomy to the UA. The development of these advances must consider their effect on safety, but at the same time, their development not be impeded through needless regulation.

The addition of a cognitive payload with an emphasis on data mission assurance can provide invaluable performance to PRS UASs. Utilization of payload management and resiliency aids in the development of reliable systems as well as reduce downtime due to faulty components. Low-cost systems often utilize commercial-of-the-shelf (COTS) equipment which may be at a lower quality standard and are more

prone to failures. Such resilient payload architecture can be utilized to monitor the sensors attached to the payload and initiate recovery operations or alert the ground crew (Coopmans 2012).

In addition, due to the offline nature of the high-resolution image collection, real-time processing such as data quality assurance or real-time autonomous target identification is not possible. An advanced cognitive payload that can process images for autonomous target identification (people, hazards, or areas of interest) or for image quality for data collection can be utilized to reduce the average flight time necessary for a mission. In-flight mission re-tasking could be accomplished with real-time information for an improve data collection (NSF 2011). A proposed system may be able to suggest areas that need to be collected again or may autonomously add these areas to its ongoing flight path. The prospect of adding more autonomy to flight planning would necessitate a further discussion on the safety factors, including ensuring its deterministic behavior and mitigation protocols for autonomous flight planning failures.

Human-automation interaction is a significant aspect that can be improved through the use of more cognitive payloads and advanced human-automation devices such as immersive goggles and more intuitive human-machine interfaces (HMI). These advances may play a significant role in improving the safe operation of UASs by utilizing more intuitive actions and information processing.

Conclusion

The concept of operations developed in this chapter was designed around the three foundations for UAS integration in the NAS described by Department of Defense (2011). For small UASs for PRS applications, these foundations are critical to implement because these are the UAs that are most likely to be the most commonly utilized. While there are many applications for UAs, the larger UAs are cost-prohibitive to the majority who would utilize their advantages. The smaller PRS UASs are presented as a cheaper and more efficient alternative for manned aircraft and larger UASs, especially where large spatial coverage is not necessary. However, the issue arises in answering the questions posed at the beginning in the chapter.

The most pertinent question addresses the users and in what capacity the users should be allowed to operate. Presumably, the most common users of these small UASs would fall into four categories: recreational users, personal usage for regular operations, commercial operations, and government/education agencies for development and scientific operations. Each of these groups have different purposes and reasons for flying UA within the NAS, but all of them have safety considerations that need to be addressed.

Recreational UAS operations may appear as the most dangerous due to the complexity of the systems; however, recreational use of the NAS with remotely controlled model aircraft has had a long history of success without strict regulation. As mentioned previously, the SUAS ARC recommended that this

nonregulation continue, with the AMA organization providing the self-regulation to maintain safety standards. This arrangement has encouraged innovation and development of the model aircraft industry and it would likely continue with the development with recreational UAs. The important aspect in this arrangement is the self-regulation of the AMA to enforce safety codes, especially flight altitude and flight operations that are already in place (AMA 2011).

Government agencies, educational institutions, and commercial operators are all groups that would look to utilize UASs on a regular basis and in operations that would exceed the recommendations of the AMA safety code. Regular usage at this level should be regulated in the methods described in this chapter's concept of operations documentation. Systems in use on a regular basis should be subject to airworthiness certification and regulation, enforced through the local aviation authority. Safety protocols and operator training should be an important part of UAS certification for these groups. This is to create a line of accountability for their actions that have a higher risk of danger or damage to the surroundings and local populace. Development of advanced technology such as SAA or advanced cognitive payload or control would not be impacted by this level of regulation but rather be encouraged by the importance of safety protocols.

The most challenging group to apply regulations towards is the middle ground between recreational use and regular personal use. While the standard safety codes regulated by the AMA may be sufficient for most users, many will want to extend beyond to higher altitudes and farther distances. This is already a contentious area for many in the RC hobbyist community in the frame of reference of first-person view (FPV) flying. In FPV flying, users will utilize long-range wireless cameras and fly their aircraft through a vision system, often beyond the safety code of the AMA. Discussions with AMA members and non-AMA members on the topic of FPV flying will lead to large variety of misinformation on the current regulations on FPV flying and F.C.C. regulations regarding video transmission. This is not an indication of poor management of the AMA but rather of an indication of the ever-changing technology and the slow response of new regulations and safety protocols. It is evident that a new method for the regulation of advanced technology is necessary.

However, there exists a close parallel to UAS operation in high-power rocketry (HPR), currently governed by the independent agencies Tripoli Rocketry Association (TRA) and the National Association of Rocketry in the USA. These agencies have special certifications for users that allow the use of their facilities for high-power rocketry. They are designed to provide a measure of the user's competence to avoid gross violations of good practice and safe operation (NAR 2012). Certification is only available to members of good standing of these groups and for higher levels of certification, an examination is required (NAR 2012). The rules and regulations for HPR is a combination of FAA regulations, the National Fire Protection Association (NFPA) regulations, and the NAR's and TRA's safety codes. The success of HPR suggests that SUAS operations, especially those in use for remote sensing applications, should follow a similar model to promote safety and ensure education among its users.

The future of UAS operations for PRS is bright and its implementation will open up a significant number of new avenues for research and data collection. While many see domestic UAS operations as a detriment to society (Paul 2012) or rife with privacy issues (Calo 2011), their immense potential as a valuable tool for water management, precision agriculture, and search and rescue operations, just to name a few, outweighs their potential downside with the proper rules and regulations in place. Management of UAS operations in the NAS is not an easy topic to address, but incrementally UAS integration into the NAS will become a reality.

Abstract

Unmanned aircraft will require a sense and avoid (SAA) capability to mitigate for the lack of a remote pilot’s ability to “see and avoid” other aircraft, which is an operational requirement. Regulators certify the airworthiness of aircraft, assuring their compliance with applicable regulations. Approvals of SAA implementations constitute part of that process. Each applicant will need to develop a Project Specific Certification Plan in close coordination with the regulator. Various tools for safety analysis and configuration control support this effort. Specification of the certification basis for SAA will need close attention, since the system addresses functions traditionally allocated to an onboard pilot. Algorithms and software will receive scrutiny due to their safety roles.

A.D. Zeitlin
The MITRE Corporation, Mc Lean, VA, USA
e-mail: azeitlin@mitre.org

Standards are developed to capture common requirements in support of systems that may use some degree of unique design innovation. A standard should suggest means of demonstrating compliance to its requirements, and so doing will greatly simplify the burden for both applicant and regulator. The closest existing standard to SAA is that for the Traffic Alert and Collision Avoidance System II (TCAS II), but SAA includes the additional function of self-separation. SAA can be implemented with various technologies in a variety of architectures.

SAA should provide two basic functions, each performing prescribed sub-functions. Considerable modeling and simulation will be required to validate system performance and support the safety case. The regulator may offer guidance to applicants through publication of an Advisory Circular.

96.1 Introduction

Airspace regulators approve aircraft and devices for flight in accordance with their responsibility to enforce regulatory requirements. Underlying those requirements is the principle of ensuring public safety. Today, the International Civil Aviation Organization (ICAO) requires airborne collision avoidance for certain manned aircraft (ICAO 2007, 2008) and describes the generic collision avoidance function as one layer in the overall scheme of safety provision (ICAO 2005). However, ICAO cautions that its presently mandated Airborne Collision Avoidance System (TCAS II in the U.S.) is not an appropriate solution for Unmanned Aircraft Systems (UAS) (ICAO 2006) and the same conclusion was reached by subsequent FAA analysis (FAA 2011). It has become widely accepted since UAS lack the ability for the remote pilot to comply with the operational regulation to see-and-avoid, that instead, a Sense and Avoid (SAA) system that includes collision avoidance needs to be developed for unmanned aircraft.

The UAS community generally recognizes an SAA function, also called Detect and Avoid (DAA), as necessary for obtaining routine access to non-segregated civil airspace. Some exceptions may be granted, such as where safety can be demonstrated by alternate means (e.g., using a manned chase aircraft, a ground observer, or relying on ATC separation or other procedures in special circumstances); or for very small UAS operations in visual range of the pilot on the ground. The U.S. Federal Aviation Administration (FAA) currently defines operational limits and mitigations when granting Certificates of Authorization (COA) for public and some civil operators and when issuing experimental certificates. These approaches are not considered feasible for scaling up to grant widespread approvals.

Whereas manned aircraft collision avoidance has been focused upon the avoidance of traffic only, SAA likely would need to add avoidance of terrain, obstacles, and possibly weather. The domain of SAA may be restricted to airborne use, or may extend to the surface, where it could be used to detect and avoid other aircraft, vehicles, people, and obstacles.

This chapter discusses the Certification process and some of its artifacts normally used to gain approval of avionics and discusses how these might be applied to a capability such as SAA. It also discusses the Standards process, identifies issues unique to UAS SAA, and discusses the role Standards play in certification.

96.2 Certification Process

This chapter discusses the certification process with reference to documents used by the FAA. Elsewhere, regulators should follow generally similar practices, although differences will undoubtedly prevail. In Europe, the Joint Aviation Authorities (JAA) develop analogous processes and regulations that frequently are similar to FAA's; these organizations seek harmonization. A difference is that the various European national authorities, rather than JAA, are the regulators there.

The discussion here is focused on approval of the SAA system, which is only part of the process of achieving airworthiness approval for the unmanned aircraft. The usual process is first to obtain certification of the aircraft's airworthiness compliance from the aircraft certification service. The second major step is to obtain operational approval from the flight standards service.

96.2.1 Project Specific Certification Plan

The applicant should not expect to find a fixed path that specifies the exact steps and documentation required. Industry and FAA have developed a guide for applicants to plan and manage the process, document those plans and their progress, and develop a successful relationship with the regulator (AIA 2004). Since systems have unique characteristics and different regimes of operation, the process must be tailored to those details. The FAA advises applicants to work closely with them, starting with the development of a Project Specific Certification Plan (PSCP). That plan would document the agreed-upon certification approach and describe processes as well as deliverable products. These normally consist of the following elements:

96.2.1.1 System Safety Assessment

Safety assessment is described in FAA (2008). This process presents a standard series of steps that provide assurance that the system's safety has been comprehensively studied and that likelihood levels of identified hazards are sufficiently low, corresponding to the severity of each. The applicant will need to compile all of the system's potential aircraft-level hazards and document them through a functional hazard assessment that assigns a severity level to each hazard, representing the worst credible operational effects. This approach has become standard methodology for safety management systems, which are recommended for airspace regulators worldwide.

Fig. 96.1 Risk matrix

Figure 96.1 presents a version of the hazard risk matrix depicting an example hazard whose severity has been determined to be “hazardous.” The matrix then shows that this hazard’s safety objective needs to be “extremely remote.” This combination of severity and likelihood would be considered a “medium” risk. Standard practice is to identify and recommend safety requirements to assure that all risks fall within the medium- or low-risk zones of the table. The high-risk zone is not acceptable.

For SAA, a different treatment is appropriate for the residual collision risk that remains when the SAA system operates as designed. It is well accepted that a collision avoidance system (CAS) cannot operate perfectly due to several factors, particularly surveillance limitations, own aircraft maneuver limitations, and intruder aircraft maneuvers. If CAS reduces collision risk by two orders of magnitude, this is

usually considered to be a well-performing system (McLaughlin and Zeitlin 1992; McLaughlin 1997). However, the acceptable level cannot be prescribed for CAS in isolation – both self-separation and collision avoidance together will need to meet a safety target.

Since collision risk already exists throughout the airspace and CAS is introduced as one of the layers of protection to mitigate that risk, the usual SMS severity-based likelihood targets should not be applied to this area. Instead, metrics are used that can be termed “performance” measures of the SAA. When collision risk does arise from actual failure, e.g., from hardware, software, communication, or human failures, the SMS approach is appropriate.

Those hazards that could affect safe flight will require further investigation and documentation using safety tools such as those described in the next three subsections.

96.2.1.2 Fault Tree Analysis

This tool collects events, including pertinent conditions and failures, to show the structure of their contribution towards a “top event,” which is a hazard of interest. For example, a near midair collision (NMAC) event might occur if two aircraft are either on a collision course or in close proximity and SAA events occurred that might fail to prevent a collision in the first case or would cause a collision in the latter case. Those events must be decomposed into the subfunction outcomes of interest that could cause each higher event. Quantifying the constituent events and then combining them in a logic expression would enable the calculation of the top event. Figure 96.2 depicts a portion of an SAA fault tree.

Examples of a collision avoidance fault tree and quantified hazards populating that tree were produced in the early safety study reports for TCAS (Lebron et al. 1983; McLaughlin and Zeitlin 1992). The hazards included surveillance-related errors, of which altimetry was central to TCAS, as it advises avoidance maneuvers in the vertical dimension. SAA systems will need to address surveillance and tracking errors according to the sensors used, communication hazards, and display and human hazards affecting ground-based decisions and commands.

96.2.1.3 Failure Modes and Effects Analysis

This tool is often used in aircraft systems to systematically examine potential failure modes and explore the worst credible consequences of those failures. In most cases, the design contains sufficient redundancy or other mitigation so that the effects are acceptable, i.e., not too frequent for the associated severity. If this is not the case, safety recommendations would be needed to provide sufficient mitigation.

96.2.1.4 Common Cause Analysis

Safety analysis tools often examine one failure event at a time, and the analysis of complex systems is facilitated by the initial presumption of independence among failures. Sometimes this is not a valid premise, and the common cause analysis seeks

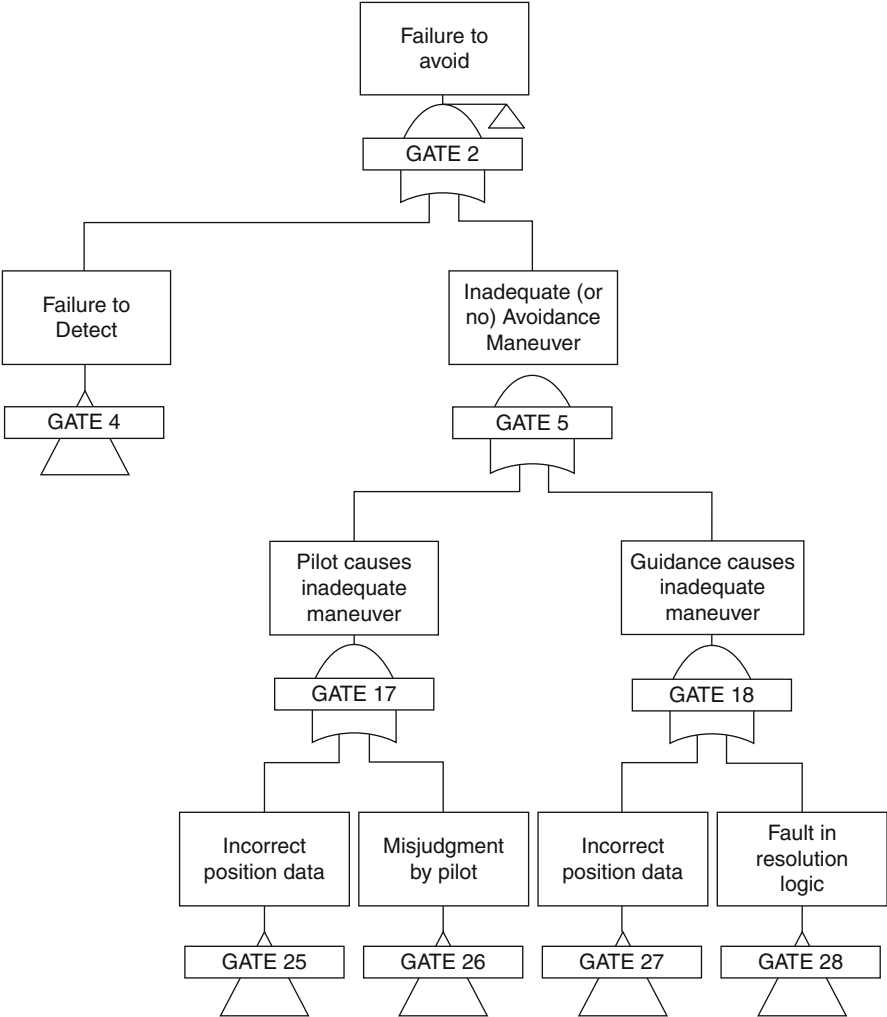

Fig. 96.2 SAA fault tree fragment

out vulnerabilities to common failures arising from a single cause. Performing this analysis and updating other safety analyses in accordance with its results would bolster the confidence in the overall safety case.

96.2.1.5 Certification Basis and Means of Compliance

The certification basis specifies the applicable regulations to which the applicant must comply in order to obtain the type certificate. SAA is novel in many respects, and it may not be obvious how to fit all of its aspects into the regulatory framework. The primary roles of SAA are to remain well clear from, and avoid collisions with,

other airborne traffic. SAA would operate in a manner analogous to the visual functions invoked by regulations 14 CFR §91.111, 113, and 181.

It is likely that the certification basis will include elements of safety, performance, and interoperability. Performance in this context refers to the extent that SAA is able to mitigate the existing risks of separation loss and of midair collision. This is distinct from safety risks arising from system or operator failures. Interoperability refers to SAA coexisting with other systems aboard own or other aircraft and exchanging data with them as required and also not causing any degradation to their function. The obvious example would be the interactions with a collision avoidance system aboard another proximate aircraft, where evidence would need to be provided that the maneuver advisories generated by the respective aircraft would be compatible, with extremely high probability.

96.2.1.6 Software

Although software does not break or wear out, it may contain hidden (or “latent”) failures that could cause hazards to occur. The section below on software standards discusses accepted methods for assurance of quality software, so that the likelihood of latent failure is commensurate with the criticality of the system functions.

96.2.1.7 Human Factors

If the UAS remote pilot is to play any role in SAA, he must be given the relevant data and advisory information in a presentation format that supports timely, necessary, and safe decision making. Possible functions for the pilot are the evaluation of risk, deciding that action is needed, and determining the specific action. These are discussed in Sect. 96.3. The pilot also should be supported in correctly deciding when action is not required, choosing a safe course after necessary SAA action is complete, and determining how far to deviate from course or from a flight level during an avoidance maneuver. These concerns all apply, whether the remote pilot is responsible for the decision (termed “in the loop”) or is monitoring and able to override an automated decision (“on the loop”). Besides providing correct and complete information to support the intended functions, the applicant will need to demonstrate a sufficiently low likelihood of providing the pilot with misleading information that might induce hazardous choices. The pilot’s training, workload, and potential distractions all enter into the evaluation. The pilot actions will need to be translated into system requirements in connection with the development of the safety case for SAA.

An avionics system advisory circular normally provides examples of relevant considerations that should parallel many SAA topics. The TCAS II circular (FAA 2009a) was written to complement the TCAS standard. It gives some description of the system and its components and suggests implementations of traffic and resolution advisory displays and pilot controls whose designs were backed by considerable research and consensus. Standards organizations with expertise in the human factors discipline were cited, but it is mentioned that alternative implementations may be approved with sufficient research and validation. A discussion of a certification

approach includes both verification tests contained in the TCAS standard and also related tests of aircraft maneuver performance. Ground and flight tests of the installed system are discussed.

96.2.1.8 Others (Operational Concept, Equipment Compatibility, Envisioned Safety Enhancements)

It is recommended that applicants work with the regulator to document the identification and resolution of important technical, regulatory, and administrative matters in issue papers. Such papers are updated as the status and resolution of issues evolve.

The PSCP also would contain an agreed-upon testing plan and specify the documentation to be produced showing compliance. The familiarity or novelty of the system bears a great deal upon the extent of both testing and documentation to be expected. As long as UAS and SAA are new to the airspace, more rigor and detail could be expected; later, familiar approaches may rely more upon experience and focus more on marginal differences.

The ultimate certification product for avionics is normally the Technical Standard Order (TSO), which is a design and production approval that designates the relevant equipment standards. The aircraft using the avionics would reference it in its application for its type certification (TC), supplemental type certification (STC), or amended type certificate. The latter two types could apply to alterations to an aircraft through installation of a system (FAA 2007). These certifications establish the regulator's approval of the aircraft design. An advisory circular also may be issued to provide guidance on complying with applicable airworthiness regulations. The circular may provide an example of an acceptable means of compliance that is well understood by the regulator, but also would state that this is not the only means of compliance that could be approved. The applicant may choose any means of compliance, but then must demonstrate compliance to the satisfaction of the regulator. Standards, which are discussed in the next section, facilitate that demonstration. FAA (2013) provides a partial draft of such a circular for SAA systems.

96.3 Standards

The purpose of a standard is to document a consensus on the requirements for a system and describe a means for demonstrating that those requirements are met. While the standard itself conveys no regulatory authority, its publication provides a service to applicants and regulators alike. Applicants, by invoking the standard and demonstrating compliance, would not need to justify its set of requirements, and regulators would not have to judge the set of requirements within each implementation. If, however, an applicant chose to depart from the standard, the resulting certification process would need to include a justification for accepting the alternate approach.

A standard would be most likely to be respected if it was written with broad input from all affected parties, particularly government, manufacturers, and user groups. In the USA, most avionics standards are developed by the aviation standards organization RTCA, Inc., and in Europe by the European Organisation for Civil Aviation Equipment (EUROCAE). These two organizations sometimes collaborate to produce joint standards, and at times a standard developed by one is endorsed by the other organization. That was the case for TCAS, but the organizations appear to be moving separately for UAS.

The contents of a standard typically include at least a description of the subject and its scope; overall system requirements; requirements for each subsystem; a means of demonstrating compliance, such as specific testing procedures; references to applicable documents; and supporting information, sometimes placed in Appendices.

RTCA, Inc., generally prepares two types of standards: Minimum Aviation System Performance Standards (MASPS) that address functional performance but allow some latitude regarding system architecture and technology selections and Minimum Operational Performance Standards (MOPS) that are far more specific to the architecture and technology.

Many standards tend towards a minimalist approach, specifying only those aspects judged necessary to be performed in a defined, consistent manner. This approach holds some appeal for manufacturers, who may exploit more flexibility in utilizing proprietary architectures and technologies or in making performance trade-offs among subsystems. Some of these standards may describe a specific implementation as an example but would still leave great flexibility to users. MASPS follow this approach to some extent.

An opposite approach to standards would specify many elements of the system in some detail. This would provide the regulator with greater assurance that supporting data for one implementation would apply to all others, as little variation would be allowed. In certain respects, commonality may be required for safety and interoperability. Examples might include physical or electrical interfaces, radio messaging, or software-intensive systems with critical functions. An instance of the latter is the MOPS for the Traffic Alert and Collision Avoidance System II (RTCA 2008), the aircraft collision avoidance system. Its algorithms were intensively simulated and tuned, and a method of maneuver coordination between aircraft was detailed. Its standard specified a complete algorithm, thus assuring that all aircraft using it would receive a known level of protection and would be able to coordinate maneuvers in the prescribed fashion.

The decision regarding minimum versus specific standards does affect the specification of compliance demonstration. A standard may provide a list of tests and associated conditions, which if passed would provide assurance that the system meets the standard's requirements. Such tests may be more difficult to devise if implementation methods are not constrained.

The First SAA Workshop Report (FAA 2009b) established two basic system functions: self-separation and collision avoidance. These two functions each need to perform the following eight subfunctions:

1. Detect – Determine the presence of aircraft or other potential hazards.
2. Track – Estimate the state (position and velocity) of each intruder based on one or more surveillance reports.
3. Evaluate – Assess collision risk based on intruder and UA states.
4. Prioritize – Determine which intruder tracks have met a collision risk threshold.
5. Declare – Decide that action is needed.
6. Determine Action – Decide on what action is required.
7. Command – Communicate determined action.
8. Execute – Respond to the commanded action.

The degree of independence of the basic functions affects the safety case, since collision avoidance is expected to act once self-separation fails to ensure separation. While there may be programmatic motivations to use the same or similar subfunction implementations (e.g., sharing some or all of the sensors supporting detect) for both functions, the safety analysis needs to give close attention to the effects of common failures. Any credible failure that would impair both self-separation and collision avoidance would be a concern and might necessitate a more robust implementation in order to meet a safety level. For sensors, this concern over a common failure might be addressed by deploying multiple technologies to improve the prospects of sensing any threat aircraft by at least one of the sensors.

This list of subfunctions is independent of system architecture. If a standard is written for SAA using a specific architecture, that needs to be specified as well as to which system elements (e.g., aircraft, ground control station, pilot) each subfunction is allocated. In some instantiations, elements from this list can be incorporated in system functions external to SAA. For example, command is likely to be allocated to the communications function and execute to the aircraft flight control system.

96.3.1 Requirements for Functions and Subfunctions

This section presents considerations that may lead to requirements for functions and subfunctions. The discussion of the two functions draws upon Fig. 96.3 taken from FAA (2013). It depicts notional boundaries, not drawn to scale, that are explained in the following paragraphs.

96.3.1.1 Self-Separation

The best insight into this system function appears in the 2nd SAA workshop report (FAA 2013). It is meant to implement the compliance with 14 CFR 91.111 to “remain well clear” of other aircraft by providing an automated substitute for see and avoid. The report acknowledges that those UAS receiving separation services from air traffic control would not use this function unless authority to do so had been delegated to them. For uncontrolled UAS, though, this function would provide the only means to prevent collision avoidance situations from developing. A specific risk-based approach to defining a self-separation volume was presented in the SAA workshop report; standards committees will need to consider operational and technical factors (such as performance aspects

Fig. 96.3 SAA function boundaries

of the surveillance capability) when specifying requirements on the volume to avoid and the associated maneuver decision time.

In Fig. 96.3, SST depicts a self-separation threshold that is defined with the purpose of achieving a selected probability of avoiding penetration of the boundary denoted WCV, standing for a well-clear violation. The WCV is chosen in accordance with calculation of collision risk in the airspace (Weibel et al. 2011), based upon observed historical encounter data (Kochenderfer et al. 2010).

96.3.1.2 Collision Avoidance

The TCAS system provides a well-established definition for a collision volume: 200 ft vertical limit and a circle of 500 ft diameter, both centered about the UAS. This volume is labeled NMAC in Fig. 96.3. The maneuver to avoid this volume, which is associated with a “near midair collision” event, needs to occur no later than the last point at which the UAS could begin a feasible maneuver. That last-chance maneuvering boundary is denoted CAT for collision avoidance threshold. Design of the associated decision time needs to account for both the latencies of a command link (if the command is communicated from a control station) and of the aircraft flight control system.

It would be desirable to jointly design SST and CAT for an implementation, as any gaps or overlaps between the WCV and CAT boundaries could be minimized; but this may not be practical for all implementations. In any event, the following considerations are essential:

- (a) The two functions together must achieve the requisite level of collision risk reduction.
- (b) The CAT will be smaller than the SST.
- (c) When the aircraft penetrate the WCV, the self-separation function must continue to operate and attempt to restore the well-clear state until the collision avoidance function activates.
- (d) While collision avoidance is issuing maneuver advisories, the self-separation function must cease to command maneuvers, as these could dangerously conflict with those of collision avoidance or, at the least, could be distracting.

96.3.2 Subfunction Considerations

96.3.2.1 Detect

Various sensor technologies are under consideration for SAA. For an airborne SAA, these include “cooperative” technologies, which exploit electronic identification provided by the target aircraft avionics, and “noncooperative.” Cooperative technologies include the ATC transponder, which already is used as the basis for TCAS (RTCA 2008), and automatic dependent surveillance – broadcast (ADS-B), which provides the target’s position, usually derived from a satellite-based estimate, its velocity, and other information (RTCA 2009). The noncooperative technologies include electro-optic (camera), infrared, and primary radar not requiring cooperative avionics on the other aircraft.

In some airspace, it can be expected that all targets will be cooperative due to regulatory requirements; in others, noncooperative sensing is essential. It is anticipated that most SAA implementations would combine more than one sensor in order to detect both kinds of traffic. Also, the noncooperative technologies have various strengths and weaknesses (Zeitlin et al. 2009). Combining sensors could exploit the respective strengths.

The various sensors differ in many measurement parameters, including their detection range, angular field of view (FOV), bearing accuracy, and update rate. They also differ in mechanical properties including weight and electrical power requirements, which is important for the smaller UAS and may lead to trades that limit the FOV or range capability. Requirements for FOV coverage will likely consider the probabilities of encountering a threat over different angular bearing sectors, considering feasible relative speeds. Clearly this would vary with the speed of the UAS as well as the characteristics of the airspace population. Another issue related to FOV ties into the conventional formulation of right-of-way rules. Currently, an overtaking aircraft must give way to the aircraft ahead, according to 14 CFR 91.113. This has led some to speculate that SAA need not detect traffic approaching it from behind. While cooperative sensing technologies generally have a 360° lateral FOV, others, such as electro-optic and primary radar, do not. Extending their FOV would require multiple sensors, with associated weight, power, and cost implications. The SAA workshop (FAA 2013) recommended that SAA must not rely on right-of-way requirements to reduce their compliance with see-and-avoid requirements. This implies that SAA must equip with an appropriate FOV so as to detect targets behind own aircraft.

A standard could reference other existing standards for the cooperative sensor technologies and could provide detection requirements for noncooperative targets. An associated requirement may be a limit on the rate of false target detection.

96.3.2.2 Track

The track function associates successive measurements for each target and performs smoothing to derive an estimate for the target’s current position and velocity.

It needs to accommodate varying update rates from different sensors; different times of measurement and missed measurements; and different accuracies. Also, some sensor technologies provide different coordinates than others or from different frames of reference. This function must account for all the differences in producing its best estimates. These estimates may also provide the track's estimated error to the subsequent functions, allowing them to put in a safety buffer that would guard against worst-case errors.

Associating measurements (or "reports") from different sensors is an important consideration, as the cooperative technologies provide a unique identifier, while the others must attempt to associate noisy measurements.

96.3.2.3 Evaluate

This function would use the track variables to calculate other variables more suitable to threat evaluation. An example of such a variable from the TCAS algorithm that is likely to be useful in a SAA context is called "tau." This is an estimate of the time remaining until reaching the closest point of approach to the target. The estimate works over any approach angle and speed. The TCAS tau only uses range and range rate, as those variables were the most accurate measurements using the TCAS surveillance. When other sensors are available for SAA, a different formulation of tau may prove to be more accurate and thus preferable. Other evaluation variables would be the calculated vertical and horizontal miss distance estimates at the closest point of approach (CPA). These would be used by the subsequent function in deciding the priority of the threat situation.

96.3.2.4 Prioritize

The prioritize function would compare track and/or calculated variables against thresholds to determine the threat status and urgency of taking action. Even if no action is indicated by the subsequent function, the priority may be communicated to the pilot on the traffic display, as TCAS does for various target symbols types. This could focus pilot attention on one or more threats potentially needing action soon.

96.3.2.5 Declare

This function combines the priority of a track's status with other rules that determine whether immediate action is required. These rules may be geometry dependent or may account for different criteria, such as confidence in the track quality or the status of coordinating maneuvers with the threat's own collision avoidance maneuver.

96.3.2.6 Determine Action

Numerous considerations play a role in determining the specific SAA action. Foremost should be the choice of a maneuver to avoid penetrating the particular volume for either self-separation or collision. (If the declaration decision was based on a risk criterion rather than upon a physical threshold, it may be difficult to represent as a physical volume.) Since more than one maneuver choice may be capable of meeting this first criterion, other rules are involved in the decision.

For example, it might be found best to defer action as long as possible, either because the track quality improves with decreasing range or because encounter data shows that potential encounters are often resolved without requiring a maneuver. In this case, the rule might defer action until only one feasible maneuver remains.

An essential rule takes precedence when the threat aircraft is also equipped with collision avoidance (as are air carriers worldwide). This rule requires the explicit coordination of collision avoidance maneuvers between the two aircraft in order to assure mutual compatibility. For example, both aircraft cannot be allowed to climb nor both to descend. One must choose a different sense for its resolution. The existing TCAS standards dictate coordination messages and protocols to ensure this compatibility between two TCAS aircraft, and these can be used or adapted for SAA. An adaptation would be needed, for example, if policy were to determine that the UAS should be given lower priority in tie-breaking situations. This direction may be justified on the basis that SAA is less mature, or on lower confidence in its sensing or tracking, or on the basis of a UAS's lesser maneuver capability.

Another criterion might consider rules of the air, for increasing the likelihood of the maneuver's compatibility with the other aircraft's (uncoordinated) visual avoidance actions. Such a rule might be considered a means of implicit coordination.

Operational criteria might consider proximity to other nonthreatening traffic or to restricted airspace areas, in order to avoid choosing a maneuver that could create a new problem with that traffic or cause an airspace violation.

96.3.3 Architecture

Several options exist for the physical architecture of the SAA. The sensors could be located on the UAS, on the ground, or even both of these in combination. Likewise, the decision making could be on the UAS, at a ground control station, or divided. Unless all functions are performed onboard the UAS, a communications link is required. It may downlink surveillance data to the ground control; it may uplink maneuver commands to the UAS; one or both of these could be implemented.

An example of divided decision making might allocate self-separation decisions to the ground control, where ample time remains to resolve a conflict. For this function, the criticality of a short-term communication outage is low. The collision avoidance function might be performed automatically onboard the UAS in order to avoid implementing an extremely robust uplink capability. For this function, little time remains before a potential collision, and the execution of the maneuver is more critical.

Many trade-offs can affect the choice of airborne or ground-based sensing. A larger UAS could equip with multiple or heavier sensors. This might provide it with a broader FOV than a single sensor. Multiple sensor technologies offer the possibility of combining their respective advantages, such as accuracy in different dimensions. However, such a SAA system would need to perform fusion of the data from the several sensors. Trade-offs might risk sacrificing some of the desired

surveillance parameters. Instead, using ground-based radar could provide coverage that surrounds the UAS and also would not require data fusion. A limitation of this approach is the fixed geographic area of the radar, whereas an airborne surveillance system travels anywhere the UAS flies. Ground-based radars also may not provide adequate accuracy and update rate for collision avoidance. However, their ability to support self-separation is more credible, as such radars are routinely used for air traffic control separation services.

96.3.4 Communications

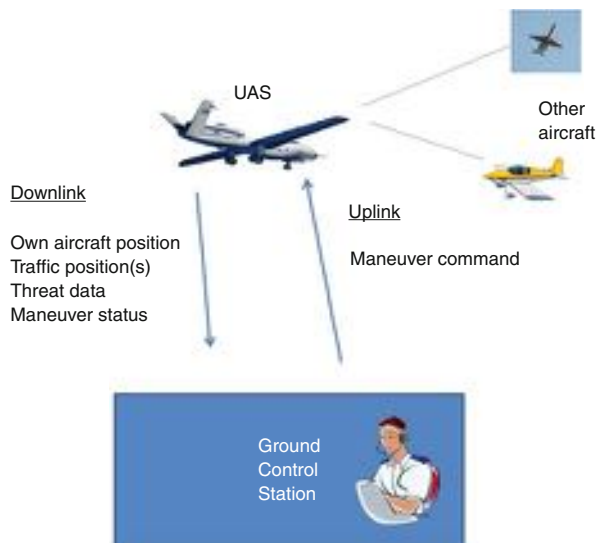

A UAS communications function has many roles. Besides navigation, the mission payload control, and monitoring the aircraft, there are SAA functions that will rely on communication to varying degrees, depending upon the SAA system architecture (Fig. 96.4). The *downlink* is important for aircraft-based SAA designs. A ground control station will need current data for situational awareness of traffic and other hazards. It also will need to obtain data for any potentially threatening aircraft if the pilot is involved in threat declaration and/or a maneuvering decision. Threat data can include that aircraft's equipage for collision avoidance and whether it has announced a resolution of its own. A design challenge may arise in providing sufficient information to the pilot with low latency and sufficient update rate. These elements place requirements on the communications downlink. If threat declaration or maneuver choices are made by onboard system elements, the ground control still must monitor these choices and be prepared to recover the flight profile after the maneuver ends. It needs to be determined whether any maneuvers would be communicated to air traffic control directly from the aircraft or by the pilot. Finally, if a maneuver is selected, or is approved, on the ground, the *uplink* is time critical and must be reliable. The consequences of a late or erroneous maneuver command could be a collision.

96.3.5 Algorithms

An SAA system is expected to use a threat algorithm to make decisions regarding the status of each tracked aircraft. It needs to determine when a maneuver may be necessary and determine the specific maneuver, unless the system leaves the choice entirely to the pilot. The algorithm needs to function for all encounter geometries and should be capable of acting when multiple aircraft are near the UAS.

There is interest in building systems that would maneuver automatically. Some developers seek to overcome communications latency, and others wish to provide collision protection even when the communications link from the pilot is lost. Removing the pilot from the decision loop forces a higher degree of reliance on the algorithm always providing a correct maneuver. In addition, a higher software assurance level may be required.

Fig. 96.4 SAA communications

The primary SAA requirement is to contribute to safety by effectively executing the self-separation and collision avoidance functions. However, of nearly equal importance is the requirement to operate in an acceptable manner to both air traffic control and other airspace users. This would involve maneuvering in predictable fashion, not flying so near to other aircraft as to endanger them, and not resolving an encounter with one aircraft in a manner that creates a new encounter with another.

A new development being pursued for collision avoidance replaces the traditional procedural algorithm with a look-up table developed by an optimized Markov decision process (Kochenderfer et al. 2010). The optimization is based upon a cost function that incorporates both the safety criteria and operational criteria discussed in this paper. It also incorporates probabilistic distributions of aircraft maneuvers and surveillance errors.

In addition to the technical challenges of developing and standardizing SAA algorithms, attention must be given to the issue of product liability. The issue was averted for TCAS when that government-funded program developed its algorithm and the standard mandated its use. It has not been determined whether any similar government involvement will transpire for SAA, nor whether standards will attempt to specify a single algorithm, nor how industry may choose to proceed knowing their unique efforts might become subject to legal action following an accident.

96.3.6 Validating Requirements

Several methods contribute to the validation of requirements contained in a standard. As mentioned earlier, conformance to the standard is expected to make a major contribution to the safety case for the system. For collision avoidance

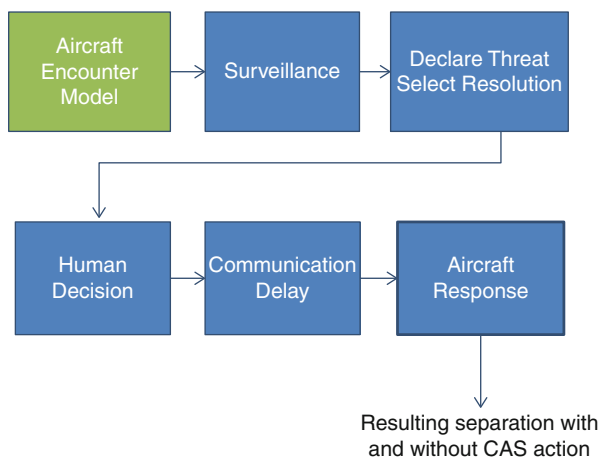

Fig. 96.5 Monte Carlo simulation technique

systems, experience shows that a substantial program of methodical encounter simulation would exercise modeled system elements and enable a calculation of the system's overall safety performance. TCAS simulations (McLaughlin and Zeitlin 1992) have used millions of simulated encounters in order to achieve an agreed statistical basis for performance.

Such a simulation is no better than the models that it contains. Encounter models are considered more trustworthy when derived from actual observed data. They can be validated by comparing separate samples of the data as well as by comparing separate implementations of the model (Zeitlin et al. 2006). Figure 96.5 depicts a system simulation that combines models of aircraft geometric encounters, SAA sensing and tracking, threat detection and advisory selection, and resulting maneuvers. It also shows an optional insertion of human performance in the “command” leg; human performance also might be incorporated in threat detection and/or advisory selection.

Monte Carlo simulation is an established technique that uses separate models like those in Fig. 96.5, whose parameters undergo independent stochastic variation, each with their appropriate distribution. While the same simulation might be used to study a single encounter of interest, the overall safety case depends on frequencies of events and resulting performance. For example, straight-and-level geometries might have a fairly high frequency, while encounters with both aircraft making very late maneuvers might have lower frequency. The latter might prove more difficult to resolve, so weighting each type by their observed frequency gives an estimate of overall performance. The TCAS model (McLaughlin and Zeitlin 1992) used 19 geometric classes, and newer correlated and uncorrelated models (Kochenderfer et al. 2010) use more classes. Typically, millions of encounters are run to model the overall airspace performance. From run to run, the separate variables change independently. For example, the encounter angle, vertical profile, and speed would

vary, while measurement noise would separately vary, and response fidelity and latency again would separately vary.

For collision avoidance, the established practice involves running each encounter twice with identical input – once with response to advisories and once without. This produces data to show the effectiveness of the CAS system, particularly the risk ratio that compares the number of NMAC events with and without CAS. Maneuver magnitudes and resulting displacements also can be obtained as well as advisory types and transitions during an encounter.

A necessity for SAA simulation is to obtain appropriate models of the various sensor technologies and integrate them into this simulation. It may be challenging to model emerging technologies in detail, and some of their performance measures could vary substantially depending upon the physical characteristics of the target aircraft (e.g., size, radar cross section, aspect angle during an encounter). Performance also might vary depending upon visual conditions, particularly for electro-optic sensing. It may be appealing to simplify the model and use conservative performance measures; evidence must be provided that actual performance would not be worse than that modeled.

Other aspects for consideration are probabilities of missed sensor reports and of false returns that could be correlated incorrectly with existing tracks. Flight trials are desirable to validate estimates of these parameters.

Likewise, appropriate models of the communications latency and aircraft maneuver response are crucial to the validity of the results.

A different technique for system validation is termed “stress testing” and also has been used for TCAS. This method uses end-to-end models like those shown above. Rather than running many trials with stochastic variations to replicate true frequencies across the airspace, this method samples key variables at intervals meant to exercise the full range of possible inputs and helps analysts identify patterns of poor performance. Even if those encounter situations were rare in the context of overall airspace exposure, stress testing identifies shortcomings that must be considered for correction before approving the system. It is accepted that SAA will not succeed in every encounter, but both its overall safety and specific limitations must be understood.

96.3.7 Verification Tests

Since the goal of the applicant is to demonstrate compliance with the requirements specified in the standard, there needs to be a process to perform that demonstration. Rather than expecting every applicant to invent such a process and convince the regulator that it is complete, the standard should provide an agreed set of test procedures. This set should be sufficient to demonstrate coverage of each requirement. Inputs, initial conditions, and outputs should be stated. Tolerances should be recommended to allow for reasonable variations within the intent of the standard.

Depending upon the system, the process may require a full end-to-end test or may test subsystems. Software might be tested in part using fast-time or state transition testing, while a full system may require RF signals or other inputs. Some degree of flight testing is likely to be required for at least a minimal demonstration of full system operation. However, flight testing is time consuming and expensive, so its extent should be limited with greater confidence built up from the other methods.

96.3.8 Software Standard

As software is the means of implementing threat algorithms and certain other parts of SAA (i.e., data fusion, tracking), the trust in those aspects is central to the approval of the system. Software is unique in its safety aspects and is covered in a standard of its own. The document (RTCA 2011), entitled “Software Considerations in Airborne Systems and Equipment Certification,” addresses the role of software in a complete system and its life cycle. It provides advice concerning the software planning, development, verification, and configuration management processes. It gives some insight into the certification process and recommends numerous artifacts, or data, to be recorded at various stages of the life cycle. In recognition of many unique approaches both known today and to be developed in the future, a section on other considerations includes advice on alternative methods, as well as changes made to approved software, and other topics.

At the system level, early consideration must be given to the relationship between software errors and failure conditions. The severity of those failures drives all the subsequent stages in terms of rigor of development and verification. It will be much easier to begin the life cycle at the correct level rather than attempt to restore inadequate rigor after development is complete.

The planning process includes such topics as the software development environment and software standards. The latter would document more detailed rules governing the specific aspects of requirements, design, and coding of the software.

The development process would document details of specific processes for the same requirements, design, and coding elements. It must be stressed that the modern approach to high-quality software is built upon the use of well-documented processes.

The verification process must detect and report errors introduced during development. This involves far more than simply testing the software. The process verifies that high-level system requirements flow down through lower level requirements levels and that all of the executable code ultimately is traceable to requirements. The process also ensures robustness to abnormal conditions and inputs.

Configuration control is described with multiple objectives designed to ensure an orderly and well-documented process, including traceability and change control.

The overview of the certification process explains that systems and equipment, including software, need to be “approved” in order to become part of a certified aircraft. Development tools can become “qualified” to an appropriate level of assurance.

The various data items described support either the planning process where the approach to certification is detailed or the compliance process where evidence is presented to show that requirements are fully satisfied.

96.4 Conclusion

Certification of SAA actually is an approval of a system's compliance with all regulatory requirements. Each certification plan is unique and should be coordinated closely with the regulator. Both standards and guidance documents such as advisory circulars should greatly simplify the demonstration of compliance. The standard contains requirements that would be validated through analysis and simulation. The standard also should present the testing requirements to demonstrate compliance by means of producing specified outputs.

UAV - Human Interfaces and Decision Support Systems

Paul Oh and Michael Goodrich

Kimon P. Valavanis and George J. Vachtsevanos

UAV: Human Interfaces and Decision Support Systems focuses on research findings and efforts that are underway by the UAV user community to reduce the current UAV operator workload levels. Until a satisfactory level of autonomy is achieved, the human will continue to function as an integral part of the UAV ground control station (GCS) loop. Moreover, intelligence acquired by UAVs must be communicated in an appropriate format to humans on the ground or to a mother ship for further analysis, assessment, and action. The human must intervene when new intelligence suggests that the operational profile must be changed.

► **Human Interfaces in Micro and Small Unmanned Aerial Systems** by Peschel and Murphy surveys the various aspects of user interfaces for a Mission Specialist role on micro and small UAS human-robot teams. Three formal human team member roles are presented, Flight Operations Director, Pilot and Navigator, and the Mission Specialist, in order to identify distinct team member role differences. For each category of UAV, the Mission Specialist role is evaluated to determine what type of user interface technologies are present and/or available, how the Mission Specialist interacts or could interact with the user interface technology, and what are the perceived consequences of this user interface technology in the context of the three identified micro and small UAS human-robot team roles. The findings of this survey suggest that current Mission Specialist performance in micro and small

UAS may be suboptimal due to the sharing of a single Pilot and Navigator-oriented user interface or a reuse of the Pilot and Navigator user interface.

► **Human Factors Perspective on Next Generation Unmanned Aerial Systems** by Goodrich and Cummings presents a comprehensive view on UAS autonomy and user interface design, motivating emerging themes in near-term and far-term UAS developments. Issues include user interface design, UAS autonomy, UAS teaming, operator workload, and payload management.

► **Cognitive Task Analysis for Unmanned Aerial System Design** by Adams provides an overview of cognitive analysis methods that can be integrated into the early system design process to account for the human element. It specifically provides an overview of task analysis, work analysis, and information flow analysis methods along with an overview of how individual methods from the different analysis classes have been combined. It is argued, and rightly so, that although UAS are complex tools requiring thoughtful designs that account for the platform itself, payloads, and human users as a holistic system, often the focus is first placed on designing the platform or payload, while the human element is considered at a later stage. As such, system design approaches do not properly consider the human cognitive limitations and do not design the system to support the human's tasks and decision making. Specific examples of applying these analysis methods to unmanned aerial systems, ranging from potential futuristic systems, to research systems, to deployed systems, are also reviewed.

► **Display and Control Concepts for Multi-UAV Applications** by Calhoun and Draper introduces a variety of display and control concepts that may be especially applicable to multi-UAV applications. Many such technologies are being investigated at the U.S. Air Force Research Laboratory and include multimodal interfaces, temporal displays, and integrated visualization concepts. The thesis is that for any candidate technology, rigorous user-centered design and evaluation needs to be conducted, which focuses on the tasks and requirements of the specific multi-UAV application being targeted. It is also important to ensure that the operator has adequate means to first observe and then direct the automation's functioning in order to be responsive to changes in the mission, vehicle status, or operational environment. What is important to capture is that advances in automation technology are leading to the development of UAV concepts in which a single pilot will be responsible for multiple UAVs. Thus, the operator's role will become more supervisory in nature, resulting in a new interface paradigm required for effective supervisory control of multiple UAVs by a single operator.

► **UAV Operators Workload Assessment by Optical Brain Imaging Technology (fNIR)** by Izzetoglu, Ayaz, Hing, Shewokis, Bunce, Oh, and Onaral discusses the utilization of functional near-infrared-based brain imaging systems, fNIRs, in the monitoring of a cognitive workload during UAV operation and as an objective measure of expertise development, that is, the transition from novice to expert during operator training. The challenge relates to the fact that UAV ground operators are required to acquire skills quickly and completely, with a level of expertise that builds the operator's confidence in his/her ability to control the UAV under adverse conditions. As UAVs are held to increasingly higher standards of efficiency

and safety, operators are routinely required to perform more information-dense and cognitively demanding tasks, resulting in increased cognitive workloads during operation. Functional brain monitoring offers the potential to help UAV operators meet these challenges, and research has demonstrated the utility of fNIRs for the purpose of monitoring frontal cortical areas that support executive functions (attention, working memory, response monitoring). fNIR technology allows for continuous monitoring of operators during training as they develop expertise, as well as the capacity to monitor their cognitive workload under operational conditions while controlling UAVs in critical missions.

Collectively, this section of the handbook introduces fundamental concepts associated with the still essential UAV-human interface, workload requirements, communication and display means, information processing, dynamic scheduling of UAV operations, assessment, and action issues, aiming at improving and optimizing decision making, mission effectiveness, and success, reducing at the same time the human-to-one-UAV ratio, which is currently close to 4:1. Consequently, long term, this will lead to mature technologies, the implementation of which will change the current human-in-the-loop requirement to the future human-on-the-loop concept.

Abstract

This chapter surveys the various aspects of user interfaces for a *Mission Specialist* role on micro and small unmanned aerial system (UAS) human-robot teams. An operational characterization of micro and small unmanned aerial vehicles (UAVs) that are presently in use is first categorized into two size groups. Following this, three formal human team member roles are presented that trend from the micro and small UAS-related literature, *Flight Operations Director*, *Pilot and Navigator*, and the *Mission Specialist*, in order to identify distinct team member role differences. For each category of UAV, the *Mission Specialist* role

is evaluated to determine (1) what type of user interface technologies are present and/or available, (2) how the *Mission Specialist* currently or could interact with the user interface technology, and (3) what the perceived consequences of this user interface technology are in the context of the three identified micro and small UAS human-robot team roles. The findings of this survey suggest that current *Mission Specialist* performance in micro and small UAS may be suboptimal due to the sharing of a single *Pilot and Navigator*-oriented user interface or a reuse of the *Pilot and Navigator* user interface.

98.1 Introduction

UAS operations involve a human-robot team (Barnes et al. 2000; Cooke et al. 2006; Goodrich et al. 2007; Murphy et al. 2008; Rash et al. 2006). For the purposes of this discussion, the UAS human-robot team is defined as the human personnel primarily responsible for UAS flight, navigation, and acquisition of mission-related information and excludes consumers of information without direct control over the payload or platform (referred to as “knowledge workers” in Murphy and Burke (2008)). Human team members may be colocated with the UAV or at a remote location and, depending on the type of UAV and mission, can vary in number. Additionally, human team member functional roles may overlap.

Murphy et al. (2008) identified three roles in a micro or small UAS team: *Pilot*, *Mission Specialist*, and *Flight Director (Safety Officer)*. The bulk of human-robot interaction literature appears to be on the *Pilot* and reducing or combining that role with that of the *Mission Specialist*. Murphy et al. also suggest that more *Mission Specialists* will be added to the team as networking access becomes more pervasive. However, the *Mission Specialist* role is not well documented.

HMI research for specific UAS human team roles does not appear in the literature, presenting a challenge for designers and developers working with current and future unmanned systems. The HMI knowledge void becomes manifest as research efforts attempt to improve UAS capabilities by instead focusing on, among other things, reducing the human-robot crewing ratio through merging human team roles and increasing UAV autonomy (Cooper and Goodrich 2008; Cummings and Mitchell 2005; Cummings et al. 2007), increasing the number of UAVs in a single UAS (Burkle et al. 2011; Manathara et al. 2011; Tsourdos et al. 2011), and making UAS smaller, more mobile, and available to more diverse domains (Parrot 2011), without first understanding how human team roles are actually interacting. As Hobbs (2010) points out, there have been no human factors analyses published on any mobile interfaces for unmanned systems. The present lack of HMI understanding inhibits researchable improvements in UAS capabilities that may be possible by considering individual (and team) interactions within a UAS human-robot team.

This work surveys the hardware and software interfaces currently used by the *Mission Specialist* role on 10 micro or small UAS human-robot teams. Understanding human-machine interfaces is a first step towards understanding how a human fulfills the *Mission Specialist* role through human-machine interaction (HMI), which is critical for investigating general human-robot interaction in UAS, reducing the human-robot crewing ratio, and improving the individual role and team performance. However, research and development to improve the HMI experience of UAS interfaces has largely focused on UAS flight and navigation (Tvaryanas 2006; Walters and Barnes 2000). A HMI approach to support the acquisition of data and mission-related information remains historically less well developed (Cooke and Chadwick 2010), particularly for micro and small UAVs, as does an understanding of the HMI aspects of the *Mission Specialist* as the human team member responsible for such acquisition.

The chapter begins by providing an overview of two categories of UAS (micro and small) and the three roles common to all systems (*Flight Operations Director*, *Pilot and Navigator*, and *Mission Specialist*). It then produces a comprehensive summary of hardware and software HMI by UAS category based on over 20 papers and systems. The chapter discusses the implications for the *Mission Specialist* role and shows, especially in micro and small UAS operations, that there exist more user interface limitations present and, ultimately, that there may be a user interface interaction conflict between the *Mission Specialist* role and the team member responsible for flight and navigation. The work is expected to (i) serve as a reference document for unmanned system designers and developers and (ii) contribute to a better understanding of human-robot interaction in UAS (and in any robot being used for real-time data collection) by identifying the human-computer interfaces used in practice.

98.2 UAS Human-Robot Teams

In this section, background information is presented on two different categories of UAVs (based on size, payload weight capacity, range, altitude, and endurance) that may be employed for a mission, and the three roles present in the human team trending from the literature (*Flight Operations Director*, *Pilot and Navigator*, and *Mission Specialist*) that perform the actual UAV operations.

98.2.1 Categories of UAVs

The composition of a UAS human-robot team depends largely on the complexity of the UAS itself (Hopcroft et al. 2006). It is, therefore, necessarily cogent to the discussion to first provide a summary classification framework of selected UAVs that a human team may operate. A two-category classification system is employed, micro and small, which is consistent with the size categorization of the U.S. Air Force (Bierbaum 1995; United States Air Force (Online)),

Table 98.1 Classifications of selected unmanned aerial vehicles (UAVs) currently in operation^a

| Group | UAV platform name | Size ^b (m) | Weight ^c (kg) | Range (km) | Altitude (km) | Endurance (h) |
|-------|-----------------------------|-----------------------|--------------------------|------------|---------------|---------------|
| Micro | AirRobot AR100B® | 1.0 × 1.0 | 0.2 | 0.5–1.4 | 0.9 | 0.2–0.5 |
| | Aeryon Scout | 0.8 × 0.8 | 0.3 | 3.1 | 0.5 | 0.2–0.3 |
| | Draganflyer X6 | 0.9 × 0.9 | 0.5 | 0.5 | 2.4 | 0.2–0.3 |
| Small | AeroVironment Raven® | 1.1 × 1.3 | 0.2 | 10.0 | 4.6 | 1.3 |
| | AAI Shadow 600 | 4.8 × 6.8 | 41.3 | 200 | 4.9 | 12–14 |
| | Northrop Grumman Fire Scout | 9.1 × 8.4 | 272 | 127 | 6.1 | 5–8 |

^aMaximum operational parameters are reported and referenced from manufacturer specification sheets – normal operational parameter values will usually be lower and domain dependent

^bDimensions given are length × wingspan

^cThe maximum payload weight the vehicle can carry

Army (United States Army (Online)), and Navy and Marine Corps (Office of the United States Secretary of Defense (Online)) (Table 98.1). It is noted that for the purposes of this work, focus is restricted to subsonic and suborbital UAVs.

The first group consists of micro UAVs. This category of vehicle represents the smallest physical size, operational range (distance of travel), altitude (elevation above ground or sea level), and endurance (time of operation) of all UAVs, and it is the vehicle type most commonly available for commercial and civilian operations, such as wilderness and urban search and rescue. Micro UAVs allow a human team, which is usually colocated, to remotely navigate and visualize information in environments where, for example, humans or other ground-based robots are not practical. UAVs in the micro-category are traditionally of a rotor- or fixed-wing design.

The second group consists of small UAVs. Small UAVs expand upon the operational range, altitude, and endurance of the human-robot team without a significant change in the physical size of the vehicle. This would be important, for example, to on-site military combat units who will colocate with the UAV but need to maintain a large displacement distance for reconnaissance operations. Increased levels of autonomy are also found in small UAVs. One of the main differences between micro and small UAVs, besides an improvement in operational characteristics, is the dominance of fixed-wing vehicles and the increased payload weight capacity in the small category; very few rotor-based vehicles have been developed with small UAV operational parameters.

98.2.2 UAS Human Team Role Descriptions

There exists a diversity of human team role nomenclature in the literature across the various UAVs that have been developed and studied (Murphy et al. 2008;

Cooper and Goodrich 2008; Oron-Gilad and Minkov 2010; Cooke et al. 2006; Hopcroft et al. 2006). However, certain human team member role trends are identifiable and, generally, fall into one of three role categories: *Flight Operations Director*, *Pilot and Navigator*, and the main focus of this work – the *Mission Specialist*. These three role labels represent a synthesis from the literature and are given in this work to describe general role function rather than preferred role identification within any specific UAS. A human team member role survey from the current literature is provided for each of the UAV classifications shown in Table 98.1.

98.2.2.1 Flight Operations Director

Proper supervisory planning, coordination, and control of any operation are critical to its success, especially for a UAS human-robot team. Across the UAS literature, one or more human team member responsible for directing the mission was found to be a reoccurring role.

Murphy et al. (2008) define the role of a micro UAV team *Flight Director* as the individual responsible for overall safety of the team members (human and UAV). The *Flight Director* is in charge of mission situational awareness and has the authority to terminate the operation at any point. Cooper and Goodrich (2008) describe for a micro UAV team an Incident Commander, who is solely in charge of managing the search effort. For the small category, Oron-Gilad and Minkov (2010) ethnographically describe a UAS *Team Commander* role. Serving as the head of the human-robot team, the *Team Commander* may communicate with other UAS human-robot teams in the field or control stations and, in addition, monitor the technical condition of the vehicle. More complex situations described did arise requiring an additional individual, a *Mission Commander*, to join the team in order to focus only on strategy and coordination.

98.2.2.2 Pilot and Navigator

Piloting the vehicle is an essential human role and common to all UAS human-robot teams. However, the degree to which one or more individuals are solely responsible for flight control activity varies.

The role of a micro UAV *Pilot* defined by Murphy et al. (2008) is the human team member responsible for teleoperating the UAV within line of sight. They further indicate that the *Pilot* is responsible for the general airworthiness of the UAV prior to and during flight and addresses maintenance issues of the vehicle. According to Cooper and Goodrich (2008) who also address a micro class UAV, the *Pilot* is responsible for both aviation and navigation. For the small category, higher levels of UAV autonomy come into play, and the formal *Pilot* role transitions to a separate offsite operations control center. Oron-Gilad and Minkov (2010) provide detail on a *Field Operator* role that gives input as needed regarding where the UAV should fly; however, this role appears to, at best, have limited UAV flight control and navigation input capabilities.

98.2.2.3 Mission Specialist

UAV operational capabilities allow a human-robot team to insert themselves remotely for the main purposes of visual investigation and recording and, in more advanced vehicle systems, delivery of an onboard payload. It is therefore incumbent that one or more members of the human team be responsible for carrying out these kinds of activities. This role is referred to as the *Mission Specialist*.

Murphy et al. (2008) define the role of a micro *Mission Specialist* as a single human team member solely in charge of collecting reconnaissance data. Specific responsibilities include viewing the real-time video output from the UAV camera, directing the *Pilot* for reconnaissance, and adjusting the UAV camera settings for optimal image capture. Also for micro UAVs, Cooper and Goodrich (2008), who denote their human team member role as the *Sensor Operator*, assign the responsibility of directing a gimbaled camera for scanning and imagery analysis. In the case of a small class UAV, Oron-Gilad and Minkov (2010) describe an *Operator* role that is responsible for looking at specific areas and targets to evaluate the occupancy status of enemy troops. In their study, the operator focused on reconnaissance and the tactical aspects of the UAV mission.

98.3 UAS Mission Specialist HMI

As a subcategory of traditional human factors research, human-machine interaction (HMI) is a design science that has developed through experimental psychology methods being applied to techniques and tools available from within the discipline of computer science (Schneiderman and Plaisant 2010). In the context of this work, the interest is on how the human team member in the *Mission Specialist* role specifically interacts with the computer technology available during a UAV mission. The attempt is to address, where available, both the hardware and software aspects of human interfacing in each of the classifications of UAVs shown in Table 98.1.

98.3.1 Micro UAS Mission Specialist HMI

The details of *Mission Specialist* HMI for micro UAVs are the least well documented among the two UAV categories, which may likely be due to the often non-domain-specific nature of use in commercial and civilian applications.

Murphy et al. (2008) used a Like 90 T-Rex rotary-wing UAV in order to survey damage in post-Hurricane Katrina and post-Hurricane Wilma operations. The *Mission Specialist* role observed the real-time video feed from the T-Rex camera on a separate display screen and used independent radio control hardware for camera positioning. A second study by Murphy et al. (2008) during a separate post-Hurricane Katrina operation involved the use of an iSENSYS IP-3 rotary-wing UAV. Here the *Mission Specialist* role wore a heads-up display (HUD) for real-time visualization and utilized radio control hardware for positioning of the payload camera. In a study on wilderness search and rescue exercises, Cooper and

Fig. 98.1 Example of a micro UAS *Mission Specialist* interacting with an AirRobot AR100B® UAV (Courtesy of Center for Robot-Assisted Search and Rescue)

Goodrich (2008) employed the use of experimental fixed-wing UAVs fitted with a gimballed camera. The *Mission Specialist* visualized the video feeds from the UAV on a display screen and controlled the camera settings using independent radio control hardware. Figure 98.1 provides an example of a *Mission Specialist* interacting with a micro UAV.

Though not formally studied in the literature, there are several commercially available micro UAVs. User interaction with these UAVs ranges from simple hardware-based radio control to more sophisticated software-based control interfaces. Skybotix Technologies offers the CoaX®, a coaxial helicopter capable of general surveillance through a fixed-mounted onboard camera. An open-source application programming interface (API) is available to allow for flight control customization by one or more team members; however, the onboard camera is not controllable (Skybotix Technologies 2011). The Parrot AR. Drone is a quadrotor UAV that has both fixed forward- and vertical-facing cameras. An open-source API is also available. The AR. Drone is unique in that it is controllable only with Apple iOS devices (Parrot 2011).

Larger micro UAVs include the AirRobot AR100B®, which is a quadrotor micro UAV that includes an interchangeable payload. The *Pilot* for flight operations uses a hardware control interface that also contains a small display screen that can project real-time video when a camera is used as a payload. An API is available for the AR100B® for control (both flight and camera) customization; therefore, a *Mission Specialist* role could separately interact with the vehicle for data-gathering purposes on a separate laptop device (AirRobot 2011). The Draganflyer X series of rotor-based micro UAVs, produced by Draganfly Innovations, Inc., is controlled primarily by a hardware interface with limited touch screen interaction for flight and navigation. An onboard camera is also controllable using the same hardware interface, but video can be broadcast wirelessly to an HUD or a separate

display station, thereby allowing a *Mission Specialist* role the ability to complete reconnaissance tasks (Draganfly Innovations, Inc. 2011). Aeryon Labs has designed the Scout, a quadrotor vehicle with a hot-swappable payload that may include a gimbaled camera. The Aeryon Scout is capable of beyond line-of-sight operations and uses exclusively a touch-based software interface for flight and navigation control. Real-time video and image data transmission during the flight is available (to any wireless display device), and a *Mission Specialist* role could independently interact with the system to control the camera and complete reconnaissance tasks using a customized version of the touch screen interface (Aeryon Labs, Inc. 2011). Similarly, the Honeywell T-Hawk is capable of real-time video streaming from a controllable gimbaled camera to a custom pen-based laptop device (Honeywell 2011).

98.3.2 Small UAS Mission Specialist HMI

UAV human-robot teams in the small category often utilize coordination similar to that of micro UAV teams; however, there is not always colocation. As such, interface technologies for the *Mission Specialist* role appears in different varieties.

Oron-Gilad and Minkov (2010) provide two investigations of combat units utilizing a small UAV during the Second Lebanon War of 2006. Both studies indicated that the *Mission Specialist* role interacted with a handheld touch screen device. Additionally, there was a dedicated tablet laptop docked to the handheld device. The control panel had traditional hardware setup for interfacing, including a keyboard, trackball, and combination mouse/joystick. It was implied that both the *Pilot* and *Mission Specialist* role had to share the same handheld device to interact with the UAV. Figure 98.2 provides an example of a *Mission Specialist* interacting with a small UAV.

Commercially available small UAVs typically come with proprietary user interface technology. The fixed-wing Raven[®], produced by AeroVironment, has a common ground control system (GCS) that interfaces with all of the manufacturer's UAV systems. The control device consists of small handheld unit with dual joysticks for flight and navigation. A single small display screen is located in the center of the handheld device, allowing for visualization from onboard cameras. A hardware button-driven menu system allows for camera control. Due to the increased level of autonomy in this system, the *Pilot* and *Mission Specialist* roles overlap, leading to a single operator being essentially responsible for both roles (AeroVironment, Inc. 2011). AAI Corporation produces the fixed-wing Shadow line of Tier II UAVs. As with the Raven[®], the Shadow has a portable GCS. Two operators visualize the mission activities using independent large display screens. A full keyboard, joystick, and button pad allow for a *Mission Specialist* role to interface with the Shadow vehicle (AAI Textron Systems, Inc. 2011). Northrop Grumman produces the Fire Scout, which is uniquely a large rotor-based UAV. Flight and navigation by two operators is accomplished through a proprietary control system (CS). Consisting of four large display screens – two per operator – the CS displays payload imagery

Fig. 98.2 Example of a small UAS *Mission Specialist* interacting with an Aero Vironment Raven® UAV (Courtesy of the U.S. Department of Defense)

for reconnaissance that would fall under the purview of responsibilities for the *Mission Specialist* role. Interfacing is done through full keyboard, joystick, and button controls (Northrop Grumman 2011).

98.4 UAS Mission Specialist HMI Findings

In this section, a comparative analysis is provided of the *Mission Specialist* role and user interface technology found across both classes of UAVs. From the findings, it is observed that for micro and smaller UAS, there may exist a technology interaction conflict that could develop between the *Mission Specialist* role and the team member role responsible for flight and navigation.

For HMI purposes and though there are always exceptions, there are two distinct categories of human teams involved with a given micro or small UAS mission: (i) active and (ii) passive. Active human teams control all aspects of the UAV in the field. Micro UAVs, which are uniquely on-site, can be transported with the human team for complete launch, control, and landing by the human team. On-site active team roles may overlap. Passive human teams in the field (more common for a small UAS mission) tend to only interact with the UAV for activities such as taking reconnaissance imagery and adjusting navigation. For a passive UAS, the UAV may or may not be transported with the human team; transport, launch, control, and landing could be done via other persons at a separate location. For passive human teams, roles tend not to overlap. In terms of the UAS interaction technology (Tables 98.2 and 98.3), it is observed that there are two categories present for UAS human teams: (i) *Pilot and Navigator* centered (active) and (ii) *Mission Specialist* centered (passive). *Pilot and Navigator*-centered technology trends towards active control of the UAV. *Mission Specialist*-centered technology trends towards passive controlling of the camera, taking reconnaissance imagery, etc.

Both categories of UAS involve some sort of hardware-based interface. In micro UAVs, hardware interfaces dominate. Active human team *Mission Specialists* tend to interface more with hardware-based technology that is designed predominantly for UAV control and navigation. Micro UAV *Mission Specialists* mostly use handheld controllers that control every aspect of the UAV. In both categories, the *Mission Specialist* was more likely to interact with a limited set of hardware-based input, including only a joystick and/or a predefined pushbutton panel. The actual technology involved for the active human team *Mission Specialist*, therefore, may take the form of a simple designated pushbutton system for camera angling, zoom, and image capture (e.g., the AirRobot AR100B® and DraganFlyer X series). Passive human team *Mission Specialists* tended to interface more with both hardware-based and software-based interaction technologies that are designed more for *Mission Specialist*-centered activities. *Mission Specialists* in this category tended to use some sort of standard computer (i.e., desktop or laptop) that has a design focus on taking reconnaissance imagery and, possibly, the ability to make navigation adjustments. In the small UAV category, the *Mission Specialist* was more likely to use a full suite of hardware input devices, including a joystick, keyboard, mouse, trackball, and some type of ancillary pushbutton panel. The reasoning behind these trends in micro and small UAV technology interaction is that in a field situation, where micro and small UAVs are colocated, mobility is a highly desired characteristic and this will obviously reflect in the interface technology.

Some form of visual display, whether integrated directly into the hardware controller or located at an adjacent or remote base station, was present in both of the UAV categories. For *Mission Specialists* in field-type scenarios, displays were generally similar in dimension (less than 14 in.). Some UAV systems found (e.g., the iSENSYS IP-3 and the Aeryon Scout) had HUD capabilities for real-time video feed visualization (although, presumably, any of the UAVs with a standard video signal output could, in theory, be integrated with commercially available HUD or other ancillary display technologies).

In terms of the software-based interactions of the *Mission Specialist* role, both categories were found to have at least one use of static imagery, real-time video, and synthetic overlaying of mission-related ancillary data, as part of the interfacing. Simple menu interaction (i.e., hardware-driven menus) was found to be more prevalent in both categories, while some complex menu interaction appeared in the small UAV categories. This is due to the greater complexity of interaction required by the larger systems and also ties to the greater variety of hardware input devices available to the *Mission Specialist* role. It should also be noted that platform-independent software was observed to take into account a greater variety of hardware inputs.

A logical consequence of these findings is that active human team *Mission Specialists* tend to have to fit within the technology design scope for a *Pilot and Navigator*. One primary concern with this type of user interfacing is that there would likely exist a direct interface interaction conflict with a separate *Pilot and Navigator* role if there was only a single controller device. An interface of this design almost necessitates that the Pilot and *Mission Specialist* roles overlap, which

is not necessarily the most recommended scenario in domains that may likely utilize micro and/or small UAV technology. In close proximity operations, such as urban or wilderness search and rescue, for example, a Pilot may need to focus solely on the flight controls rather than on *Mission Specialist* tasks for collision avoidance (Murphy et al. 2008; Cooper and Goodrich 2008).

98.5 Conclusions

In this survey, three human team member roles (*Flight Operations Director*, *Pilot and Navigator*, and *Mission Specialist*) were observed to trend across both operational categories of small and micro UAS. Consistent for both UAS categories was the unique responsibility of the *Mission Specialist* for data acquisition and interpretation during UAV operation. The survey offers three findings:

The HMI technology used by the *Mission Specialist* had the three primary characteristics: mobile, small, and visual. Mobility was observed in all of the interfaces that the *Mission Specialist* interacted with. Handheld controllers that could be carried and handled by one individual were the most common form of interaction device. Inputs were accomplished by the *Mission Specialist* through interactions with small controls, most commonly isotonic joysticks and pushbuttons on the handheld controllers. Interactive feedback to the *Mission Specialist* was visual and took the form of small video displays, graphical menus, and real-time video.

In the literature, the *Mission Specialist* either shared the same interface with the *Pilot and Navigator* role, was given a duplicate of the *Pilot and Navigator* interface, or was a passive viewer. No UAV system in the literature had a dedicated *Mission Specialist* interface; however, the availability of API customization in commercial UAV systems does allow for that possibility. Given that the *Mission Specialist* is a unique human team role, a distinct or different modality of HMI technology from that of the *Pilot and Navigator* would be expected. Therefore, existing interfaces, in general, do not support the functionality of the *Mission Specialist* role.

The responsibility of the *Mission Specialist* is for data acquisition and, often, interpretation. The possibility for direct manipulation of the imagery for verification, including extracting single static images and a video series for real-time playback while the flight continued to be recorded, appeared present in only one (Oron-Gilad and Minkov 2010) of the ten surveyed UAV systems (the full extent of which, however, was not clear). It should also be noted that this interaction was accomplished through the UAV interface with the broadest array of available HMI technology (isotonic joystick, keyboard, mouse, trackball, pushbutton panel, and touch screen). Interpretation support (such as synthetic overlays) and other software-initiated functions were present on five of the ten systems surveyed, but these options were only commercially documented. These observations suggest that there is a heavily reliance on the hardware-oriented interaction by current *Mission Specialists*. Current HMI for the *Pilot and Navigator*-centered interface could be

limiting the software capabilities that may improve *Mission Specialist* performance in small and micro UAS missions.

These three findings of this survey suggest that current *Mission Specialist* performance in small and micro UAS may be suboptimal due to the sharing of a single *Pilot and Navigator*-oriented interface or a reuse of the *Pilot and Navigator* interface. Further research is warranted to better understand the distinctions between the *Mission Specialist* and *Pilot and Navigator* roles and, specifically, what user interfaces are best suited for supporting the *Mission Specialist* role on the UAS human team.

Abstract

This chapter presents a synthesis of past work on Unmanned Aerial System (UAS) autonomy and user interface design and uses this synthesis to motivate emerging themes in near-term and far-term UAS developments. Issues include user interface design, UAS autonomy, UAS teaming, operator workload, and payload management.

This chapter is a fusion of work from two previously published papers by the authors, integrated and extended to give a fresh perspective on the issues:

- ML Cummings, S Bruni, S Mercier, PJ Mitchel (2007) Automation architecture for single operator, multiple UAV command and control. *Int C2 J* 1(2):1–24.

Goodrich from this chapter.

99.1 Introduction

Accomplishing a dangerous and complicated mission, while minimizing risks and costs, is a primary goal in many military situations. Because Unmanned Aerial Vehicles (UAVs) can provide information and/or munitions deployment without exposing a human to harm, they naturally support such a goal and are becoming ubiquitous. For example, many military intelligence, search, and reconnaissance (ISR) missions can benefit from using Unmanned Aerial Vehicles (UAVs) and Unmanned Ground Vehicles (UGVs). Civilian applications can also benefit from using UAVs including wilderness search (Goodrich et al. 2008), disaster damage assessment (Murphy et al. 2008), and infrastructure inspection.

With reduced radar signatures, increased endurance, and the removal of humans from immediate threat, unmanned (also known as uninhabited) aerial vehicles have become indispensable assets to militarized forces around the world, as proven by the extensive use of the Shadow and Predator in recent conflicts. Despite the absence of a crew onboard in any of these UAVs, human operators are still needed for supervisory control. Although less mature, civilian uses of UAVs also require supervisory control for complex operations like border patrol, agriculture monitoring, and disaster response.

UAVs require human guidance to varying degrees and often through several operators, which is what essentially defines a UAS (Unmanned Aerial System). For example, the Predator and Shadow each require a crew of two to be fully operational. However, it is often desirable to design systems such that the current many-to-one ratio of operators to vehicles can be inverted.

In order to develop UAV technologies to effectively support single operator, multiple UAV control, the focus should be on the creation of an organization of human operators, software agents, and UAVs such that mission effectiveness is maximized at a minimum cost. The remainder of this chapter examines the role of autonomy and user interface design on UAS design, with an emphasis on not only placing UAVs at the right locations at the right time but also on managing mission-critical payloads of those UAVs. The chapter begins by identifying key attributes of the supervisory control problem for UASs. Since military UAVs represent state of the art, the first half of this chapter use military systems to provide context.

99.2 Supervisory Control of Multiple UASs

The move from platform-centric warfare to network-centric warfare (NCW) represents a shift in the role of humans both in mission planning and actual operation.

As has already been evidenced in the development of fly-by-wire, highly automated aircraft and missile systems (such as Tomahawk and Patriot), military operators are less in direct manual control of systems but more involved in the higher levels of planning and decision making and remote operations.

This shift in control from lower-level skill-based behaviors to higher-level knowledge-based behaviors is known as human supervisory control (HSC). HSC is the process by which a human operator intermittently interacts with a computer, receiving feedback from and providing commands to a controlled process or task environment, which is connected to that computer (Fig. 99.1) (Sheridan 1992). All UAVs in the U.S. Department of Defense inventory operate at some level of supervisory control as depicted in Fig. 99.1.

Human supervisory control in UAV operation is hierarchical, as represented in Fig. 99.2. The innermost loop of Fig. 99.2 represents the basic guidance and motion control, which is the most critical loop that must obey physical laws of nature such as aerodynamic constraints for UAVs. In this loop, operator actions are focused only on the short term and local control (keeping the aircraft in stable flight), and generally human control in this loop requires skill-based behaviors that rely on automaticity (Rasmussen 1983).

The second loop in Fig. 99.2, the navigation loop, represents the actions that some agent, whether human or computer-driven, must execute to meet mission constraints such as routes to waypoints, time on targets, and avoidance of threat areas and no-fly zones. The outermost loop represents the highest levels of control, that of mission and payload management. In this loop, sensors must be

Fig. 99.1 Human supervisory control of a UAV

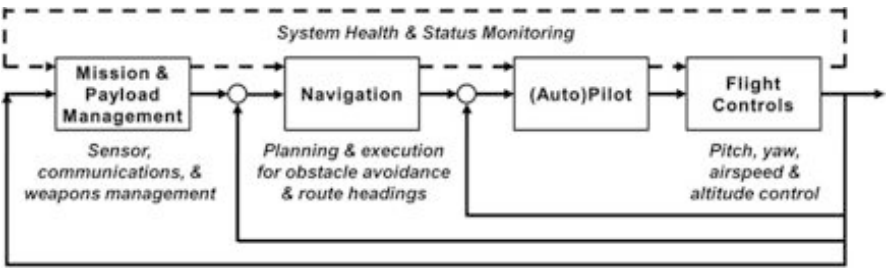

Fig. 99.2 Notional supervisory control loops for unmanned aerial vehicles

monitored and decisions made based on the incoming information to meet overall mission requirements. In this loop, decisions require knowledge-based reasoning that includes judgment, experience, and abstract reasoning that in general cannot be performed by automation.

Finally, the system health and status monitoring loop in Fig. 99.2 represents the continual supervision that must occur, either by a human or automation or both, to ensure that all systems are operating within normal limits. The control loop line is dashed as it represents a highly intermittent loop in terms of the human, i.e., if the human is engaged in another task, with the highest priority given to the innermost loop, health and status monitoring becomes a distant, secondary task.

From the human-in-the-loop perspective, if the inner loops fail, then the higher (outer) loops will also fail. The dependency of higher loop control on the successful control of the lower loops drives human limitations in control of a single and especially multiple UAVs. If humans must interact in the guidance and motion control loop (hand fly a UAV), the cost is high because this effort requires significant cognitive resources. What little spare mental capacity is available must be divided between the navigation and mission management control loops. Violations of the priority scheme represented in Fig. 99.2 have led to serious problems exemplified by numerous Predator crashes. When operators become cognitively saturated or do not correctly allocate their cognitive resources to the appropriate control loops in the correct priorities, they violate the control loop constraints, potentially causing catastrophic failure.

While Fig. 99.2 demonstrates supervisory control at the single vehicle level, Fig. 99.3 represents a notional system architecture that will be required for single operator control of multiple UASs. In order to achieve this futuristic system, operators will need to interact with an overall mission and payload manager while relegating routine navigation and motion control tasks to automation. The challenge in achieving effective management of multiple UAVs in the future is not only to determine if automation can be used to reduce workload but how and to what degree in each of the control loops in Figs. 99.2 and 99.3, as well as what kinds of decision support will be needed by operators given the high-workload environment.

One important consideration in developing the architecture depicted in Fig. 99.3 is the degree of centralization/decentralization of both the UAVs and the human. For example, in current single operator, multiple UAV operational paradigms, the operator independently controls all the vehicles in a serial fashion, and the vehicles do not work collaboratively to solve problems. Such an approach necessarily limits the number of vehicles the single operator can control since effectively the incoming tasks per vehicle represent a queuing network with a single server (the human) who has limited capacity (Cummings et al. 2007).

On the other end of the control spectrum are decentralized networks of UAVS with distributed autonomy across the vehicles such that the UAVs can locally reason independent of the network, while sharing information between the vehicles and a human supervisor at opportunistic times. Such control paradigms are task-based for the operator as opposed to vehicle-based for the centralized case (Clare and Cummings 2011). These architectures with significant advanced and increased

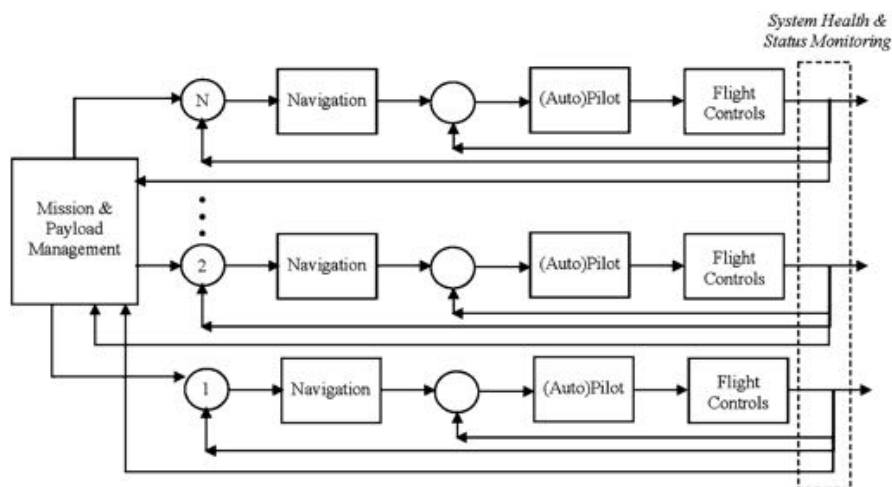

Fig. 99.3 Notional supervisory control loops for single operator, multiple UAV control

autonomy are what will enable significantly more UAVs to be controlled by one person, often referenced as swarm control.

99.3 Single Operator Management of Multiple UASs

Increasing the autonomy across the three control loops discussed previously (Figs. 99.2 and 99.3) is the critical architecture component for allowing one or a small team of operators to effectively control multiple UAVs. By increasing UAS autonomy, operator workload will theoretically be reduced as it could reduce the number of tasks for the operator, and it should reduce the level of interaction even at the highest levels of control in Figs. 99.2 and 99.3. For example, those UAVs that are flown in an autopilot mode relieve the operator from the manual flying tasks that require significant cognitive resources. This frees the operator to perform other critical tasks like mission planning and imagery analysis.

Higher levels of automation across the control loops depicted in Figs. 99.2 and 99.3 will be critical in achieving the single operator, multiple UAV control vision; but how, when, where, and what level of automation should be introduced are still difficult problems. For example, delegating navigation is necessary for organizations where a human must manage multiple UAVs. When the human must sequentially manage payloads, such delegation becomes even more critical.

While workload mitigation can occur through increasing automation, it can inadvertently cause higher workload as well as loss of situational awareness, complacency, and skill degradation (Parasuraman et al. 2000). For example, some UAV researchers have found that intermediate levels of management by consent (automation as an assistant to the operator) are preferable to manual or more fully automated

control (Ruff et al. 2002). However, management by consent means that the number of tasks could be high since operators must always be in the loop, potentially saturating operators, especially in the multiple UAV domain. Moreover, as has been shown in multiple UAV control research, operator performance can dramatically decrease under management by consent given increasing workload and various decision aids (Cummings and Guerlain 2007; Cummings and Mitchell 2008).

Given that an increasing number of tasks will have to be automated to achieve single operator control of multiple UAVs, particularly for swarm management, the question then becomes what to allocate to automation. Previous research has demonstrated that in the scheduling and execution of high-level tasks, of multiple UAVs, management by exception can improve operator performance (Cummings and Mitchell 2008). Management by exception occurs when automation decides to take an action based on some set of predetermined criteria and only gives operators a chance to veto the automation's decision.

While this control scheme can be effective in time-critical, high-risk domains like shutting down a near-critical nuclear reactor, in intentional, highly uncertain domains like command and control, it can be dangerous. Under this control scheme, operators are more likely to exhibit automation bias, a decision bias that occurs when operators become overreliant on the automation and do not check to ensure automated recommendations are correct (Mosier and Skitka 1996).

Automation bias was operationally seen in the 2004 war in Iraq when the U.S. Army's Patriot missile system, operating in a management-by-exception mode, engaged in fratricide, shooting down a British Tornado and an American F/A-18, killing three. The system was designed to operate under management by exception, and operators were given approximately 15 s to veto a computer solution. Unfortunately, the displays were confusing and often incorrect, and operators admittedly lacked training in the highly complex system (32nd Army 2003). Given the laboratory evidence that given an unreliable system, humans are still likely to approve computer-generated recommendations (Cummings 2004), it is not surprising that under the added stress of combat, Patriot operators did not veto the computer's solution. Automation bias is a significant concern for command and control systems, so it will be critical to ensure that when higher levels of automation are used, especially at the management-by-exception level, this effect is minimized.

99.3.1 A Meta-analysis of Previous Multiple UAV Studies

There have been numerous research studies published that have examined various aspects of multiple UAV control. A meta-analysis was performed across those studies that focused either explicitly on operator capacity or human supervisory control aspects of multiple vehicle control in order to determine any significant trends or lessons learned, particularly in regard to levels of automation and the control loops discussed above.

99.3.1.1 Previous Studies

One solution investigated by Dixon et al., to reduce UAV operator workload in the control of one or more small- to medium-sized UAVs, such as the Shadow, consisted of adding auditory and automation aids to support the potential single operator (Dixon et al. 2004). They showed that a single operator could theoretically fully control a single UAV both in terms of navigation and payload if appropriate offloading strategies were provided. For example, aural alerts improved performance in the tasks related to the alerts, but not others.

Conversely, it was also shown that adding automation benefited both tasks related to automation (e.g., navigation, path planning, or target recognition) and non-related tasks. However, their results demonstrate that human operators may be limited in their ability to control multiple vehicles that need navigation and payload assistance, especially with unreliable automation. These results are concordant with the single-channel theory, stating that humans alone cannot perform high-speed tasks concurrently (Welford 1952; Broadbent 1958). However, Dixon et al. propose that reliable automation could allow a single operator to fully control two UAVs in a centralized setting.

Reliability and the related component of trust is a significant issue in the control of multiple uninhabited vehicles. Ruff et al. (2002) found that if system reliability decreased in the control of multiple UAVs, trust declined with increasing numbers of vehicles but improved when the human was actively involved in planning and executing decisions. These results are similar to those found by Dixon et al. (2004) in that systems that cause distrust reduce operator capacity.

Ruff et al. (2002, 2004) determined that higher levels of automation actually degraded performance when operators attempted to control up to four UAVs. Results showed that in centralized settings, management by consent (in which a human must approve an automated solution before execution) was superior to management by exception (where the automation gives the operator a period of time to reject the solution). Management by consent appeared to provide the best situation awareness ratings, the best performance scores, and the most trust for controlling up to four UAVs.

Dunlap (2006) also subscribe to management by consent in their development of a distributed architecture to control multiple unmanned combat aerial vehicles (UCAVs). In this system, a UCAV plan is proposed by the automation, and the operator can either accept or reject the plan or submit an alternative. This recommendation can include both target assignments and routing. While they tested four, six, and eight UCAVs with increasing levels of environmental complexity, their final design limited the UCAV loadout at four. In one experiment, they noted that automation bias was a prevalent problem, stating the operators “had become attenuated to automatically accepting the usually correct proposals from the UCAVs,” which resulted in an increased kill rate for no-targets under the higher levels of automation.

In terms of actually predicting how many UAVs a single operator can control, there are only a few studies that examine this question, and they all focus on

the centralized architecture. Cummings and Guerlain (2007) showed that operators could experimentally control up to 12 Tactical Tomahawk Land Attack Missiles (TLAM) given significant missile autonomy. Operators only had to interact in the mission management loop, and all other loops were highly automated. In a UCAV setting, Cummings and Mitchell (2008) demonstrated that the number of UCAVs that a single operator can control is not just a function of the level of decision support automation but also the operational tempo and demands. Operators under low workload performed well regardless of the level of decision support, but under high workload, performance degraded. When considering operational and workload demands for a suppression of enemy air defenses mission, operator capacity was estimated at five UCAVs.

In a demonstration of the capabilities of a single operator attempting to control multiple Wide Area Search Munitions (WASMs), given high levels of autonomy across all control loops in Fig. 99.3 with only higher-order goal tasking for mission management, Lewis et al. (2006) posit that an operator can effectively control up to eight WASMs. The assumption is that the automation embedded in the vehicle's coordinates, without human intervention, specific tasks such as target detection and choice of the most appropriate member to execute the mission, which are capabilities that are not yet operational. The WASM study is similar to the Tactical Tomahawk study in that all flight-control and navigation functions are allocated to the automation alone, and the human intervenes for very high-level goal management.

Thus, there have been a cross section of studies that have examined operator performance and capacity in the control of multiple UAVs; however, it is not clear how many meaningful comparisons can be made across the different domains primarily because of two parameters: (1) what constitutes *control* and (2) what level of automation was used to aid the operators. In order to more directly compare these studies, the following section will discuss the scale on which comparisons can be made.

99.3.1.2 Level of Automation Trends

In this meta-analysis, the maximum number of UAVs that an operator effectively controlled in each study was extracted. It should be noted that in all of these reported studies, the control occurred in simulated test beds of medium fidelity and that all of these studies represent centralized control architectures. Approximate levels of automation (LOAs) across the control loop(s) from Fig. 99.3 were subjectively identified. While numerous levels and scales of automation and autonomy have been proposed (Parasuraman et al. 2000; Endsley and Kaber 1999; Wickens et al. 1998; Endsley 1995), the ten-level scale originally proposed by Sheridan and Verplank (1978) (SV-LOA) was chosen, as this is a commonly referenced taxonomy. Some of the categories in Table 99.1 were combined to reflect functional similarities. For example, levels 7–10 were combined since the human can take no action. Recognizing that different stages of information processing can be supported by automation (Parasuraman et al. 2000), the decision and action selection stage is represented in the assessment.

Table 99.1 Levels of automation

| SV-LOA | Our LOA | Automation description |
|----------|---------|---|
| 1 | I | The computer offers no assistance: human must take all decision and actions |
| 2 | II | The computer offers a complete set of decision/action alternatives |
| 3 | III | The computer offers a selection of decisions/actions |
| 4/5 | IV | The computer suggests one alternative and executes that suggestion if the human approves (management by consent) |
| 6 | V | The computer suggests one alternative and allows the human a restricted time to veto before automatic execution (management by exception) |
| 7/8/9/10 | VI | The human is not involved in the decision-making process, the computer decides and executes autonomously |

In Table 99.2, which presents a summary of these findings, the numbers of UAVs potentially controllable by a single human operator are referenced along with estimated levels of automation for each of the three control loops (MC – motion control inner loop, N – navigation, MM – mission management outer loop). It should be emphasized that the LOAs selected were approximate since they were both subject to interpretation and assigned post hoc from studies not originally intended to answer the research question. In addition, in many simulations, the LOA was not fixed so the range of LOAs was identified in these cases. In this comparison, an air traffic control (ATC) study was also included since it embodies many of the same principles of human supervisory control that are relevant to the control of multiple UAVs (Hilburn et al. 1997). Since air traffic controllers’ primary focus is safe navigation of aircraft, there is no associated mission management control loop.

Table 99.2 reveals interesting trends. Without explicitly discussing it in their respective studies, all researchers automated the inner motion control loop as depicted in Figs. 99.2 and 99.3. Thus, some form of autopilot was needed to relieve operator workload and free cognitive resources for higher loop control. To achieve the goal of one person controlling many UAVs, operators should only monitor the piloting/maneuvering of the vehicle, not do it themselves. However, this is a cultural problem more than it is a technological problem, as this technology is available today in all UAVs, but resisted in some communities, i.e., some organizations still insist that a human “fly” the vehicle instead of commanding it using various flight profiles.

Figure 99.4a demonstrates a general increasing trend in the number of vehicles an operator can control as a function of increasing automation in the navigation control loop of Fig. 99.2. Thus, given increasing navigation support and a fully autonomous flight-control system, operators can handle more UAVs when they do not have to attend to local and even global navigation concerns. The highest operator capacity was seen in the Tomahawk missile and WASM domains because, as they are one-way UAVs traveling at high speeds, there is little time for human intervention.

Table 99.2 Multiple UAV study comparison

| | Experiment | LOA | | | Max UV# |
|---|-----------------------------------|-----|------|--------|---------|
| | | MC | N | MM | |
| 1 | Dixon et al. (2005) (baseline) | VI | I | I | 1 |
| 2 | Dixon et al. (2005) (autopilot) | VI | IV | I | 2 |
| 3 | Dixon et al. (2005) (autoalert) | VI | I | IV | 2 |
| 4 | Ruff et al. (2002, 2004) | VI | IV–V | IV | 4 |
| 5 | Dunlap (2006) | VI | IV | IV | 4 |
| 6 | Cummings et al. (2007) | VI | IV | III–IV | 5 |
| 7 | Lewis et al. (2006) | VI | VI | IV–V | 8 |
| 8 | Cummings and Guerlain (2007) | VI | VI | IV | 12 |
| 9 | Hilburn et al. (1997) (ATC study) | VI | V | N/A | 11 |

When examining the mission and payload management control loop, [Fig. 99.4b](#) demonstrates the ability of operators to control more vehicles as they are provided with increasing automated decision support. It is interesting to note that given some automated navigation assistance and management-by-consent automation in the mission management loop, there is a convergence of operator capacity at 4–5 vehicles per operator. The next remarkable increase in operator capacity in centralized control settings (8–12 vehicles) is not seen until management by exception is introduced in the mission management or navigation loops. These increased levels of automation will be critical for increased operator capacity since, as previously discussed, if operators are required to attend to local navigation functions, they simply do not have the cognitive resources to successfully attend to all of the tasks in the mission and payload management loop.

As mentioned previously, to truly allow one operator the ability to control significantly more vehicles than the studies represented in [Table 99.2](#), the control architecture must shift from centralized, vehicle-based to decentralized, task-based. The decentralized approach leaves the human just in the knowledge-based mission management loop and offloading the lower two loops in [Figs. 99.2](#) and [99.3](#) to the automation. Thus, the limiting factor is not the number of vehicles an operator is controlling, but rather the number of tasks generated from each vehicle. The higher the autonomy and reasoning across a network of UAVs, the fewer tasks the team of vehicles generates.

In recent experiments, it was demonstrated that with a task-based, decentralized control system, doubling operator task load led to an operator workload increase of only ~50 %. Also in these studies, operator workload never approached unmanageable thresholds despite the doubling of task load. Thus, a task-based, decentralized control system may be robust to high task load situations, in effect allowing an operator to control theoretically limitless numbers of UAVs as long as they are generating, as a group, a manageable set of tasks (Clare and Cummings [2011](#)).

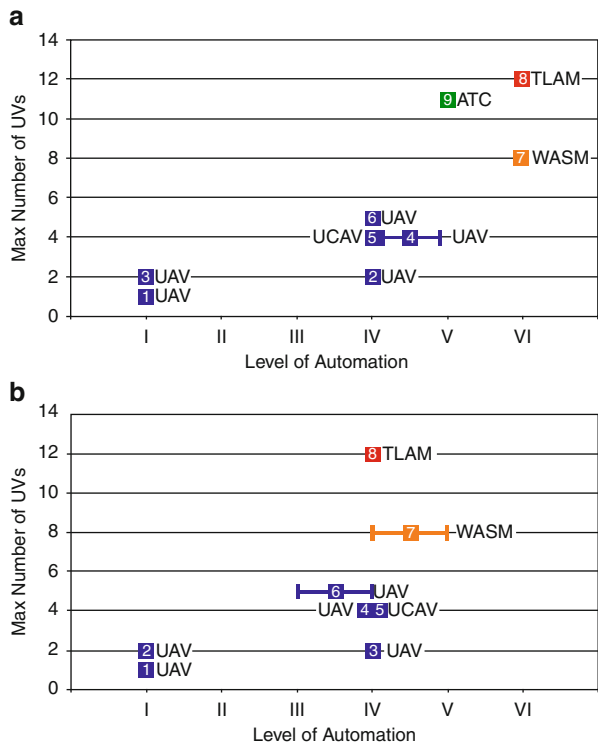

Fig. 99.4 Max number of UAVs vs. LOAs for the (a) navigation loop and (b) mission management loop

99.4 The Knowledge-Based Loop: Managing Payloads

It can be difficult to operate a remote UAS when an operator is required to spend most of his or her time in the mission and payload management outer loop in Fig. 99.2. Such tasks are typically knowledge-based and require judgment and reasoning, not easily codified in an algorithm. One such task that causes high workload in today's UAV operations is the surveillance task such as watching video feed. The perceptual problem associated with this task is the "limited angular view associated with many remote vision platforms creates a sense of trying to understand the environment through what remote observers often call a 'soda straw'" (Woods et al. 2004).

Conventional, workstation-based UAS interfaces do not integrate multiple sources of information into a coherent representation. Many interfaces include a map, UAS platform operations, and flight-control parameters in separate locations on the screen. Most systems deployed today show the footprint of the camera, but this is

often the extent of the integration. For operators using conventional displays, the cognitive workload associated with just getting enough awareness to control flight and navigation (i.e., the inner loops in Fig. 99.2) can be high enough that it is difficult to interpret imagery, plan strategies, and do other higher-level tasks that are relevant for the mission. This problem is frequently solved by adding more humans to the team who are responsible for mission-level issues (Burke and Murphy 2004) although, as noted in Sect. 99.3.1.1, offloading tasks to automation can theoretically enable an operator to manage both navigation and payload management.

A better approach to this problem is to represent real sensor information in an ecological way (Vicente et al. 1995). In the robotic domain, one important and useful ecological technique is the use of mixed-reality interfaces. Such interfaces combine real data with virtual elements and range from augmented reality to augmented virtuality interfaces (Milgram and Kishino 1994). An example of such interfaces, taken from Cooper (2007), is shown in Fig. 99.5. In this interface, satellite imagery and terrain maps are fused to create a virtual representation of the world. The UAV is projected into this virtual representation, and waypoints, compass, and other flight information are displayed within this virtual representation. Perhaps most importantly, video information is projected into the virtual world, giving context and stability for information detected in the camera. Most systems currently deployed project a sensor footprint (though perhaps without video) in this way, and most also provide separate video feeds on larger, higher-resolution displays to support video analysis.

Because a mixed-reality display is not constrained to a single perspective (e.g., pilot's perspective and payload operator's perspective), there are a number of different ways for information to be presented in a mixed-reality display. This chapter now briefly describes the *chase perspective* and the *map-based perspective*. Each technique is appropriate for certain types of tasks and modes of interaction between the human and a UAV.

Fig. 99.5 A mixed-reality display fusing control, navigation, and sensor information

99.4.1 Reactive Navigation and the Chase Perspective

The chase perspective is illustrated in Fig. 99.5. This perspective presents sensor information in a way that supports locomotion and is a typical representation used in racing games because it allows the direct perception of the relationship between the vehicle and the afforded directions of vehicle movement. An additional example of the chase perspective is shown in Fig. 99.6 (Quigley et al. 2004). In this display, a virtual UAV is included in the display to represent the pose of the UAV relative to the ground. This virtual UAV is overlaid on the video image received from the UAV and allows the operator to directly perceive the attitude of the aircraft with respect to the ground. (In the figure, two virtual UAVs are shown; one indicates the actual pose of the UAV as received from telemetry, and the other indicates the commanded pose of the UAV.) The chase perspective shown in Fig. 99.6 is taken from an interface that runs on a 7-in. or smaller display.

Note that the chase perspective for the UAV is earth-centered rather than pilot-centered; in the human factors literature, these differences of perspective are known as outside in and inside out, respectively. When the operator is on the ground, banking right is not accompanied by a pilot-perceived change in the earth's horizon nor is it accompanied by other vestibular cues. Since the operator is on the ground, the chase perspective adopts a ground-based perspective wherein a bank command is depicted by having the virtual UAV dip its wing in the commanded direction, thus matching the model of the aircraft to the mental model of the remote operator.

It is possible to take this ground-centered perspective a step further. Although the technology discussed in the next few paragraphs is a bit outdated, it is still relevant since it can be directly applied to controlling UAVs using tablet-based displays when those tablets are equipped with inertial sensing, as in “flying by iPad,” especially given the increasing use of smart phone and tablet devices in control applications for UAVs (Jackson et al. 2011; Cooper and Goodrich 2005). Since a fixed-mount

Fig. 99.6 Integrating a chase perspective with flight control

camera, typical of cameras mounted on micro aerial vehicles, rotates when the UAV banks, the operator must switch from a ground perspective to the UAV perspective in order to interpret video. This switch might be a cause of cognitive workload because the ground-based operator must interpret rotations in the video caused by a banking UAV.

An interface that makes both video and bank angle have a ground-centered reference frame is shown in Fig. 99.6. This interface is built for a control device called the PhyCon (for Physical Icon) (Quigley et al. 2004). Rather than using a handheld computer to issue commands to the UAV, a physical model of the UAV is used. When the operator banks the model, the actual UAV also banks. The PhyCon is almost certainly not viable for practical systems, but it does reinforce the idea that the inertial sensors from modern smart phones and tablets can be used for human control of UAVs. Although it is somewhat difficult to see in the figure, the pose of the aircraft is projected onto the video from a ground-centered reference frame using the chase perspective. This is a type of mixed-reality interface (Milgram and Kishino 1994). (In practice, there are actually two virtual depictions of the UAV. The first virtual UAV is depicted using the actual telemetry from the UAV. The second virtual UAV is depicted using the commanded pose from the PhyCon. Having both of these projected into the augmented reality display allows the operator to see that the actual UAV is responding appropriately to the commanded pose.)

The video feed is digitized and displayed on a computer (in this case, a laptop which presents the video through an eyeglass-mounted display). Prior to presenting the imagery, the telemetry from the UAV is used to rotate the image so that the horizon stays approximately level. This is depicted in Fig. 99.7. Rotating the image so that the horizon stays level means that both the video and the UAV attitude are depicted in a ground-relative reference frame.

An important lesson from Cooper (2007) is that chase perspectives are best suited to so-called reactive searchers. In a reactive search, an operator is not systematically

Fig. 99.7 North-up perspective

navigating through a search pattern or a series of waypoints. Instead, the operator is using real-time video information to directly control the UAV so as to track a moving target, follow a trail or terrain feature, or inspect a pipeline or convoy. Chase-based perspectives are useful in such domains because they create a tight coupling between flight dynamics and video information. Figure 99.6 enables this tight connection by changing the orientation of the UAV in response to video information, and Fig. 99.5 enables this tight connection by allowing the operator to control a controllable, floating waypoint (labeled the “carrot”) that the operator can reactively control.

99.4.2 Systematic Navigation and the Map-Based Perspective

The chase perspective primarily supports reactive control. When it is necessary to operate at the level of navigation or planning, it is often useful to have a map of some sort. For example, a common UAV mission is to search an area for a missing person or a target. Issuing commands for these searches and depicting the progress of these searches may be easier for the operator if a map-centered reference frame is used (Plumlee and Ware 2003), and in a direct comparison of a chase perspective and map-based perspective it was found that the map-based perspective was more useful for systematic search (Cooper 2007). The task is to present map information in a useful way and then to integrate the video into the map using this map-centered perspective.

Figure 99.7 depicts a mixed-reality display that integrates a virtual map with video from a robot (Cooper 2007). The video is depicted in this virtual world in such a way that video, map, and UAV pose information are simultaneously visible. There are a number of desirable features of such an interface, including (a) the ability to determine what has been searched and what needs to be searched, (b) the ability to perceive how the robot is oriented with respect to landmarks in the world, most importantly, a fixed north-up orientation, and (c) the ability to augment map information with icons or other semantic labels.

The ability to determine what has been searched and what needs to be searched has been shown to be very useful in wilderness search and rescue (Morse et al. 2010) as has the ability to keep a stabilized camera view in a north-up orientation (Morse et al. 2008). Map-centered displays, with either a north-up or linked orientation (Plumlee and Ware 2003), can be augmented with mission-specific symbology.

It is important to note that map-based interfaces have been used to construct augmented reality displays in aviation. These displays, which may be either heads-up or head-down and which may be retrofitted to older aircraft (Prinzel et al. 2004), are referred to as *synthetic vision* displays (Schnell et al. 2004). Several human factors studies have been conducted, many showing that there is an increase in navigation-related situation awareness with negligible loss in aviation-related situation awareness (Alexander and Wickens 2005), presumably because a greater field of view and subsequent sense of realism can be obtained with such displays.

99.5 Multi-operator, Multi-UAV Supervisory Control and Payload Management

The previous sections explored how autonomy and the user interface affected the state of the art in human supervisory control of single and multiple UASs. In this section, emerging trends are summarized that will likely impact the next generation of UASs.

The first emerging area follows immediately from the increases in complexity that occur when a human is required to manage multiple UASs. *Decision support systems* (DSSs) will be needed (a) to help humans manage attention between different vehicles, sensors, and mission parameters and (b) to help humans allocate and schedule resources so that assets are used efficiently. In single operator, multiple UAV control as depicted in Fig. 99.3, DSSs will be needed to assist primarily in the mission payload management task, as well as possibly lower-level tasking such as navigation tasks.

Given that the large majority of military UAVs, as well as likely future civilian UAV applications, are surveillance missions, an important question is whether a single operator can manage multiple video feeds that will occur in such multi-UAV surveillance missions. Such missions are only possible with high degrees of automation in the lower-level control loops in Fig. 99.3, as well as also in the mission management loop. Such automation could take the form of automated target detection, which is currently a very active area of basic research but with no major breakthroughs as of yet for airborne systems.

Another form of automated assistance in such settings could take the form of scheduling tools that prompt operators when to switch their attention across different UAVs under their control. Such DSSs rely on developing operator models that also consider the operational context of the vehicles in order to make recommendations to operators for not only when to switch but to which UAV or task that needs attention. While such attention management is key to efficient single operator–multiple UAV control, developing operator models that are robust in the inherently stochastic world of command and control is difficult (i.e., Bertuccelli et al. (2010)), so this is also an open area of current research.

The second emerging area is one of organization, particularly *organizational issues that arise when multiple humans share management responsibilities* for multiple UASs. The philosophy behind work in this area is that future operational models of human-UAS teams will have N humans manage M vehicles where N is much less than M . One key organizational issue is whether specific humans are assigned to fixed UASs or whether the humans can interact with any UAS according to mission demands (Mekdeci and Cummings 2009; Lewis et al. 2010). A second key organizational issue is how humans can provide mutual support to each other so that resulting behavior exploits the advantages of highly effective teams without invoking the negative behaviors (such as social loafing) that can arise when responsibility is distributed across an organization (Whetten et al. 2010).

The third emerging theme is the need to form a *common operational picture* when multiple sensor payloads are distributed across a wide geographical area (Sirak

2007; Feitshans et al. 2008; Velagapudi et al. 2008). This theme builds on current operational models where specific humans are responsible for controlling unmanned air and ground platforms but where other humans can benefit from information being returned from those platforms. This is particularly important in military applications where micro-UAVs might be used by a small squad of soldiers and large UAVs might be used as a strategic asset. Although different groups of humans might be responsible for controlling operational, tactical, and strategic UAVs, each group of humans might benefit in the role of so-called information consumers (Goodrich and Schultz 2007) of a common operational picture.

The fourth emerging theme is an extension of the third theme and seeks to automatically allocate UAV resources by providing information to and requesting information about a particular mission. Although this has been explored in other contexts, it is easily illustrated in wilderness search and rescue where the path of a sensor footprint may be automatically planned as the result of (a) search experts providing information about the likely influences on missing person movement, (b) incident commanders providing information about the relative difficulty of air and ground resources detecting a missing person, and (c) the UAV technical search specialist providing information about where the UAV should begin and end a search but allowing the UAV to optimally search the area in between (Lin et al. 2010).

Abstract

Unmanned aerial systems are complex tools requiring thoughtful designs that account for the platform, payloads, and human users as a holistic system. Often, the focus is first placed on designing the platform or payload, and the human element is considered later. Unfortunately, such system design approaches do not properly consider the human cognitive limitations and do not design the system to support the human’s tasks and decision-making. This chapter provides an overview of cognitive analysis methods that can be integrated into the early system design process to account for the human element. Specifically, this chapter provides an overview of task analysis, work analysis, and information flow analysis methods along with an overview of how individual methods from the different analysis classes have been combined. Specific examples of applying these analyses methods to unmanned aerial systems, ranging from potential futuristic systems to research systems to deployed systems, are also reviewed.

100.1 Introduction

The proliferation of unmanned aerial systems (UAS) with varying onboard capabilities has led to widely varying human–UAS interaction systems. For example, the Predator UAS, operated by the United States Air Force, essentially re-creates a traditional cockpit inside a ground-based control station, complete with stick-and-rudder controls. There exist research-based UAS architectures that measure atmospheric composition by flying preprogrammed flight paths to obtain precise scientific data (Goetzendorf-Grabowski et al. 2006). Finally, UAS systems exist that require the human to perform line-of-sight remote control with little or no onboard autonomy (Murphy et al. 2008). Thus, UAS platforms span the spectrum of autonomy levels (Endsley and Kaber 1999; Parasuraman et al. 2000) that directly impact the system capabilities and the human’s task of interacting with the system (Sheridan 1992, Sheridan 2002).

Given the largely varying UAS system capabilities, it is clear that the overall system design places high demands on the human operators. Human–UAS interaction design is fundamentally interrelated with UAS autonomy design and is essentially a multidimensional trade-off between application requirements, precision, response time, neglect tolerance, portability, and team size (Crandall et al. 2005; Quigley et al. 2005). The system designers must balance these trade-offs appropriately.

The capabilities of a particular combination of airframe, autopilot, and control algorithm delineate the set of affordances that frame the human–UAS system and deployment constraints (Gibson 1979; Norman 1988). These affordances implicitly define the possible available interaction control modalities and the associated cognitive demands (Adams et al. 2007). Each UAS application has a unique set of constraints that define the feasible interaction space, and analyses can be conducted regarding the characteristics of various system capabilities. Application constraints, especially human factors considerations, need to be incorporated into the system design in order to eliminate infeasible interaction modes and to promote appropriate system design (Adams et al. 2007).

Many approaches exist for deriving human centric system requirements and specifications. This chapter provides an overview of analysis methods, including cognitive task analysis, cognitive work analysis, and information flow analysis along with the benefits of combining the analysis methods and examples supported by the literature.

100.2 Analysis Techniques

100.2.1 Task Analysis

Task analysis is the process of identifying and examining the tasks to be performed by users when interacting with a system (Kirwan and Ainsworth 1992). Task analysis encompasses a range of techniques that capture actions and cognitive processes necessary for a human attempting to achieve a goal while using a system.

The objective is to effectively and efficiently integrate the human into the system in a systematic way. Cognitive task analysis extends task analysis techniques in order to better understand the humans' knowledge, thought processes, and goal structures that directly impact the task performance (Chipman et al. 2000; Hollnagel 2003). Overall, cognitive task analysis seeks to understand the cognition required by the human user to complete tasks and how to turn that understanding into tools that assist the human (Crandall et al. 2006).

A broad range of cognitive and noncognitive task analysis methods exist. Each method has a set of advantages, and disadvantages and many practitioners offer differing opinions of which methods are the best. Many sources review the various (60+) analysis methods; thus, this chapter does not recount all the methods (Annett and Stanton 2000; Crandall et al. 2006; Diaper and Stanton 2004; Hollnagel 2003; Kirwan and Ainsworth 1992; Schraagen et al. 2000).

The ability for humans to supervise, command, and interact with unmanned aerial systems is cognitively demanding. Often, UASs are deployed in highly dynamic and uncertain domains. If the UAS is remotely controlled using line of sight, then the human pilot must focus on the vehicle itself to successfully complete missions. If the human pilot does not have direct line of sight, but rather must use a human-machine interface or control station, then the human is constrained by the information system displays. The ability to supervise, command, and interact with the UAS becomes increasingly difficult when the system incorporates additional personnel, such as a sensor operator, distributed personnel, or a mixed airspace that incorporates both manned and unmanned systems.

When choosing a task analysis method for UAS system design, the choice of method will likely depend upon a number of criteria. If the focus of the analysis effort is on physical vehicle design, then the choice of analysis will likely differ from the case in which the analysis focuses on the human aspects as well.

The ability to provide situational awareness to remotely located human operators of UASs and their associated but distributed stakeholders is critical to mission success. UAS deployments tend to fall into two broad categories, those completed within the line of the pilots' sight and those that are distributed or remotely located. Either deployment scenario requires a focus on the pilot's situation awareness (Endsley 1988); however, situation awareness for distributed team situations is inherently more complex (Salmon et al. 2008). The goal directed task analysis (GDTA) is a type of cognitive task analysis that places a direct focus on situation awareness (Endsley et al. 2003). Specifically, the GDTA focuses on the dynamic situation awareness requirements while identifying the basic goals and decisions that the personnel must fulfill independent of the information source. The goals and decision questions can be used to identify the cognitive demands that impact situation awareness and the required capabilities that UASs must have in order to appropriately integrate into an existing system, such as a manned air space.

Humphrey and Adams (2011) augmented the GDTA goal-decision-SA structure when applying the technique to the analysis of the integration of unmanned systems, both ground and aerial into first response to chemical, biological, radiological,

nuclear, and explosive (CBRNE) incidents. The application of the GDTA to the CBRNE domain analyzed the human responders as system components in order to understand how unmanned systems can be designed for effective integration into the overall domain or system. Specifically, Humphrey and Adams (2011) extended the GDTA with a loose representation of the goal timing/dependences, the ability to represent tools and thought processes associated with a subgoal, and the individuals and groups associated with subgoals. They also developed a method for tracking unique situation awareness information requirements across multiple goals and tasks for very large, complex domains.

Adams et al. applied the GDTA to an existing research system that employs mini-UASs for wilderness search and rescue, or WiSAR (Adams et al. 2009; Goodrich et al. 2008, 2009). The purpose of the analysis was to identify effective operational paradigms for coordination among the UAS operator, the incident commander, and the ground searchers. Unlike Humphrey and Adams' CBRNE GDTA analysis, the WiSAR domain analysis was a textbook application of the GDTA (Endsley et al. 2003). The analysis resulted in a set of primary goals that were decomposed into a number of subgoals and associated decision questions (Adams et al. 2009). Each subgoal and task was numbered and placed in an order that loosely matches the timing of the search events, similar to Humphrey and Adams' CBRNE research (2011). A difference was that two complex information requirements that applied to multiple goals and subgoals were called out as separate detailed lists, which represented the environmental characteristics and the missing person information (Adams et al. 2009). The GDTA resulted in an understanding of the situation awareness information requirements indicating what information the UAS can gather to inform and augment the information provided by the human searchers. The GDTA also identified a number of cognitively demanding tasks that the system personnel must complete. As well, the analysis identified search techniques and potential communication breakdowns between the searchers and the UAS operator and incident commander.

Beyond the applications of Adams and colleagues (Humphrey and Adams 2009, 2011; Adams et al. 2009), other examples of applying GDTA to unmanned systems exist. Riley et al. (2006) conducted a GDTA of an existing urban search and rescue unmanned ground vehicle in order to understand the situation awareness requirements for tasking and controlling a single vehicle. Riley and Endsley (2005) applied the GDTA to a proposed military system containing both unmanned ground and aerial systems in order to understand the situation awareness for control and tasking for a collaborative task involving multiple unmanned systems and operators. Conners et al. (2008) used GDTA for developing collaborative control interfaces for teams of operators tasked with managing multiple unmanned systems, while Cosenzo et al. (2009) applied the GDTA to the development of a common interface design for soldier-machine interaction with manned and unmanned ground systems. Hanson et al. (2001) applied cognitive task analysis, including the GDTA, to the supervision of composite striker packages composed of manned and unmanned aerial systems, with a primary focus of increasing the mission controller's situation awareness.

The hybrid cognitive task analysis method proposed by Nehme et al. (2006), and extended in Almirao et al. (2007), involves generating a scenario task overview, an event flow diagram, situation awareness requirements, decision ladders of critical decisions, and a requirements summary table. The hybrid cognitive task analysis' scenario task overview and event flow diagram provide system goals, while the list of situation awareness requirements and decision ladders represents information. The resulting requirements summary table represents the type of requirement, a requirement description, and the source of the requirement. Nehme et al. (2006) applied the hybrid cognitive task analysis method in order to generate information and display requirements for futuristic unmanned systems (underwater and aerial) applications.

Cooke and Shope (2004) designed a synthetic task environment, a simulation for Predator UAS operation based on a cognitive hierarchical goal-based task analysis conducted with U.S. Air Force Predator personnel (Gugerty et al. 1999), actual operation deployments, and results from an existing synthetic task environment (Martin et al. 1998). Hou et al. (2007) also applied hierarchical goal analysis to the development of an intelligent adaptive interface for the development of a multiple UAS tactical workstation.

As can be seen, the existing research, as applied to UASs, has used different methods. The analyses had different foci and purposes, thus resulting in different outcomes. This outcome is expected, since task analysis is intended to be applicable to multiple problems and domains, and the analysis can be applied for different purposes.

100.2.2 Work Analysis

Another important aspect when designing new technology is an appropriate understanding of the work domain. Cognitive work analysis permits an analysis of the human work based on domain constraints that can be device-independent and independent of worker competencies (Burns and Hajdukiewicz 2004; Vicente 1999). Cognitive work analysis is composed of five phases: work domain analysis, control task analysis, strategies analysis, social organization and cooperation analysis, and worker competencies analysis.

The work domain analysis permits a representation of the system independent of specific events, tasks, activities, and actions. The work domain analysis is an event-independent analysis that provides robust results applicable to all situations, including events that subject matter experts and system developers cannot anticipate (Jamieson et al. 2007; Miller and Vicente 2001). The control task analysis extends the work domain analysis findings by identifying the activities necessary to achieve the purposes, priorities, values, and functions within the work domain (Naikar et al. 2006) and provides an understanding of the information processing steps in relation to the required knowledge for achieving the stated goals. The control task analysis focuses on decomposing the system activities into control tasks for the various response situations and processes (Jamieson et al. 2007; Vicente 1999). The focus of the strategies analysis is to develop a process description of how the work should be

completed (Vicente 1999). Specifically, the strategies analysis attempts to identify the different means by which a task can be completed. The social organization and cooperation analysis focuses on identifying how the social and technical factors in the system can work together in such a way as to enhance the system performance (Vicente 1999). The final step, the worker competencies analysis, seeks to identify the competencies those using the system must possess in order to function effectively (Vicente 1999). The result of this analysis is a consolidation of the requirements from the first four phases as well as a determination of how the requirements can be achieved when considering the humans' capabilities and limitations (Vicente 1999).

The applied cognitive work analysis technique is grounded in the standard cognitive work analysis but is designed to be a "pragmatic, effective processes" for the design of revolutionary systems (Elm et al. 2003). This method was developed in order to better integrate cognitive analysis and the design and development of revolutionary systems. The method involves developing a functional abstraction network model capturing the domain concepts and relationships, identifying cognitive work requirements and information and relationship requirements, specifying the representation design requirements, and developing presentation design concepts.

Cummings (2003) developed the modified cognitive work analysis, which augments cognitive work analysis with an analysis of the global social, organizational, and ethical factors and the development of a system simulation. In general, both the modified cognitive work analysis and cognitive work analysis processes provide an understanding of the socio-technical context in which workers perform tasks (Vicente 1999). Cummings' modified cognitive work analysis is applicable not only to causal systems but also to intentional systems. The modified cognitive work analysis has been applied to naval warfare (Cummings and Guerlain 2003), and cognitive work analysis has been applied to a number of domains including emergency management (Vicente 1999).

Nehme et al. (2006) argue that traditional cognitive work analysis and cognitive task analysis cannot support the development of futuristic systems (i.e., systems that do not exist), because these methods require access to existing users, systems, and documentation. However, Drumm et al. (2003) applied work domain analysis to the design and development of a first-of-a-kind military system, where a first-of-a-kind system has no existing equivalent. Drumm et al. (2003) also modified cognitive work analysis for the design of teams by conducting a work domain analysis, an activity analysis, and a tabletop analysis to ascertain the feasibility of the proposed team designs. Humphrey and Adams (2010, 2011) built on Drumm et al.'s concepts to analyze the CBRNE domain for the purpose of informing the design and development of a first-of-a-kind unmanned systems to support teams of responders.

Humphrey and Adams' (2009, 2011) CBRNE domain analysis provided an event-independent analysis with results applicable to all situations, including events that subject matter experts and system developers cannot anticipate (Jamieson et al. 2007; Miller and Vicente 2001). The resulting understanding of the work domain's impact on the human-based CBRNE system permitted the identification of critical response activities that must be considered when developing unmanned systems.

Humphrey and Adams (2011) extended the cognitive work analysis (Cummings 2003; Vicente 1999) on multiple fronts. First, they adapted a concept of dividing the domain into multiple abstraction–decomposition spaces (Naikar et al. 2005). Others (Drumm et al. 2003; Jenkins et al. 2008) analyzed their domains by decomposing the teams into a hierarchy and sub-teams. The CBRNE domain contains many sub-teams (or subsystems) with unique, but sometimes overlapping, skill sets, tools, and responsibilities. Thus, Humphrey and Adams (2011) adapted Drumm et al.’s concept to the much larger CBRNE analysis in order to better identify roles and interaction customizations.

The cognitive work analysis’ control task analysis captures the relationship between actions and knowledge states (Vicente 1999) as well as some of the action dependences and scheduling via decision ladders (Rasmussen 1976). An additional modification by Humphrey and Adams was the use of statecharts (Harel 1987) to represent the control task analysis’ decision concurrency and hierarchical relationships succinctly (Humphrey 2009; Humphrey and Adams 2011). The representation of such constraints is paramount to understanding the team decision-making process (Gonzalez 2004). Humphrey and Adams’ analysis included the analysis of the global social, organizational, and ethical factors (Humphrey and Adams 2011). The analysis of relevant social groups identified 56 individuals or groups who may be affected by the CBRNE system. A communication flow map represents how different social groups communicate and depicts the direct and authorized communication interactions, but it does not represent how and by whom information is produced, consumed, or transformed.

Adams et al. (2009) applied the cognitive work analysis’ work domain analysis and the control task analysis to a research-based micro-UAS system for the WiSAR domain. In addition to providing insight into potential critical events, the work domain analysis captured (a) the high-level objectives of the WiSAR search process, (b) the priorities to be maintained during WiSAR, (c) the general functionality of the human-based WiSAR response, (d) the physical functions conducted and supported by the human responders and physical response devices, and (e) the physical devices required to conduct WiSAR. A standard work domain analysis (Vicente 1999; Naikar et al. 2005) represented by an abstraction–decomposition space was conducted. The decomposition dimension represents the different levels of detail required to reason about the search domain, with the rows representing the abstract functional decomposition for the different response concepts or the procedures to be reasoned over within the non-UAS, human-only WiSAR domain. The result is a categorization of the purposes, values and priorities, processes (functions), and physical resources (including the human responders) required for WiSAR. The work domain analysis indicated specific tasks and processes, as well as certain physical components required for an efficient search that locates the missing person as quickly as possible. The work domain analysis results informed the UAS-enabled WiSAR team’s organization and tactics as well as the development of operator interfaces to support managing system states based upon the current human-based response procedures and processes. The analysis strongly impacted the system design by clearly identifying that the WiSAR response has two key subsystems: information acquisition and information analysis.

The WiSAR control task analysis focused on decomposing the system activities into control tasks for the various response situations and processes (Jamieson et al. 2007; Vicente 1999). This analysis developed a decision ladder (Rasmussen 1976) to represent the information processing activities and the associated knowledge states required for conducting WiSAR (Adams et al. 2009). The control task analysis represents the control tasks necessary for understanding the current state of the WiSAR activities, which informs the control tasks required to achieve the desired system state and the resolution of the search activities. The control task analysis required an understanding of the work that needs to be completed with regard to the work processes, specifically the search procedures, and provided a very important lesson in that the search is essentially an iterated refinement of the probability describing the likely location of the missing person (Goodrich et al. 2008, 2009).

Rasmussen (1998) applied cognitive work analysis to modeling the changes to command and control when UASs are integrated into suppression of enemy air defense missions. Gonzalez Castro et al. (2007) conducted a cognitive work analysis focused on developing procedures, functions, and a proposed ground control station for continuous target surveillance via an UAS. The scope of this analysis was a well-defined problem for a single vehicle, and their analysis was not intended to inform vehicle design. Stilson (2008) analyzed the work requirements in order to develop a representational structure of work and a display design of a multiple UAS manager for the Predator unmanned aerial system. Pratt et al. (2008) also applied cognitive work analysis to determine the crew organization and protocols for deploying small tethered UASs during structural inspections in the field. Most recently, Jenkins (2012) applied cognitive work analysis to systematically understand the constraints for military air operations and define information requirements in order to postulate the implications of introducing UASs. Additional examples of applying CWA to display design for UASs exist (Stoner et al. 2006; Yagoda and Coovert 2012).

Cognitive work analysis and its derivations are intended to understand the work domain and, through the analysis steps, shift the focus to the human components. Many analysis examples employ the work domain analysis and cognitive task analysis steps, but very few examples exist of analyses that complete all designated steps. As is demonstrated by the cited examples of applying cognitive work analysis to UASs, even an application that only includes components of the analysis technique can be beneficial to system design.

100.2.3 Information Analysis

A subset of the cognitive task analysis methods focus on information analysis. Simple information flow diagrams represent the decisions and actions performed to complete a task by capturing the information flowing through the system, but such diagrams quickly become cumbersome for complex systems, particularly those that include large teams of humans (Kirwan and Ainsworth 1992). The limitation is the inability to easily represent multiple different individuals who are responsible for a single task or how information is modified as it flows through a system or organization. The function–information integration method represents the

information flow through the system, including data dependencies (Essens et al. 2000). This method provides a clear understanding of the information flow and dependencies but does not easily represent the association of different humans responsible for the task or the human organization. Operational sequence diagrams represent the information collection required to complete a task (Kirwan and Ainsworth 1992). Temporal operational sequence diagrams add the time required to complete each action. Partitioned operational sequence diagrams permit the representation of small team-based tasks at different task abstraction levels. The operation sequence diagram techniques are too simple to represent very complex, dynamic, and highly uncertain systems that contain UASs and multiple stakeholders. Additionally, information flow and operation sequence diagrams do not provide a clear understanding of how information may be used for each task, for example, tasks for which some information is required, while in other cases information may be optional.

Boy's cognitive function analysis results in linking artifacts that are being designed by considering a user's activities, the required tasks, and the organizational environment (Boy 1998). Boy extended the concept to multiple agent systems composed of humans and machine agents (Boy and Ferro 2004; Boy 2011); however, there appears to be limited validation of the ability to use the method for analyzing large scale, ad hoc multiple agent systems. In particular, the cited examples are quite constrained when compared to the analysis of very complex, highly dynamic, and highly uncertain domains that UASs may encounter. Boy (2011) indicates that the cognitive function analysis provides a "notion of context"; however, it is not possible to predict all possible contexts that deployed UASs and their human stakeholders will encounter. Boy's orchestra metaphor, employed to extend cognitive function analysis for multiple agents, is intended to be applied to problems that require multiple entities to develop contracts and coordinate with one another in real time while having specialized abilities (Boy 2009b). Boy's method has been applied to manned aviation domains (e.g., Boy and Ferro 2004, 2009a), but not to UAS domains.

Humphrey and Adams (2010) cognitive information flow analysis integrates the results from cognitive task and work analyses in order to provide a focus on the flow, understanding, and usage of information in large, ad hoc team domains. Specifically, this method is intended to allow the designer to understand how information is produced, consumed, and transformed in the system and by whom. Information is produced when it is gathered via humans, system sensors, or is the result of creating a new information product from existing information. Information is consumed when it is used by processes or individuals to satisfy a system function. Information is transformed when it is consumed by a system process that results in creating a new information product.

The cognitive information flow analysis combines results and provides a new perspective that includes the flow of information, potential information bottlenecks, and who is responsible for receiving and using the information as well as creating new information products. A limitation of many cognitive task analysis and the cognitive work analysis methods is that they do not explicitly represent what information is used by the stakeholders, which is important in

team-based environments, such as UAS deployments with multiple stakeholders (Adams et al. 2009; Goodrich et al. 2008; Murphy et al. 2008; Pratt et al. 2008), or how information items are produced, consumed, and transformed. Specifically, the GDTA employs goals that represent information to be consumed or used, but does not explicitly represent what information is produced or how it is changed. The cognitive work analysis' control task analysis represents how knowledge states are produced, consumed, and changed; however, knowledge states and information components are not equivalent. A knowledge state is a holistic, cognitive state a decision maker is in either before the decision or after. Information components are individual pieces of knowledge that assist a decision maker in making a decision or are produced by the decision maker as a consequence of the decision. The modified cognitive work analysis communications flow map creates a hierarchy of humans representing direct and authoritative lines of communication, but does not represent how and by whom information is produced, consumed, or used. The cognitive information flow analysis addresses these limitations by focusing explicitly on the flow of information through tasks and identifies groups of individuals responsible for the tasks. The flow of information represents the production, consumption, and transformation of information, which can directly inform system and interface design requirements that support decision-making.

100.2.4 Combining Analysis Techniques

It is well known that there exist various benefits and pitfalls associated with each analysis approach, as well as the individual techniques within the analysis categories (Humphrey and Adams 2011; Kirwan and Ainsworth 1992; Vicente 1999; Xu 2007). Much debate has ensued as to the benefits of individual cognitive task analysis methods compared to one another and the benefits of cognitive task analysis as compared to cognitive work analysis. As such, comparisons of the methods have been reported. Miller and Vicente (2001) compared hierarchical task analysis with an abstraction–decomposition space, or work domain analysis, and presented the associated advantages and disadvantages. Jamieson et al. (2007) also compared hierarchical task analysis and work domain analysis. Miller and Vicente (2001) and Jamieson et al. (2007) conclude that the two techniques have differences but that the differences are complementary.

Due to the limitations associated with individual analysis methods, it has become common to combine multiple methods when analyzing systems (Crandall et al. 2006; Humphrey and Adams 2010, 2011; Potter et al. 2000). The applied cognitive work analysis (Elm et al. 2003) is an example of a method intended to capitalize on the various benefits. Laberge et al. (2007) combined hierarchical task analysis and work domain analysis results when identifying information requirements for developing an intersection decision support display for rural drivers. Kaber et al. (2006) applied GDTA and constructed an abstraction–decomposition space (e.g., work domain analysis) of a high-throughput organic compound screening operation. Kaber et al. found that combining the analyses results facilitated system design by providing a better understanding of the automation needs, the existing technologies,

the operator needs, and the interface design limitations. Diaper et al. developed pentanalysis to integrate task analysis with data flow analysis (Diaper et al. 1998), while Ntuen et al. combined various cognitive task analysis methods with work domain analysis (Ntuen et al. 2006).

Humphrey and Adams (2011) employed both cognitive task analysis, via the GDTA, and cognitive work analysis, via the modified cognitive work analysis. Humphrey and Adams also created the cognitive information flow analysis to combine the results and provide a unique understanding of the system (Humphrey and Adams 2010). Specifically, the intent was to define tasks for unmanned aerial and ground systems based on an analysis of the human-based tasks (Humphrey and Adams 2009), result in unmanned system design specifications (Humphrey and Adams 2011), define emergency response human–robot interaction roles (Humphrey 2009), and identify the information flow, and teaming and design of a system of interfaces to support a large (nine levels) command hierarchy (Humphrey 2009). Humphrey and Adams specifically employed both the GDTA and the modified cognitive work analysis in order to balance each method's cited limitations; see Humphrey and Adams (2011) for limitations.

Humphrey and Adams specifically wanted to include a representation of the humans in the incident response system. This perspective differs from traditional cognitive task and work analysis that views the human as a system user. As well, many cognitive task and work analysis methods focus on a single human user, rather than a team of individuals. A number of analyses have focused on relatively small teams of one to four team members (see Schraagen and Rasker (2003) for a review), while a few analyses have incorporated teams of 20–25 members (Annett and Cunningham 2000; Essens et al. 2000; Zachary et al. 2000). The ability to scale the analysis techniques to very large teams, such as the hundreds of humans represented in the CBRNE domain, is not simplistic. As a result, Humphrey and Adams (2011) augmented both the GDTA and the modified cognitive work analysis. An important aspect is that Humphrey and Adams (2011) conducted the analyses in a manner that viewed the human responders as system components. This perspective was deemed appropriate because the humans complete tasks that are necessary for the overall system to achieve the system goals. Adams et al. (2009) analysis of mini-unmanned aerial systems for WiSAR also considered the human responders as system components.

Humphrey and Adams' GDTA permitted a focus on the information required by personnel and the information that unmanned systems must provide in order to emulate human responder provided information (Humphrey and Adams 2011). However, the GDTA does not focus on the required information processing steps, how information is transformed by the system, and the timing of response activities and does not capture the activities that occur simultaneously or the conflicts that occur between simultaneous goals. Humphrey and Adams (2011) augmentations to the GDTA were intended to overcome these limitations. Additionally, the GDTA does not focus on unexpected events that may occur in the work domain, which was provided by modified cognitive work analysis. An understanding of the work domain's impact on the human-based system allows for the identification of critical events that must be considered when designing the unmanned system and the

associated system of interfaces. The work domain analysis captured high-level objectives, the priorities to be maintained, the general functionality of the human-based system, the physical functions conducted and supported by the humans, and the physical devices required by the system.

Humphrey and Adams (2010) cognitive information flow analysis was designed to assist the design and development of systems by explicitly representing how and by whom information items are produced, consumed, and transformed. Specifically, the cognitive information flow analysis was developed to combine the results from the GDTA and cognitive work analysis methods in a manner that provided new insights for system development while building on the strengths of the GDTA and the modified cognitive work analysis and addressing some of their cited limitations. Specifically, the cognitive information flow analysis identifies how information from the unmanned systems is used to complete different goals and tasks within the system and how this information is transformed by different system tasks and provided to personnel who require the information for task planning, ultimately resulting in new task assignments for the unmanned systems. This combination of the GDTA, cognitive work analysis, and cognitive information flow analysis provided a general response system level of context when analyzed as a whole, rather than the individual analysis representations.

Adams et al. (2009) also employed multiple techniques in their analysis of the WiSAR domain, in particular the GDTA and the cognitive work analysis' work domain and control task analyses. The combination of the analysis techniques provided a base of information that allowed the UAS developers to better understand the human-based WiSAR response and to formulate the correct questions earlier in the development process. The analysis informed the design and development of autonomous UAS algorithms, the associated operator interfaces, and the human roles and responsibilities (Goodrich et al. 2008, 2009). However, it is important to note that these analysis techniques were not the sole contributors to the design and development of the UAS-enabled WiSAR technology. The early technology development, via early flight tests and field trials, informed the analysis conducted by Adams et al. and the analysis results informed the later technology development, thus successfully integrating the analysis techniques into the systems engineering process.

The combination of analysis techniques can lead to a richer representation of the task requirements, work domains, cognitive demands, system representations, and human roles for the system being analyzed. However, combining techniques should be done as a means of obtaining information not captured by one or more of the techniques, rather than simply capturing the same or a significant subset of the information. The techniques should be chosen to compliment the weakness of each other and result in new insights. However, if a particular technique can meet all of the analysis objectives, then it may not be necessary to employ multiple analysis techniques. Information gathering, analysis development, and maintaining the analysis are very complicated for complex systems such as UASs; this difficulty is increased by conducting multiple types of analyses.

100.3 Conclusion

The representations of applications of the analysis methods in the literature abound. These examples cross domains, methods, and purposes. The application of cognitive task analysis, cognitive work analysis, and information analysis techniques is relatively new to the unmanned system domain and in particular to UASs. However, the basic lessons learned from applying such techniques across different problems are important when considering their use for UASs. The intent of employing such methods is to understand the underlying cognitive and work demands associated with system operation. UASs range from the very simple remotely controlled systems available as toys, to the very complex, long flight duration military UASs. The planned deployments for such systems include benign image collection; very dynamic and dangerous domains, such as first response; and very dense and dynamic air spaces, such as military deployments incorporating both manned and unmanned aircraft systems. The future design of such systems and their associated human-machine system interaction needs to accommodate these complexities and the associated demands placed on the humans. It is clear that cognitive task analysis, cognitive work analysis, and information flow analysis techniques are critical to the development of future systems. Unfortunately, there is no single clear method that is appropriate for all system design and development endeavors. Advocates exist for particular methods, such as cognitive task analysis, who do not believe that cognitive work analysis is appropriate, and vice versa. Thus, it is necessary to analyze the objectives to be achieved by conducting the analysis, the scope of the analysis, the constraints on the analysis, and the capabilities of each method prior to commencing the analysis.

One issue associated with task analysis and cognitive work analysis techniques is the difficulty of translating the analysis results into actual interaction design, specifically user interface design (Potter et al. 2003). This particular issue has been noted by many (e.g., Humphrey and Adams 2011, Xu 2007) and should be considered when determining the analysis scope and objectives. Humphrey and Adams (2010) cognitive information flow analysis provides insight into the type of information required for a particular type of use, but does not specify the interaction design. One approach to informing design for revolutionary systems, meaning systems that require an innovative design, is applied cognitive work analysis (Elm et al. 2003).

Conducting these types of analyses is very time-consuming and cannot be completed based upon simply reviewing the existing literature or system design documents. These types of analyses require direct interaction with the system users, preferably while they are using the existing system. However, it is not always possible to conduct the data collection on the actual system; rather, it may be necessary to seek other means of collecting the data. Adams et al. (2009) employed field trials of wilderness search and rescue training sessions; however, Humphrey and Adams (2010, 2011) were limited in their analysis of the chemical, biological, radiological, nuclear, and explosive device incident response domain.

Such incidents do not occur frequently, and researchers are not permitted into the contaminated area; however, it is possible to observe training exercises that occur across the country. Successful UAS design, development, and deployment are highly dependent on a thorough analysis of the existing or planned system, including the demands placed on the integrated humans. Thus, it is absolutely necessary to identify and analyze actual or potential users of the resulting system in order to have a valid analysis.

Abstract

Advances in automation technology are leading to development of unmanned aerial vehicle (UAV) concepts in which a single pilot is responsible for multiple UAVs. With these highly automated UAVs, the operator’s role will become more supervisory in nature. In response, a new interface paradigm is required for effective supervisory control of multiple UAVs by a single operator. This chapter introduces a variety of display and control concepts that may be especially applicable to multi-UAV applications. Many of these are technologies being investigated at the United States Air Force Research Laboratory and include multimodal interfaces, temporal displays, and integrated visualization concepts. For any candidate technology, however, rigorous user-centered design and evaluation needs to be conducted that focuses on the tasks and requirements of the specific multi-UAV application being targeted. It is also important to ensure that the operator has adequate means to first observe and then direct the automation’s functioning in order to be responsive to changes in the mission, vehicle status, or operational environment.

101.1 Introduction

Unmanned aerial vehicles (UAVs) are becoming an increasingly critical aspect of military operations and are starting to be more extensively used in civilian applications as well (Department of Defense (DoD) 2007). With these successes comes a vision for even more capable systems that can accomplish missions with greater complexity, including the ability of a *single operator* to control *multiple platforms simultaneously*. Currently, most UAV systems require two or more operators to fly the vehicle while managing the onboard sensor(s). Single-operator control of multiple UAVs is envisioned to be a particularly time-critical, cognitively demanding work environment (Scott et al. 2006). Additionally, with newer, highly automated UAVs, the operator's role will become more supervisory in nature: monitoring the environment and situation along with the automated activation of programmed events, managing changes to the mission plans and automated systems, and collaborating intermittently with others in a distributed control network (Chen et al. 2010). In response, a new interface paradigm is required for effective supervisory control of multiple UAVs by a single operator.

A number of approaches for multi-UAV employment by a single operator are being considered. Eggers and Draper (2006) describe several for controlling multiple aircraft (interleaving, sequential, and simultaneous) as well as list operationally inspired questions that a designer should consider when developing a multi-UAV control system. These authors stress that the particular mission, its required effectiveness, and the associated UAV capability requirements should be the key drivers for a multi-UAV control system design. More specifically, the missions to be accomplished and the level of platform/sensor sophistication influence the range and levels of platform automation, as well as degree to which the system should flexibly accommodate operator intervention. This, in turn, determines the operator's display and control requirements.

In addition to the many mission-specific design drivers, there are also several generalized human factors challenges to consider when designing a multi-UAV control station for single-operator control. Any operator interface design should serve to mitigate known automation-induced problems such as complacency, bias, vigilance decrement, mode confusion, automation brittleness, and attention/cognitive tunneling (Endsley and Kaber 1999). Moreover, it is important to keep the operator continually informed of automation functioning and planned activity for accurate situation assessments and command decisions. This will involve ensuring the operator's information displays provide the *right* information at the *right* time for the operator to maintain adequate situation awareness for effective decision-making across different situations and/or vehicles. Thus, intelligent aids are needed that locate, select, and/or filter information based on specific context to help streamline information gathering and assessment tasks, especially when the operator is multitasking (St. John and King 2010). To meet all these requirements, innovative display approaches will need to be considered that provide the required information intuitively and in a compact manner. This is because presenting information using

conventional status displays for each vehicle would require considerable display space, increasing the areas that need to be visually scanned and thus complicating information retrieval.

In addition to information display issues, there are also control factors to consider. One involves determining and supporting the appropriate levels and types of interactions with the automated systems. Multi-UAV systems will necessarily involve more supervisory control interactions with little to no manual control via stick or throttle. A key challenge will be instantiating these new methods for intuitive vehicle and platform control such that many vehicles can be simultaneously managed. However, for some complex, rapidly evolving, and time-critical missions, current limitations in automation technology may preclude rapid precise control via highly supervisory means. In these special cases, the capability may still be needed for an operator to assume direct manual control for a limited period of time. Therefore, the capability to assume increased manual control might need to be incorporated into the design of certain UAV applications. Alternatively, a distributed control architecture could be developed that enables the operator to easily handover control of a UAV to an operator/station that is dedicated to handling these special missions/situations (Eggers and Draper 2006). It is also important to ensure control actions are intuitive, and it needs to be obvious which vehicle(s) will be impacted by a specific control input. For multi-UAV control, additional functionality will be required that can be rapidly employed when the operator is dealing with an especially difficult or unanticipated event – for example, a single command that results in multiple vehicles continuing in a safe manner (e.g., all loiter present location), enabling the operator to focus on the vehicle needing dedicated attention.

A number of research and development efforts are addressing the human factors issues identified above. The present chapter will introduce several display and control concepts that may be applicable to multi-UAV control, as well as identify directions for further research. Due to space limitations, the primary focus will be on technologies developed and evaluated at the United States Air Force Research Laboratory (AFRL) at Wright-Patterson Air Force Base.

101.2 Multi-UAV Operator Ground Control Station Test Beds

There have been a number of multi-UAV ground control simulations developed recently to support human factors research pertaining to future multi-UAV supervisory control issues, to name several: *MIIRO* (Multi-Modal Immersive Intelligent Interface for Remote Operation; Calhoun et al. 2007a), *MUSE* (Multiple UAV Simulation Environment; Kim et al. 2007), *ALOA* (Adaptive Levels of Autonomy; Johnson et al. 2007), *RESCHU* (Research Environment for Supervisory Control of Heterogeneous Unmanned Vehicles; Boussemart et al. 2009), *MUSIM* (Multiple-UAS Simulator; Fern and Shively 2009), *AMASE* (AVTAS (Air Vehicles Test and Simulation) Multi-Agent Simulation Environment; Duquette 2011), and *VSCS* (Vigilant Spirit Control Station; Feitshans et al. 2008). These test beds vary in terms

of functionality, flexibility, and emphasis areas, and they provide an indication of the wide variety of potential designs associated with multi-UAV control.

The Vigilant Spirit Control Station was developed by the Human Effectiveness Directorate (AFRL, 711 Human Performance Wing) to fulfill several purposes. First, the system primarily supports laboratory research evaluations of candidate operator interface technologies due to its capability to present prototype interface designs and collect usage data during preplanned trials. Second, it aids in stimulating a synthetic environment for the modeling of various vehicle payloads, sensors, and human factors testing tools because the simulation is high fidelity and designed to realistically represent the tasking and workload envisioned for future multi-UAV control. Finally, the Vigilant Spirit Control Station routinely supports high-fidelity simulation demonstrations as well as live flight testing of UAVs. To accomplish this, the simulation has the ability to communicate in a standard way with various commercial UAV platforms and operate in a manner that meets potential safety of flight issues. Besides meeting interoperability requirements, it also has dynamic mission planning interfaces. To meet all these objectives, its design utilizes an open architecture and a highly flexible modular approach in order to provide a variety of tools. This enables this multi-UAV Vigilant Spirit Control Station to be configured to accommodate diverse missions and vehicle payloads across multiple vehicle platforms. Moreover, tools outside its current core capability can be accommodated due to the simulation's robust and flexible software architecture (Feitshans et al. 2008).

Generally, all multi-UAV ground control simulations include two types of management interfaces: (1) vehicle/mission and (2) payload (e.g., sensors). In the next two sections, both types of interfaces will be addressed, in turn, by describing concepts that may be useful for implementing multi-UAV supervisory control. The majority of specific examples are drawn from the developments associated with AFRL's Vigilant Spirit Control Station (see Rowe et al. 2009), and many of these are depicted in figures. Note that illustrations of these concepts in this chapter are intended only to convey examples of candidate operator interface attributes; they are not meant to convey optimal design solutions for any function.

101.3 Multi-UAV Interface Concepts for Vehicle/Mission Management

This section will focus on candidate interface concepts for supporting an operator's tasking in managing multiple UAVs. First, *display concepts* will be addressed, starting with a description of displays designed for the Vigilant Spirit Control Station. This will be followed by an introduction to several novel display technologies, including view management, glyphs, timeline formats, and perspective displays. Finally, nonvisual display approaches, tactile and auditory, will be discussed. This section will conclude by providing several *control concepts* for vehicle/mission management, starting with techniques employed in the Vigilant Spirit Control Station. Novel control concepts under development, including speech-based control and gesture input, are also described.

101.4 Display Concepts for Vehicle/Mission Management

Primary Displays. Figure 101.1 depicts a representative mission management display configuration from the Vigilant Spirit Control Station (Rowe et al. 2009). Each panel or window can be considered a *tool* by which the operator is provided information to perform mission management functions. These include, for instance, a vehicle alert and summary tool and a tactical situational display (TSD) to provide advanced mapping capability. The *vehicle alert and summary tool* (along the left in Fig. 101.1) is intended to provide a quick look assessment of pertinent UAV information tailored to the current mission phase. To facilitate a quick crosscheck, one row per UAV is provided at the top listing basic navigation parameters (Fig. 101.2). Below that, dedicated panes are presented for each UAV. An analogy is that each UAV has a baseball card depicted with several information elements such as the vehicle's identification number (1, 2, etc.), speed, heading, altitude, estimated time of arrival to the next waypoint, operating mode, and payload information (sensor cameras, weapons, or radar systems). Various alerting mechanisms are also provided in this tool to indicate system faults such as loss of communication, global positioning sensing, low fuel/battery life, and other mission-specific alerts. Static symbology is used to represent the vehicle; however the concept of glyphs (explained below) may provide a more rapidly interpretable graphical representation of vehicle status that minimizes the use of alphanumeric. Advanced vehicle caution and warning alert systems might also be designed to immediately convey the operational ramifications of the contingency (e.g., sensor inoperable above 30,000 feet) to ease the prognostic requirements on the operator.

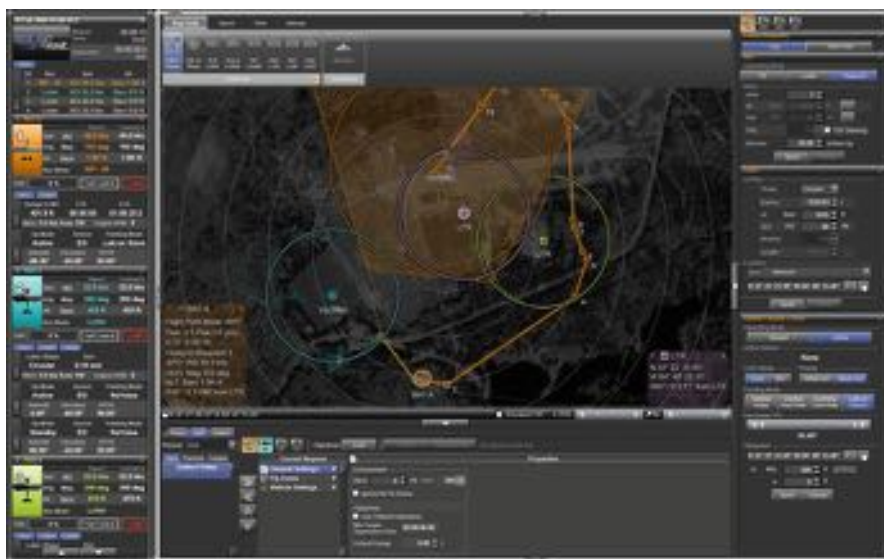

Fig. 101.1 Illustration from Vigilant Spirit Control Station

Fig. 101.2 Sample vehicle alert and summary tool from Vigilant Spirit Control Station

In future multi-UAV supervisory control scenarios, a map display will be considered a primary operator interface for both control and display of information. In the center larger window of the Vigilant Spirit Control Station, a *tactical situation display* (TSD) provides a common mission operating context consisting of spatially relevant information and geo-referenced imagery (Fig. 101.3; Rowe et al. 2009). Specific mission-related information is presented including each UAV’s position, air and ground tracks, airspace management aids, mission plans, and, if available, sensor viewing locations (footprints) and target locations. The mapping functionality of the TSD is analogous to using standard commercial mapping tools available on the Internet. Figure 101.3 shows a representative TSD format.

One challenge associated with mission management displays is how to best link information associated with each vehicle across multiple windows (i.e., utilizing the concept of visual momentum; Woods 1984). Color is used for this purpose throughout the Vigilant Spirit Control Station to uniquely identify each UAV and

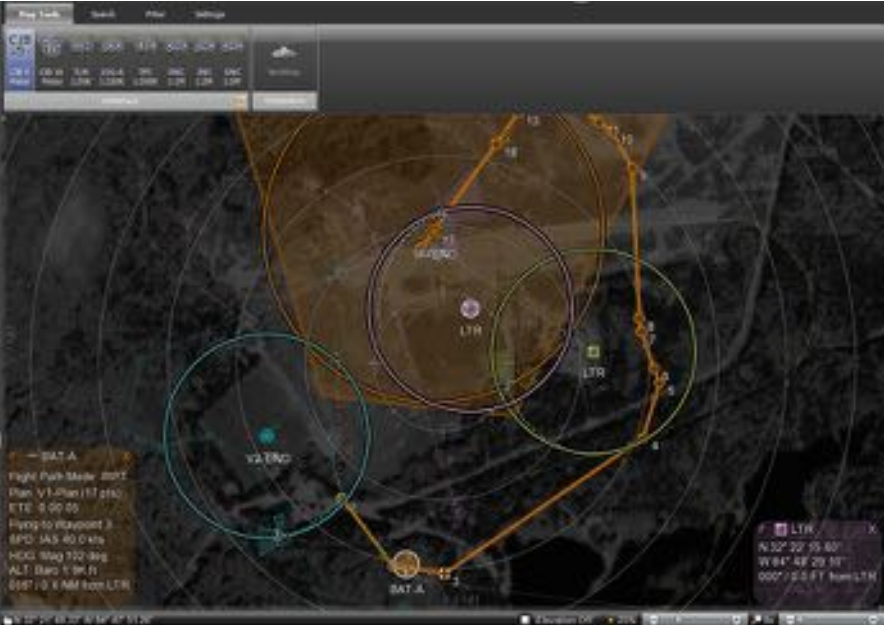

Fig. 101.3 Sample tactical situation display format from Vigilant Spirit Control Station

link its associated data such as flight plans, loiter locations, and sensor information. For example, the route symbology for a particular vehicle on the TSD is colored to match the color employed for that vehicle’s alert and summary tool.

View Management. Operators of multiple UAVs will be presented with an increased amount of information reflecting the multiple vehicles being managed. Moreover, more information will be available to be displayed, such as from the envisioned networked operations and existence of a Global Information Grid (GIG). Thus, a tremendous amount of information will be available, both in what feeds the data streams populating displays such as the TSD but also the additional information that can be presented via computer-generated symbology to augment or highlight displayed information. As one example, there are several candidate synthetic vision symbology concepts proposed to aid an operator to land UAVs as well as achieve sense and avoid functionality, including integrated, multidimensional conflict avoidance (Tadema 2011). As a result, it is likely that information elements will overlap, contributing to the visual clutter and impacting the information’s visibility.

There are numerous techniques for *view management* which maintain visual constraints on the projections of objects on a display (Bell et al. 2001). By making an adjustment in the manner information is presented, problems with information elements occluding each other can be minimized. Likewise, a more sophisticated intelligent system can ensure that information does not become illegible, and labels are automatically reoriented and repositioned based on the operator’s viewpoint.

Besides managing the view to optimize the visibility of the information, an intelligent system can highlight information that is critical for operator attention. Identifying useful coding methods to indicate qualifiers or meta-information (Bisantz et al. 2009) such as the criticality, urgency, source, timeliness, and reliability of information is one topic needing further research.

Another research area is determining how best to manage what information is displayed at any one time (St. John et al. 2004). The Vigilant Spirit Control Station has some limited filtering options, for instance, based on phase of flight and whether to hide labels. However, it would be more useful to have an intelligent multi-agent system that is capable of taking into account the real-time location and tasking of each UAV as well as current mission goals and environmental conditions. In this manner, decisions on what information to present (versus hide), as well as what information to highlight (versus de-emphasize), can be determined. For a multi-UAV application, it may be that the information detail needs to correspond to which UAV requires more dedicated attention at that moment. For example, if one vehicle's health degrades, additional information pertaining to just that one vehicle would be presented.

While having information presentation driven by context will result in less cluttered displays, it also increases the likelihood that information that the operator desires is not currently being displayed. Thus, any application of an intelligent de-cluttering system needs to include efficient means by which the operator can access *all* information elements. Likewise, the degree to which operators can control features (e.g., opacity) of information elements needs to be determined so that mission effectiveness increases without imposing additional workload (or attentional tunneling).

Glyph Symbolology. Presenting information in a more compact and/or integrated manner can also reduce display clutter. One approach involves mapping individual dimensions (variables) for a given entity to attributes of a particular multi-attribute graphical shape or symbol, such that variations and anomalies among these graphical entities are readily perceived by the operator (Chuah and Eick 1998; Whitaker and Thomas-Meyers 2006). This will conserve display space in that contextually relevant systems/mission status information is integrated into the same symbol and, as a result, it streamlines monitoring tasks by reducing the operator's need to visually scan and integrate information (Chuah and Eick 1998). The design of MIL-STD-2525B symbolology (DoD 2005) follows this convention, and modifications to this symbolology set have the potential to increase the saliency of state changes even more. Alternately, design of *glyphs* or *ymbicons* (hybrid symbolology combining best elements of symbols and icons; Smallman et al. 2005) that are tailored for multi-UAV control might be useful in maximizing information presentation.

Design and evaluation of glyph prototypes are underway at AFRL. As an example, one glyph prototype is shown in Fig. 101.4. For this modified MIL-STD-2525B symbol, many parameters of a single vehicle are depicted including type and characteristics of the vehicles. The vehicle's heading, pitch, and altitude (in thousands of feet) are also presented. The left and right bars depict, respectively,

Fig. 101.4 Notional glyph showing UAV information

Fig. 101.5 Notional glyph showing time until UAV handoff

the data link and fuel status. The shade and color of these bars change, in real time, to reflect the vehicle’s state. Although this is presented simply as an example, it is clear that well-designed glyph symbology has the potential to reduce (1) the workload associated with operator monitoring of multiple vehicles and (2) the delay in reacting to certain system anomalies.

Multi-UAV applications in which an operator hands off control of a specific vehicle to another control station (e.g., to address a system malfunction or a more demanding dynamic mission) might also benefit from a glyph display approach. Figure 101.5 shows one example of how the status of a pending handoff might be depicted.

When selected, a glyph can also be appended with symbology and readouts that provide additional information. In Fig. 101.6, the first glyph shows readouts along the left that pertain to a UAV’s call sign, heading, altitude, speed, fuel, and frequency. To the right are some selectable icons for tools to manage the route and handoff. The second glyph example shows one method of how caution and warning alerts might be presented to operators.

It is important to note that the glyphs depicted above are all notional examples, presented simply to convey the potential benefits associated with this

Fig. 101.6 Notional glyphs with additional information displayed when selected

design approach. Systematic evaluations remain to be accomplished, especially for candidate multi-UAV control applications. Besides depicting the status of vehicles, a glyph approach for information presentation might also be useful to keep track of payload and/or progress on task(s). Research in this area needs to evaluate the extent to which the symbology rapidly and accurately conveys required information, especially when the symbol is copresented with other required information on an integrated control station display.

Timeline Interface. Another display concept that may facilitate vehicle/mission management for multi-UAV applications is one that focuses on the temporal aspects of a mission, such as a *timeline interface*. Critical information regarding all relevant UAVs and their respective tasking is presented on a single temporally referenced display. Such a presentation may improve simultaneous awareness of the current and projected status of all vehicles and thus improve the operator's ability to meet temporal constraints imposed by changes in the mission or cooperative missions. A timeline display is hypothesized to especially improve level 3 situation awareness (Endsley 2000): the projection of the situation into the future and the corresponding proactive management of resources against future mission needs. Thus, a temporal display may be very useful for providing time-based information needed for multi-UAV supervisory control, in addition to a map-based display and other status indicators.

Presentation of information on a timeline has been considered for numerous military applications (Scott et al. 2006; Rousseau et al. 2007). Additionally, temporal displays specific for UAV supervisory control applications have been designed and evaluated. Hanson et al. (2004) describe a task-based panel that supports synchronization and analysis of mission plan changes for UAV teams. As part of a UAV supervisory control simulation interface, Cummings and Mitchell (2005) designed a decision support display that included timelines for multiple UAV missions. Information was plotted as color-coded blocks across time to depict scheduled tasks, mission events, waypoints, windows of opportunity, and estimated time of arrival at targets. A later study evaluated the utility of augmenting each UAV's timeline with a configural decision aid referred to as StarVis (Cummings and Brzezinski 2010). Variables related to a target acquisition task (scheduling problem type as well as number and priority of targets impacted) were mapped to features of

a single geometrical form. The aid included a what if functionality to show effects of any control input under consideration. The results showed the value of the aid in controlling an individual UAV. However, when the aid was used to represent changes across all UAVs, performance dropped. These results demonstrate the importance of not saturating operators with information and that displays should not only help operators detect and identify problems, but also solve problems (Cummings and Brzezinski 2010).

More recently, a timeline prototype was developed and integrated into AFRL's Vigilant Spirit Control Station (Fig. 101.8). In the mission view (Fig. 101.7, upper lines), each horizontal bar represents the start and end times for a mission, and the bar color denotes which vehicle is performing that mission. In the vehicle view (Fig. 101.7, lower portion), a horizontal line is devoted to each vehicle with symbology overlays pertaining to the tasking and status of the vehicle's systems (e.g., ready to deploy, performing a mission, and fuel shortage). An experiment was conducted in which participants completed trials with and without the timeline interface. Documentation is still in preparation, but the results showed that performance on tasks involving temporal awareness (e.g., judging which UAV to assign to a pop-up mission) as well as multiple secondary tasks (e.g., communications, change detection, and information retrieval) was improved when the timeline interface was included in the control station design. Effort is now being devoted to expanding the timeline to better support the supervisory control of time-coupled tasks required in multi-UAV collaborative missions. This new design will also employ glyphs to represent vehicle and task status as well as a task-centric timeline versus the vehicle-centric approach illustrated in Fig. 101.7.

To support the development of a timeline interface prototype for multi-UAV control, evaluations were also conducted on specific design issues. For instance, one evaluation addressed how the display should be oriented (Spriggs et al. 2010). The majority of timeline designs are oriented horizontally, following the conventional

Fig. 101.7 Prototype timeline interface integrated into Vigilant Spirit Control Station

Fig. 101.8 Example of using color shading to code terrain elevation

approach used for timelines and program management schedules. For a multi-UAV application, this suggests that each horizontal line represent an individual vehicle. Since Western culture involves reading from left to right, the horizontal timeline may encourage attention to be focused on a single vehicle and interfere with the ability to complete a vertical scan for detecting temporal conflicts across vehicles. If the timeline is oriented vertically, left to right scans might provide more efficient retrieval of the status of all vehicles for a specific time slice. Moreover, a vertical orientation may benefit multi-UAV coordination tasks across time. However, the results from a part-task experiment showed little performance differences between horizontal and vertical views of a multi-UAV timeline.

Displays for Representing Third Dimension. The display technologies described above focus on how to present vehicle/mission information in two-dimensional (2-D) graphical formats. There are also other techniques for depicting relevant information in three dimensions that need to be evaluated to determine their utility for multi-UAV supervisory control applications. Terrain shading on the map may be beneficial for detecting hazardous terrain that can compromise vehicle safety (Rowe et al. 2009; Fig. 101.8). When relative altitudes are of primary importance, a vertical situation display (VSD) may be beneficial. These displays represent the vertical dimension in a veridical manner, and examples are available (see Cummings et al. 2007).

Fig. 101.9 Sample perspective prototype views showing tactical common operating picture (Analytical Graphics, Inc. 2006). http://www.agi.com/downloads/products/by-product-type/applications/stk/stk-for-c4isr/0305_T3DCOP_case_study.pdf

Both TSDs and VSDs provide planar views of the operating environment, with each display type sacrificing information along a hidden dimension. *Three-dimensional (3-D) perspective displays* offer the potential to provide all three dimensions to the operator in one integrated display (see Fig. 101.9, for example; Analytical Graphics, Inc. 2006). With perspective displays, the image is actually in two dimensions, but by employing an oblique viewing angle, all three dimensions can be represented to a greater or lesser extent. In considering a perspective display for UAV applications, it is important to first consider the possibility of naïve realism in assuming that the operator's ability to extract information is correlated with the realism of the display (Smallman and St. John 2005). In fact, some research to date has shown that perspective views typically do not enhance overall situation awareness and only benefit certain specific tasks (Smallman et al. 2005). This is most likely because the perspective distorts some information by foreshortening (depending on the angle of the perspective) and introduces ambiguities by confounding all three dimensions. For localizing objects and determining the relative distances between objects (important tasks for multi-UAV situation awareness), research has shown that a 2-D coplanar image presentation is better than a static perspective view (St. John et al. 2001). Even the displayed symbology can be more difficult to interpret in a perspective view due to distortions introduced by perspective. However, the use of contour lines and grid lines for terrain may improve the utility of a perspective view, as could the use of drop lines and drop shadows for depicting the relative altitudes of vehicles (St. John et al. 2001). Additionally, the benefits of perspective displays will likely increase if the operator is able to control the view angle dynamically (Dao et al. 2006). The benefit of a perspective view for certain tasks, though, may be sufficient rationale for its inclusion in control stations. For instance, Veltman and Oving (2003) determined that a 3-D map improves UAV camera control and related task performance. The authors recommend that the operator be able to choose

between 2-D and 3-D views. In this manner, the 3-D view would be available on demand either as a mini-view to augment orientation or as a result of morphing from a 2-D view to shallower viewing angles (Smallman et al. 2005). It may also be useful to present multiple views simultaneously with picture-in-picture techniques in which an alternate view is presented in a smaller window that overlays a portion of the TSD. This enables the operator to benefit from both views: the 2-D view for *veridical global information* (the position of objects relative to other objects in the earth reference frame) and the 3-D view for *relative local information* (position of objects relative to the viewing position of the camera). Advances in *true* 3-D display technologies that create a true sense of depth by imitating one or more of the visual depth cues may also accelerate employment of 3-D displays in UAV control stations (McAllister 2002).

The above concepts involve presenting information visually. Since multi-UAV supervisory control will require significant visual demands, any display and/or control approach that minimizes the visual load for both acquiring information and commanding actions may improve task performance, as predicted by the Multiple Resource Theory (Wickens 2002). For instance, *multisensory interfaces* may enhance time-sharing (pertinent information from different sources comes through different sensory channels simultaneously) and improve attention capture (two or more senses transmit identical or supporting information simultaneously). Additionally, such interfaces may result in a more intuitive presentation of information.

Tactile Displays. *Tactile presentation of information* is a promising display technology (van Veen and van Erp 2003). Information is transmitted through the skin by varying one or more dimensions of vibratory stimulation (locus, amplitude, frequency, duration, and spatial/temporal separation). Tactile messages are silent and unobtrusive, and their displays are omnidirectional in that the operator does not have to be looking at a particular location to be alerted. They can also be designed to convey spatial information (e.g., as implemented in a belt or vest; see Draper et al. 2007). Additionally, tactile information can be received simultaneously to visual and aural information.

The use of tactile displays as a means of informing UAV operators of serious system malfunctions was evaluated (Calhoun and Draper 2006). In these evaluations, small electromechanical vibrating factors were mounted in elastic bands over one or both inner wrists (Fig. 101.10; Calhoun et al. 2005; Calhoun and Draper 2006). In the test scenarios, the tactile cues were reserved for critical warnings to maximize their saliency (Wogalter and Leonard 1999). In a series of simulation evaluations, the results demonstrated that tactile cuing was an effective redundant alert (paired with a visual alert) and a suitable substitute for an aural redundant cue. Furthermore, operators reported the tactile cues were beneficial and that the stimulation was not uncomfortable or a distraction in attending to other tasks. However, analysis of the performance data did not show an advantage for tactile alerts over aural alerts. Further research is required to determine if tactile cues would prove more effective than aural cues in noisy environments when each is employed a sole alert, rather than redundantly with a visual alert. It is also possible that tactile

Fig. 101.10 Tactile wrist pads as high priority alert cue

alerts may be especially useful in noisy environments when long vigilance durations are required, a condition not tested to date.

Aural Displays. The *aural alerts* used in the evaluations described above were monaural and failed to leverage the natural spatial auditory processing capabilities of humans. It is possible that multi-UAV supervisory control can benefit from the ability of operators to determine the spatial location of sound sources and monitor events at multiple locations simultaneously (Simpson et al. 2004). Advances in spatial auditory display technologies have made it possible to recreate and present to an operator the spatial information that would naturally be available in a real-world listening environment. For instance, spatial audio could be used to assist operators in finding items of interest in the spatial environment by having the cues emanate from directions that the operator should attend to (Bolia and Nelson 2003). Spatial audio cueing might also improve speech intelligibility and reduce workload for operators listening to multiple radios or intercom channels (Bolia and Nelson 2003). This could be useful to operators who often engage in verbal communications with a variety of distributed team members, not only because of its potential to improve communications effectiveness but also because spatial awareness of talker location would provide the operators with an additional cue to the identity of the talkers based on a predetermined mapping of communications channels.

The use of *spatial audio* has been combined with other features in a Multi-Modal Communication (MMC) network-centric communication management suite (Finomore et al. 2011). With the goal of improving the communication performance of command and control operators, this tool provides an enhanced ability to manage communications from voice and text-based systems in a single intuitive dynamic display. MMC captures, records, and displays radio and chat communication to the operator, providing instant access and full control over all current and past information exchanges. Moreover, there are additional functions that may be useful for multi-UAV control. For example, the ability to perform searches across communication and chat channels for information and set up alerts for keywords that are instrumental to the mission could ease the operator's task of monitoring multiple streams of communication as well as other displays.

101.5 Control Concepts for Vehicle/Mission Management

The previous section focused on information *display* concepts for vehicle/mission management. This section will address associated vehicle/mission *control* technologies, including direct manipulation concepts, speech-based control, delegation control, and gesture commands that may be useful for multi-UAV applications. Once again, it is important to note that the operator control concepts described in this chapter should be viewed only as examples of candidate interface attributes; they are not intended to convey optimal design solutions for any application.

As with the display concepts described earlier in this chapter, the controls currently employed in the AFRL's multi-UAV Vigilant Spirit Control Station will be described first. This station was developed with the assumption that all vehicles are highly automated, enabling the operator to focus on tasks involving the payload (e.g., monitoring each UAV's video; Rowe et al. 2009). Thus, for this supervisory control, there is no hardware for Hands on Throttle and Stick (HOTAS) control. Rather, control is accomplished via higher level commands using the command and control tool presented on the right side of the ground control station (see Figs. 101.1 and 101.11). With this tool, controls are conveniently located for a variety of tasks: vehicle navigation, loiter management, sensor payload management, and dynamic mission planning. Besides exercising control functions with defined keyboard and mouse inputs, the station also supports alternative control techniques such as speech-enabled control and touch inputs. All control inputs are linked to associated information on other displays such as the TSD.

Direct manipulation control concepts are also supported such as interacting directly with TSD symbology to quickly issue various commands. This type of human-machine interaction is considered *direct manipulation* because the operator is directly manipulating a visual representation that metaphorically represents the actual system or task (Shneiderman 1987). Typically, inputs using direct manipulation are viewed as more natural or intuitive. Control may also be more rapid because the interaction taps the human's analogical reasoning power when determining what actions to take when executing the task. Also, the results of the interaction are typically immediately visible. For example, by selecting a symbol representing a UAV on the TSD, a context-sensitive suite of commands can be called up. Using this tool, the operator can manipulate the constraints and parameters of a particular command directly on the geo-registered map, which greatly simplifies the input. As an example, see Fig. 101.12. Here manipulations of the Steering Command Widget symbology on the TSD enable the operator to quickly vector a UAV in response to air traffic control commands or away from a potential threat, such as restricted airspace or nearby air traffic. To designate a new heading for the UAV, the operator selects and drags the vector, and the new heading is indicated by the position of the vector on the compass rose, as well as a readout in the heading box. If the vector is within the compass rose, the heading value changes in 5° increments. When the vector is longer, outside the compass, the heading changes by a single degree. Once the desired heading value is indicated, a button is selected to send the heading to the vehicle control system.

Fig. 101.11 Sample command and control tool in Vigilant Spirit Control Station

Fig. 101.12 Sample UAV Command Widget selectable on tactical situation display in Vigilant Spirit Control Station

Two of the AFRL-developed multi-UAV display concepts described earlier support direct manipulation. First, the prototype timeline display (Fig. 101.7) was designed to also have control functionality. Control inputs to manage the vehicle's actions can be accomplished by clicking directly on symbology overlaid on the UAV's respective timeline (e.g., to command the vehicle to return to base). Also, pop-up missions can be assigned to an individual UAV with a drag-and-drop action, moving the task from the mission view to the respective UAV's line in the vehicle view.

A second example is the glyph display concept. A glyph display element could be implemented such that hovering over it with the mouse calls up a polar menu of tools, configured dynamically based upon current context, for the operator to select (Fig. 101.13). This arrangement minimizes the distance between the glyph and respective tool selection and benefits from the advantages of direct manipulation.

Many of the above-described control actions involve selection of symbology elements with the mouse. With a touch screen system, inputs can be accomplished by directly touching the display surface with one or more fingers (depending on the type of hardware). This type of input may also be applicable for a multi-UAV ground control station. One concern is to ensure that the location/angle of the touch screen does not impose fatigue issues. More importantly, the nature of the inputs needs to be carefully evaluated. Operations that involve the entering of values and/or text with touch are less ideal. In general, touch screens are best suited for information retrieval (involving the pointing of items or an area on the display). Limited manipulations of displayed information (e.g., redefining a path) can also be accomplished. For example, the drawing tools and display functions of the FalconView mission planning system were applied in an evaluation to enable sketch-based inputs of

Fig. 101.13 Notional glyph with associated menu of tools

ingress paths, search regions, and other tactical areas of interest for UAV-based munitions (Lewis et al. 2006). Preliminary results indicated the control was intuitive, but defining inputs for each individual UAV was limiting; functionality to enable assignment of routes to more than one UAV at a time is desirable. Durlach et al. (2006) evaluated a prototype whereby a UAV was controlled by touching a location on a sensor image. This research demonstrated several issues to address including the need to have adequate feedback that the touch input has registered, as well as the difficulties in translating a single-touch input into three-dimensional commands to a UAV. Additional design guidelines for touch panel keypads and keyboard are available (Plaisant and Sears 1991; Scott and Konzola 1997).

For many data entry task types, *speech-based control* may provide a much more efficient input mechanism for multi-UAV control. While machine performance is still inferior to human performance, (impacted by numerous factors such as the size of the vocabulary and noise environment), increasingly sophisticated automated voice recognition systems have made UAV systems responding to voice commands progressively more feasible. The operator's commands would need to be simple though, as the ability for computers to derive meaning by analyzing linguistic phenomena (natural language processing) remains an immature technology. Nevertheless, categorical commands can substitute for many manual inputs in UAV operations. In contrast, commands to transmit continuous analog spatial information, particularly in dynamic situations, are less efficient. And there are other guidelines to be considered in implementing speech-based control, such

as to employ a speaker independent, continuous speech recognition system that requires no prior system training (Rudnicky 1996; Gardner-Bonneau 1999; Draper et al. 2007). Implementation should also consider providing visual feedback of each spoken command and the use of a conveniently located push-to-talk button to activate the speech recognition system.

AFRL conducted an experiment examining the utility of conventional manual input versus speech input for a variety of tasks performed in single-UAV control (Draper et al. 2003), and it was demonstrated that speech input was significantly better than manual input in terms of task completion time and accuracy, maintenance of flight/navigation path, and operator subjective ratings. Across tasks, data entry time was reduced by approximately 40 % with speech input. This performance advantage, coupled with the other benefits of speech input (e.g., head-up and hands-free control), warrants additional research to confirm that speech input is also beneficial in operational control station auditory environments and does not conflict with intercom operations and intra-crew communications.

An even more promising application of speech-based control for multi-UAV supervisory control is its use in a delegation approach to interact with automated systems. With *task delegation*, such as Playbook[®], the operator communicates with UAVs by using a compiled set of plans or plays with short, easily commanded levels that can also be modified as needed. This approach is designed to minimize the workload associated with delegating a plan, much like a quarterback uses establish plays to communicate to a football team (Miller et al. 2004; Miller and Parasuraman 2007). For multi-UAV applications, this delegation approach may provide a control architecture whereby the operator can flexibly change the tasking and role of automation during the course of a mission, by specifying various constraints, stipulations, contingencies, and alternatives to the automation, all within the context of operationally relevant plays. AFRL is in the process of evaluating this approach for UAV control and providing the ability to seamlessly transition between different levels of control, ranging from a level where the operator's manual inputs command a vehicle's path to higher level plays (e.g., "monitor target here" [and *here* is designated with a touch input on the map]) as well as intermediate levels (e.g., quick temporary maneuvers with a verbal command "UAV 1, hook left"). To date, operator feedback has indicated that this delegation approach has definite value for future multi-UAV applications (Calhoun et al. 2012).

The control technique of issuing a voice command in conjunction with indicating a location or item via touch or selection with a mouse increases overall functionality by using multiple input devices (Oviatt 1996). A *spatial dialog* interaction and communication technology has been proposed to apply *multimodal interactions* to improve remote virtual presence and collaboration across all elements of a distributed command and control team, including the autonomous vehicles (Chun et al. 2006). With spatial dialog, TSD inputs that involve a spatial component can capitalize on the integration of speech recognition, gesture interaction, and touch panels. The operator communicates plans and queries to the autonomous unmanned systems with speech commands that include temporal and spatial (e.g., *here* and *there*) parameters while making gesture inputs on the display (Chun et al. 2006; Green et al. 2007). A particular information element or location can also be tagged

by the operator with a voice name such that when the operator states that name again later with a verbal action command, the system understands which element to apply the action to (Batkiewicz et al. 2006). More lengthy voice memos can also be associated with specific information elements. These voice notes and annotations are an intuitive way to rapidly capture operator observations regarding an event or location which may be beneficial to enhance information communication with all entities in a networked operation space or to increase the situation awareness of a new operator when UAV control is handed over.

Besides using a simple gesture input to indicate a specific location or information element, more complex gesture commands can be used to provide additional control options. With this implementation, the gesture indicates not only the subject/focus to which the command applies, but the action to be performed. For instance, making an input in the shape of a Z (for zoom) with the stylus movement can command a zoom action as well as indicate the direction of the zoom. Once the pen or finger is released, the zoom would stop (Chatty and Leocoanet 1996). Two-handed graphical interaction has also been proposed, with the dominant hand assigned to drawing, while the nondominant hand moves the mouse to select tools, lock objects, zoom, etc. (Leganchuk et al. 1998). This would enable hold-and-pull interactions and simultaneous designation of two information elements. With the recent increase in products that enable inputs with a finger tap, pinch, swipe, etc., it is very timely to evaluate gestural input for interacting with multi-UAV control station displays. For further information, see Wigdor and Wixon (2011).

101.6 Multi-UAV Interface Concepts for Payload Management

Many of the interface concepts described above for *vehicle/mission management* may also be useful for *managing the payloads* of UAVs. For instance, use of glyphs for *displays* might be useful to provide an at-a-glance indication of payload status. For *control* functionality, an example is the use of a verbally commanded play that triggers the features of a sensor to be automatically configured appropriately for the planned mission. In fact, with highly autonomous vehicles, it is envisioned that a verbal goal-directed command specifying the objective in terms of the payload (e.g., what target to image) could result in automatic routing of multiple vehicles, automatic configuration of respective payloads, as well as completion of other tasking required to accomplish the mission (Calhoun et al. 2012). As these two examples illustrate, it is recommended that the concepts already described in this chapter also be considered as to how they might be applied to support payload management.

The remainder of this chapter will focus on other display/control concepts relevant to payload management. Many of these involve the use of overlaid computer-generated symbology. Others provide tools tailored to manage video streams. Consideration of these novel approaches is particularly important managing the multiple payloads afforded by a multi-UAV application environment.

Each UAV will have at least one associated payload, and these payloads can also vary by type (e.g., electro-optical, infrared sensor). The Multi-UAV Supervisory Control Interface Technology (MUSCIT) demonstrations have shown that the operator's visual load and attentional demands are often driven by the task of sensor management (manipulating the sensors and detecting/identifying targets of interest; Patzek et al. 2012). This workload also increases substantially with the number of UAVs being supervised, potentially resulting in a significant decrement in task performance. Therefore, interface designs need to support this highly critical and demanding sensor management task within the overall context of flight/mission management, for instance, by colocating or even integrating critical mission and flight information with the sensor management interface to reduce visual scan demands.

One approach to ease the sensor management task itself is to overlay relevant information elements directly on the imagery, as described by Hunn (2006). Calhoun and Draper (2009) report on the impact of *overlaying synthetic database information on video imagery* for several UAV operator tasks. The results showed that the synthetic symbology can improve situation awareness, reduce workload, and improve the designation of points of interest at nearly all the update rates evaluated (Draper et al. 2006). A *picture-in-picture construct* can also be applied to integrate real and synthetic imagery. Calhoun et al. (2007b) have shown the value of condensing the real-world video imagery such that it occupies a portion of the display area and is framed with a synthetic generated imagery border (Fig. 101.14). With the synthetic imagery aligned and registered with the UAV video imagery, the result is a virtual expansion of the available sensor field of view (well beyond the physical limits of the camera). This increase of spatial awareness potentially mitigates the UAV camera's narrow field of view, the basis of what has been referred to as the soda straw analogy or keyhole effect, a critical issue with UAV operations (Woods et al. 2004).

Multimodal displays and controls can also assist operators in focusing on the imagery from the sensors. For instance, with speech recognition, operators can request information about a system and then hear the information reported via speech synthesis, without changing eye gaze direction (Patzek et al. 2012). Aural and tactile alerts can also be employed (Calhoun and Draper 2006).

In the AFRL's Vigilant Spirit Control Station (see Rowe et al. 2009), several interface concepts designed to aid operators in managing multiple payloads are under evaluation. As shown in Fig. 101.14, all the videos are located adjacent to one another in the sensor management area of the control station. Functionality is also provided to control the view of the sensor feeds. For instance, the sensor can be placed in a latitude/longitude slaved mode or can be steered with the mouse/cursor via a point and click steering method. Zooming can be controlled with the mouse's scroll wheel. The rationale for *integrating the mouse sensor steering* was to reduce control time and errors in UAV video selection/manipulation and alleviate the need to switch between two input devices (e.g., a sensor stick and mouse).

Controls to manipulate the respective sensor presentations using a *digital video recorder* (DVR) have also been implemented. The DVR enables a playback

Fig. 101.14 Picture-in-picture (PIP) concept, with real video imagery surrounded by synthetic generated terrain imagery and symbology

capability, allowing an operator to reexamine any portion of a video (see Fig. 101.15). This capability to capture a segment of video to allow a second look and confirmation process may be especially useful if the vehicle's platform is such that a more stabilized view of the target is desired (Feitshans et al. 2008). Another potentially beneficial feature is the ability to “bookmark” a video segment by clicking directly in the video to designate locations of interest. When a location is designated, a computer-generated flag is overlaid on the imagery to mark the location of the tagged target. The color of this virtual flag corresponds to the assigned color of the UAV/sensor feed from which it was tagged. These virtual flags are persistent across sensors in that a flag generated in one sensor video is seen in another sensor video if that flag falls within the second sensor's field of view. In addition, a flag is placed on the map to correspond to the geo-location of the tagged object, color-coded to correspond to the UAV/camera source. These tools require further evaluation to ensure that they enhance overall mission effectiveness rather than negatively change attention dynamics (e.g., operator being distracted by focusing on recorded materials and not adequately attending to real-time sensory imagery). Research at AFRL is also addressing how additional information (e.g., weather feeds) might be integrated with the goal of *fusing information* to maximize intuitive information transfer (Carretta et al. 2009).

Fig. 101.15 Right monitor shows sensor videos from four UAVs and associated control and DVR tools in a Vigilant Spirit Control Station

Fig. 101.16 View of digital recording tool implemented in Vigilant Spirit Control Station

The Vigilant Spirit Control Station depicted in Fig. 101.14 shows the imagery from four cameras, each an equal window size. The station can also be implemented to enable the operator to enlarge one of the sensor videos, for instance, by touching it (Durlach et al. 2006). A tool whereby the video being attended to (e.g., determined by mouse clicks in the window) automatically enlarges the window and reduces the operator’s need to manipulate the zoom function is also a possibility (Porat et al. 2011). To further *reduce the need for zoom manipulations* (and potentially reduce workload), a maintain coverage area tool may be useful that automatically manipulates the zoom level to maintain the desired imagery size of a designated location, regardless of the vehicle’s position in a maneuver (Oron-Gilad et al. 2011).

Figure 101.17 shows the Vigilant Spirit Control Station configured with one large window showing the video of the selected UAV, along with small thumbprints of videos from the other UAVs. Use of a larger window can facilitate inspection of

Fig. 101.17 Alternate Vigilant Spirit Control Station layout with both large and small video windows

the video. However, for this configuration (as well as any with multiple videos), switching attention between different UAVs and their associated camera views has the potential for negative transfer of context to occur, such that the specific information and tasking involved with the first video/mission might delay or degrade the operator's ability to effectively perform tasks with the new video/mission. For instance, if the operator has a mental model of friendly forces being south of the target in the first mission, will the operator inappropriately apply this mental model to the new mission? To help operators quickly acquire situation awareness associated with the new camera view, an automated aid was conceived that uses synthetic vision technology to present a gradual scene transition process. With this transition, first, the camera imagery for one UAV seamlessly fades into a synthetic imagery correlate of the real video image. The scene then follows a fly-out, fly-in metaphor over several seconds (similar to computer mapping tools), finishing with a transition back from synthetic to real video imagery at a new camera view of the new geographic area (Fig. 101.18; Calhoun and Draper 2009). During the semicontinuous transition, points of interest (landmarks, roadways, troop locations, etc.) are highlighted with overlaid, geo-registered computer-generated symbology. The results from a simulation evaluation provide support that an automated *camera view transition aid* can improve task performance and situation awareness (Calhoun et al. 2010).

Another approach to help operators manage real-time video feeds from multiple UAVs employs model-inspection techniques and extends the picture-in-picture concept of viewing a video feed in the context of surrounding terrain. With the SUAVE (simple UAV environment) experimental system, as UAVs stream videos, individual geo-referenced frames are sampled and projected to replace the texture of an existing height map of satellite imagery (Abedin et al. 2011). In that the actual video is not being viewed, the *sampled imagery fused* in this fashion is asynchronous with the ability to trade off spatial and temporal resolution. If data is sampled at high spatial resolution, then large regions can be populated and searched, although some data may be obsolete. Temporal resolution can be maintained by sacrificing spatial resolution with the UAVs covering areas at a higher frequency. Research to date indicates that use of this asynchronous 3-D terrain model where the *fused video*

Fig. 101.18 Conceptual illustration of transition display aid to acquire situation awareness in new camera view

can be viewed in context improves target identification performance compared to a synchronous (multiple video feeds) condition where information is presented to the operator as it is acquired.

The tools just described are especially supportive of operators where each UAV is imaging a different area. However, multiple UAVs can be tasked to image the same location, with the goal of maintaining persistent coverage of a target of interest. Given the movement of the UAVs, existence of obstructions, and other factors, the particular UAV that can provide the best view of the target at any given time will vary. A casting rays tool may aid such tasks by presenting *ray traces overlaid on the imagery*, one from each UAV to the location to be imaged (Porat et al. 2010). Multiple coding methods can be employed such that each ray trace presents additional information. For example, ray width may indicate sensor distance from the target (wider is closer), with line style indicating view quality (dashed is limited or obstructed line of sight), color indicating UAV source, and an adjacent angle symbol indicating the inclination of the sensor (a wide angle indicates susceptibility to occlusion). This additional information is intended to aid the operator in deciding which sensor to select for viewing the target while maintaining focus on the sensor imagery and reducing the time spent analyzing the situation on the map. Follow-on evaluations are underway at AFRL to expand this concept by implementing a *predictive vantage ray* tool which also includes coding to indicate when a sensor will likely acquire or lose a target, as well as a supporting timeline that indicates the estimated time slots each UAV can image the target of interest.

The ability to view a location from multiple UAV viewpoints is a definite advantage. However, with current sensor technology, this equates to having multiple soda straws that the operator needs to mentally integrate to acquire the big picture. While information on tactical maps that reflect the footprints of multiple sensors can help construct a mental model of the mission environment, the operator will still have to devote considerable cognitive effort to determine and understand the

relationships between multiple views. This is especially difficult considering the environment dynamically changes. With advancements in computer technology, it is anticipated that available data streams from multiple heterogeneous sensors and geospatial data can be fused with synthetic symbology to create a *virtual (acoustically, visually, etc.) world of the entire mission area of interest*. There are numerous challenges to be addressed in developing this virtual representation of the battlespace. For instance, how can live and virtual representations of the same operational environment be blended to provide an immersive rendering and yet the source of each information element can be determined? Effort is also needed to develop an intuitive interface by which the operator would interact with the telepresence virtual world. Ideally, the world will be viewable from multiple perspectives and the interface will enable the operator to move fluidly throughout the representation of the operational environment, making real-time adjustments to the assets contributing to ongoing missions.

101.7 Conclusion

Several display and control concepts are introduced in this chapter that may be applicable to multi-UAV control applications. Certainly, with advances in display and control technology, there are many more possibilities than those described here. With this plethora of candidate solutions, a designer might be inclined to focus attention on one promising technology and apply it (or a few) to all possible multi-UAV interface applications. This technology-focused approach, however, should be avoided as multi-vehicle control applications, and associated control station requirements, can vary widely and thus can be quite disparate. Instead, for each multi-UAV control application, a user-centered design approach should be utilized (e.g., Endsley 2011) with UAV operator involvement during all cycles. This approach parallels a systems engineering process with emphases on iterative user and task analysis, design prototype implementation, and testing. For task analysis, the multi-UAV operator's specific tasks, operational mission, and environmental constraints need to be taken into account. The design step involves creating candidate solutions (from rough concepts to a fully functional prototype) tailored to meet identified task needs and constraints. Regardless of the fidelity of the design concept, iterative evaluation is necessary within the context of the targeted multi-UAV application.

Abstract

The use of unmanned aerial vehicles (UAVs) is expected to increase exponentially over the next few years. UAV ground operators are required to acquire skills quickly and completely, with a level of expertise that builds the operator's confidence in his/her ability to control the UAV under adverse conditions. As UAVs are held to increasingly higher standards of efficiency and safety, operators are routinely required to perform more informationally dense and cognitively demanding tasks, resulting in increased cognitive workloads during operation. Functional brain monitoring offers the potential to help UAV operators meet these challenges. Recent research has demonstrated the utility of near-infrared-based functional brain imaging systems (fNIRs) for the purpose of monitoring frontal cortical areas that support executive functions (attention, working memory, response monitoring). This technology provides portable, safe, affordable, noninvasive, and minimally intrusive monitoring systems with rapid application times for continuous measures of cortical activity. fNIR technology allows continuous monitoring of operators during training as they develop expertise, as well as the capacity to monitor their cognitive workload under operational conditions while controlling UAVs in critical missions. This chapter discusses the utilization of fNIR in the monitoring of a cognitive workload during UAV operation, and as an objective measure of expertise development, that is, the transition from novice to expert during operator training.

102.1 Introduction

According to the Department of Defense (DoD) Unmanned Aircraft Systems Roadmap 2005–2030 (2005), unmanned aerial vehicles (UAVs) have gained prominence because of their ability to perform dirty, dangerous, and dull missions while personnel remain in a remote location. The recent increase in UAV operations, however, is not without emerging challenges. Critical issues that have been identified include (i) an increase in operation failures due to human error, largely attributed to either inadequate training, or the increased mental workload being placed on ground flight crews and (ii) limited flight certifications and regulations to govern unmanned aircraft, specifically in the NAS (National Airspace System). Based on 194,000 h of operation, the DoD's 2005 roadmap reported that 17 % of system failures for U.S. military UA fleet were due to human/ground control error, whereas 19 % were attributed to flight control error. In addition to this report, Rash et al. (2006) showed that material-related failures were reduced due to advances in technology; however, human-related operation failures had increased (60–80 %). Given the military's experience coupled with recent studies suggesting that the primary factor found to be related to the increase of accident rates for UAVs is human operator failure, integration of the neurophysiologically informed human operator management system with the training procedures and

ground control systems is essential to address these challenges. An objective measure of expertise level to validate adequate training and real-time monitor of mental workload can enable safe operation of UAVs in the theater as well as in the NAS.

102.1.1 Mental Workload

There is no singular definition of mental workload (Cain 2007). There are at least two major theoretical approaches to the construct: (1) mental workload may be defined such that a given task's requirements are viewed as an independent, external variable with which the working participants have to cope more or less efficiently, or (2) mental workload may be defined in terms of an interaction between task requirements and human capabilities or resources (Hancock and Chignell 1986). Both approaches can offer essential and well-founded contributions to different problems. In either of these paradigms, the definition of workload involves the "objective" effects of task difficulty on the participant, and the participant's effort involved in maintaining performance. Workload is an intervening variable between task and environmental demands and the operator's performance, defined by the relationship between task demand and the participants' resource supply, that is, the portion of operator's limited mental capacities actually required to perform a particular task. That is, workload can be defined in terms of some "objective" criteria for task difficulty or in terms of the participant's capacities to perform the identified task. As such, workload can be dissociated from performance. Two people performing the same task can have identical performance, yet one operator may have significant cognitive resources free to allocate to concurrent tasks, whereas the second operator may be just on the brink of performance failure. The difference between the required capacity and the available capacity of an individual can be referred to as the mental or cognitive reserve.

Historically, there have been four basic methodologies for the measurement of mental workload: (1) primary task performance, (2) subjective ratings (e.g., NASA Task Load Index (TLX)), (3) central and peripheral measures of physiological response, and (4) secondary task techniques (Meshkati et al. 1995). Each of these measures plays an important role in the experimental study of workload. However, physiological measures of central nervous system (CNS) functioning hold the most promise for operational monitoring of UAV pilots, as they provide continuous and unobtrusive monitoring of the operator and do not interfere with an operator's work as do secondary task performance or subjective measures of workload (Gevins and Smith 2003; Gevins et al. 1997; Hancock and Desmond 2001; Scerbo et al. 2003; Wilson and Russell 2003). Further, neurophysiological measures of autonomic response (e.g., skin conductance, electrooculogram, electrocardiogram, and respiration) can be unobtrusive and provide an objective measure of workload. However, measures of autonomic responses, that is, the fight or flight system,

assess emotional stress, whereas some of the difference in workload may more appropriately be measured using a measure of cognitive workload, rather than stress. Measures of CNS response can provide information on both.

102.1.2 Expertise Development

A given individual will develop expertise more quickly with increased time on task and/or by utilizing the most appropriate and effective mode of practice for the task to be learned. Native ability may contribute to the speed of an individual's progression and may assist in determining individual differences in enhanced development of expertise in a given course of training. The literature dealing with the effect of practice on the functional anatomy of task performance is extensive and complex. Practice and the development of expertise have been studied across a range of motor, visuomotor, perceptual and cognitive tasks, and from disparate research perspectives. To briefly summarize this literature, four main patterns of practice-related activation change can be distinguished (Kelly and Garavan 2005). Practice can lead to (1) an increase in activation in the brain areas involved in task performance; (2) a decrease in those areas or (3) a functional redistribution of brain activity, in which some initial areas of activation decrease, whereas other initial areas of activation increase; and (4) a functional reorganization of brain activity, that is, the pattern of activation increases and decreases occur in distinct brain areas as well as the initial areas.

The majority of studies examining task practice have found decreases in the extent or intensity of activations, particularly in the attentional and control areas (Kelly and Garavan 2005). This finding is true whether the task is primarily motor (e.g., a golf swing (Milton et al. 2004)) or primarily cognitive in nature (e.g., the Tower of London problem (Beauchamp et al. 2003)). Decreases in activation represent a contraction of the neural representation of the stimulus (Poldrack et al. 1999) or a more precise functional circuit (Garavan et al. 2000). This finding provides an important overlap with the literature on expertise. There is considerable evidence that expertise tends to be associated with overall lower brain activity relative to novices, particularly in the prefrontal areas (e.g., Milton et al. 2004). Both practice and the development of expertise (the latter of which includes individual differences in ability) typically involve decreased activation across attentional and control areas, freeing these neural resources to attend to other incoming stimuli or task demands. As such, measuring activation in these attentional and control areas relative to task performance can provide an index of level of expertise. Functional near-infrared (fNIR) spectroscopy technique has been widely used to monitor frontal cortical areas that support executive functions. Importantly, there is evidence from fNIR technology-based studies showing that differences in workload can be assessed in the dorsolateral and ventrolateral prefrontal cortices during performance of complex tasks and that the level of expertise development can be objectively monitored (Ayaz et al. 2012; Izzetoglu et al. 2004).

102.2 Measures of Cognitive Functioning of UAV Operators

Commonly employed techniques such as electroencephalography (EEG), event-related brain potentials (ERPs), magnetoencephalography (MEG), positron emission tomography (PET), single positron emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI) have dramatically increased our understanding of a broad range of cognitive and emotional states. Methods that directly measure the summation of neural function, such as MEG, EEG, and ERPs, allow researchers to monitor the direct consequences of brain electromagnetic activity with temporal resolution on the order of milliseconds. However, these technologies also have limited spatial resolution (Strangman et al. 2002) and are susceptible to electromagnetic artifacts in the field. In contrast, indirect methods, such as PET, SPECT, and fMRI, monitor the hemodynamic and metabolic changes associated with neural activity with impressive spatial resolution but are limited in temporal resolution and are associated with neuronal activity through a poorly understood neurovascular coupling function (Strangman et al. 2002). In addition, PET and SPECT do not allow for continuous or repeated measurements because they require the use of radioactive isotopes, which also limits their use in children.

Functional magnetic resonance imaging (fMRI) is currently considered the “gold standard” for measuring functional brain activation. However, fMRI is expensive to operate and requires massive installations and a large infrastructure to operate. In addition, fMRI confines participants to restricted positions, is highly sensitive to motion artifacts, and exposes participants to loud noises. As such, with the exception of EEG, these technologies cannot yet easily be deployed in an operational environment.

102.2.1 Functional Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) has been increasingly applied for the noninvasive measurement of changes in the relative ratios of deoxygenated hemoglobin (deoxy-Hb) and oxygenated hemoglobin (oxy-Hb) during brain activation. In the late 1980s, Delpy designed and tested an NIRS instrument on newborn heads in neonatal intensive care (Cope et al. 1988). In the late 1980s and early 1990s, Dr. Britton Chance and his colleagues, using picosecond long laser pulses, spearheaded the development of time-resolved spectroscopy techniques in an effort to obtain quantitative information about the optical characteristics of the tissue (Patterson et al. 1989). These efforts by Chance, Delpy (Cope et al. 1988), and others (Fishkin and Gratton 1993) expedited the translation of NIRS-based techniques into a neuroimaging modality for various cognitive studies (Hoshi and Tamura 1997; Villringer and Chance 1997).

The combined efforts of these researchers led to the development of three distinct NIRS implementations, namely, time-resolved spectroscopy (TRS), frequency

domain, and continuous wave (CW) spectroscopy (Strangman et al. 2002). In TRS systems, extremely short incident pulses of light are applied to tissue, and the temporal distributions of photons, which carry information about tissue scattering and absorption, are measured. In frequency domain systems, the light source is amplitude modulated to the frequencies in the order of tens to hundreds of megahertz. The amplitude decay and phase shift of the detected signal with respect to the incident are measured to characterize the optical properties of tissue (Boas et al. 2002). In CW systems, light is continuously applied to tissue at a constant amplitude. The CW systems are limited to measuring the amplitude attenuation of the incident light.

CW systems have a number of advantageous properties that have resulted in wide use by researchers interested in brain imaging relative to other near-infrared systems; they are minimally intrusive and portable, affordable, and easy to engineer relative to frequency and time domain systems (Boas et al. 2002; Chance et al. 1998). These CW systems hold enormous potential for research studies and clinical applications that require the quantitative measurements of hemodynamic changes during brain activation under ambulant conditions in natural environments.

102.2.1.1 Underlying Principles of fNIR in Brain Activity Assessment

Understanding the brain energy metabolism and associated neural activity is important for realizing principles of fNIR in assessing brain activity. The brain has small energy reserves and a great majority of the energy used by brain cells are for processes that sustain physiological functioning (Ames 2000). Ames III reviewed the studies on brain energy metabolism as related to function and reported that the oxygen (O_2) consumption of the rabbit vagus nerve increased 3.4-fold when it was stimulated at 10 Hz and O_2 consumption in rabbit sympathetic ganglia increased 40 % with stimulation at 15 Hz. Furthermore, glucose utilization by various brain regions increased several fold in response to physiological stimulation or in response to pharmacological agents that affect physiological activity (Ames 2000). These studies provide clear evidence that large changes occur in brain energy metabolism in response to changes in activity. The levels of compounds involved in energy metabolism and energy metabolites can be outlined as:

- Brain cells consume energy when activated. Oxygen is required to metabolize the glucose. The concentration of oxygen in brain is about $0.1 \mu\text{mol g}^{-1}$ (Hansen and Nedergaard 1988) of which 90 % is in oxy-Hb in brain capillaries. This concentration can support the normal oxygen consumption (about $3.5 \mu\text{mol g}^{-1} \text{min}^{-1}$) for 2 s (Ames 2000). For that reason, an increase in neural activity in the brain is followed by the rise in local cerebral blood flow (CBF) (Buxton et al. 2004).
- Oxygen is transported to neural tissue via oxygenated hemoglobin (oxy-Hb) in the blood.
- The oxygen exchange occurs in the capillary beds.
- As oxy-hemoglobin gives up oxygen, it is transformed into deoxygenated hemoglobin (deoxy-Hb).

- Local cerebral blood flow (CBF) increases much more than the cerebral metabolic rate of oxygen (CMRO₂); therefore, local blood is more oxygenated and less deoxy-Hb present (Buxton et al. 2004).

Based on this brain energy metabolism, methods and imaging modalities, such as fNIR and fMRI (Kwong et al. 1992; Ogawa et al. 1990) for measurements of deoxy-Hb and/or oxy-Hb, are implemented to provide correlates of brain activity through oxygen consumption by neurons.

Because oxy-Hb and deoxy-Hb have characteristic optical properties in the visible and near-infrared light range, the change in concentration of these molecules during increase in brain activation can be measured using optical methods. Most biological tissues are relatively transparent to light in the near-infrared range between 700 and 900 nm, largely because water, a major component of most tissues, absorbs very little energy at these wavelengths (Fig. 102.1). Within this window the spectra of oxy- and deoxy-hemoglobin are distinct enough to allow spectroscopy and measures of separate concentrations of both oxy-Hb and deoxy-Hb molecules (Cope 1991). This spectral band is often referred to as the “optical window” for the noninvasive assessment of brain activation (Jobsis 1977).

Photons introduced at the scalp pass through layers of tissue and are absorbed and scattered mainly by oxy-Hb and deoxy-Hb molecules. Because a predictable quantity of photons follows a “banana-shaped” path and leaves the tissue, these photons can be measured using photodetectors (Gratton et al. 2005). If wavelengths are chosen to maximize the amount of absorption by oxy-Hb and deoxy-Hb, changes in these chromophore concentrations cause alterations in the number of absorbed photons as well as in the number of scattered photons that leave the scalp. These changes in light intensity measured at the surface of the scalp are quantified using a modified Beer–Lambert law (MBLL), which is an empirical description of optical attenuation in a highly scattering medium (Cope 1991; Cope and Delpy 1988).

Fig. 102.1 Absorption spectrum in NIR window: spectra of oxy-Hb and deoxy-Hb in the range of 700–900 nm allows spectroscopy methods to assess oxy-Hb and deoxy-Hb concentrations, whereas water absorption becomes substantial above 900 nm, and thus majority of photons are mainly absorbed by water

By measuring absorbance/scattering changes at two (or more) wavelengths, one of which is more sensitive to oxy-Hb, the other to deoxy-Hb, changes in the relative concentration of these chromophores can be calculated. Using these principles, researchers have demonstrated that it is possible to assess hemodynamic changes in response to brain activity through the intact skull in adult human participants (Ayaz et al. 2012; Bunce et al. 2006; Hoshi and Tamura 1997; Izzetoglu et al. 2011; Strangman et al. 2002; Villringer and Chance 1997).

102.2.1.2 CW fNIR System

The CW fNIR system was originally described by Chance et al. (1993). The current generation, flexible headband sensor developed in the Drexel's Optical Brain Imaging laboratory, consists of four LED light sources and ten detectors.

The fNIR system is composed of a computer that runs COBI Studio software (Ayaz et al. 2011) to acquire data from a flexible sensor pad through a hardware box. The sensor pad is a modular design consisting of two parts: a reusable, flexible circuit board that carries the necessary infrared sources and detectors and a disposable, single-use cushioning material that serves to attach the sensor to the participant's forehead (see Fig. 102.2). The flexible circuit provides a reliable integrated wiring solution, as well as consistent and reproducible component spacing and alignment. Because the circuit board and cushioning material are flexible, the components move and adapt to the various contours of the participant's head, thus allowing the sensor elements to maintain an orthogonal orientation to the skin surface, dramatically improving light coupling efficiency and signal strength.

Fig. 102.2 Overview of the CW fNIR system. Flexible sensor housing four LED light sources, ten photodetectors and wires. Computer running COBI Studio collects data through hardware control box

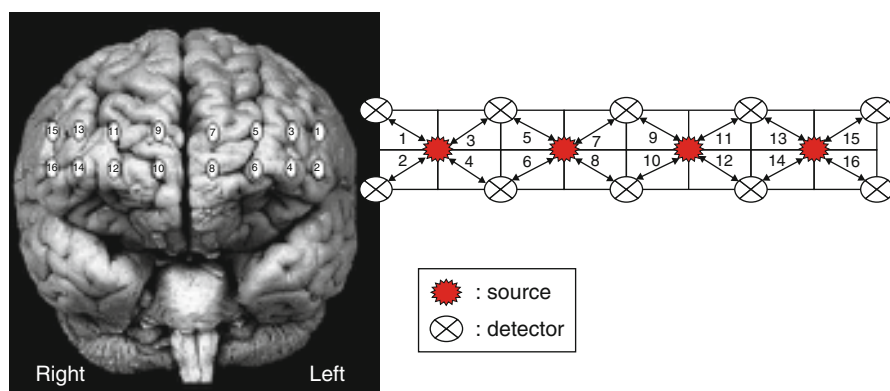

Fig. 102.3 Spatial map of the 16-channel fNIR sensor on the curved brain surface, frontal lobe

The flexible sensor covers the forehead using 16 channels (Fig. 102.3), with a source-detector separation of 2.5 cm. The light sources (manufactured by Epitex Inc.; type no: L4X730/ 4X805/4X850-40Q96-I) contain 3 built-in LEDs having peak wavelengths at 730, 805, and 850 nm with an overall outer diameter 9.2 ± 0.2 mm. The photodetectors (manufactured by Bur Brown; type no: OPT101) are monolithic photodiodes with a single supply trans-impedance amplifier having the size of 0.90×0.90 in. (Bunce et al. 2006). The fNIR sensor, illustrated in Fig. 102.2, reveals information in localizing brain activity, particularly in dorsolateral prefrontal cortex (Izzetoglu et al. 2004, 2005). Figure 102.3 shows a spatial map of the 16-channel fNIR sensor on the curved brain surface, frontal lobe (Ayaz et al. 2006).

The following case studies demonstrate implementation of the CW fNIR system in workload and expertise assessments (Ayaz et al. 2006).

102.3 Case Studies

102.3.1 Cognitive Function Assessment During Simulated UAV Mission Task

The purpose of this case study was to monitor an operator's brain activity during the performance of flight simulator missions. The UAV Predator add-on (First Class Simulations) for Flight Simulator X (Microsoft) provides multiple methods for controlling a realistically functioning and realistically represented UAV model based on the popular Predator UAV. Using the UAV Predator add-on with Flight Simulator, ten missions were designed which incorporated a variety of cognitive workload factors (e.g., crosswinds, cloud cover, visual search tasks, navigation, changing objectives) and that vary in their level of difficulty from easy to extremely challenging. Each mission lasted no longer than 2 h and was designed to require at least 1 h of performance. As an individual successfully completed each mission,

Fig. 102.4 Participant operating the Predator UAV simulator with fNIR sensor on

they were introduced to progressively more difficult missions. Information on events within the simulation, the aircraft's latitude, altitude, and speed, as well as data on the motion of the controllers, was recorded for subsequent assessment along with the fNIR data.

Microsoft Flight Simulator X is a readily available flight simulation program with current support from the company as well as from a large worldwide community of developers, both for the program itself and its software development kit (SDK). It takes full advantage of modern computer hardware to deliver a realistic simulation of every aspect of flight with a variety of aircraft and under a wide range of conditions. Flight Simulator X does not come with a UAV model, so the Predator add-on by First Class Simulations has been used. This add-on provides a realistic aircraft model of the MQ-1 Predator UAV, as well as a realistic interface that can be adapted in many ways. The multiple displays from the typical vertically stacked configuration are adapted to a horizontal arrangement to better suit the multi-monitor configuration (Fig. 102.4).

102.3.1.1 Method

Procedure

Several highly challenging flight scenarios were designed, representing a variety of tasks required of UAV operators (coordinate-based navigation, landing, visual

search/target categorization, etc.) and incorporating a variety of workload factors (e.g., crosswinds, cloud cover, fuel constraints). After a short training session for the purpose of familiarization with the protocol and simulation, participants were asked to fly these scenarios during eight subsequent flight sessions. Each participant performed one flight session per day, each lasting approximately 2 h, for a total of 18 h over 9 days. All participants signed informed consent statements approved by the Human Subjects Institutional Review Board at Drexel University and by the U.S. Army Medical Research and Materiel Command (USAMRMC), Office of Research Protections (ORP), and Human Research Protection Office (HRPO).

The following procedures and tests were designed and implemented during the human experiments:

Session 1: After signing an informed consent, each participant completed the Edinburgh Handedness (Oldfield 1971) questionnaire and a brief questionnaire regarding previous flight and video game experience. Following the fNIR sensor placement on the participant's forehead, each participant performed a 1.5-h introductory flight, during which they are introduced to the UAV simulation, given an overview of the interface, and then they were required to complete a guided tutorial session in order to develop familiarity with the simulation and the very basic proficiencies required (Fig. 102.4).

Sessions 2–9: Each subject attempted one or more of the flight scenarios (Fig. 102.5), with the fNIR device attached with behavioral and neural data obtained during the flight. At the end of each session, a confidence survey and the NASA-TLX are administered to allow subjects to self-rate overall performance.

Data Analysis and Results

Data analysis was performed on the fNIR data while participants performed a visual search/target categorization task (Menda et al. 2010). In this protocol, each participant performed one scenario per session in which they were asked to fly along a coastline and search for a submarine, knowing only that the submarine will be just offshore. When they noticed the submarine, participants were asked to press a button that caused a time-stamped marker to be sent to the fNIR data acquisition software. Five healthy participants with no neurological or psychiatric history

Fig. 102.5 Visual demonstration of UAV-simulated missions

Fig. 102.6 Normalized average HbT in all 16 channels from 5 participants in the target search task. *Pink* represents average HbT in the 100 s before reported target sighting; *blue* represents the same measure within 100 s after reported target sighting

(ages 18–35) voluntarily participated in the study. These data compare average oxygenation changes before and after detection of the submarine.

Time synchronization markers that indicate key events during flight were time-correlated with fNIR data. A linear phase, finite impulse (FIR) low-pass filter with a cutoff frequency of 0.2 Hz was applied to the 16-channel raw fNIR data to eliminate high-frequency noise. For oxygenation calculations, a modified Beer–Lambert law was applied to the data to calculate oxy-hemoglobin and deoxy-hemoglobin concentration changes. fNIR signal data were then averaged over 100 s before and after each participant indicated locating the submarine in each trial. The averages of total hemoglobin (HbT) concentration changes were calculated for pre- and post-blocks and normalized using z-score calculation for each pair independently. Figure 102.6 displays average total hemoglobin concentration changes over all recorded trials from five participants. Separate 2 X 5 (Block, Pre; Post X Trials) repeated measures ANOVAs on both factors were calculated for channels 2 and 4. Channels 2 and 4 were significant; for the main effect of block for channel 2, $F(1,16) = 23.67$, $p < 0.01$, and for channel 4, $F(1,16) = 53.25$, $p < 0.01$ (Menda et al. 2010).

102.3.2 Cognitive Workload Assessment in UAV Interface Development

The aim of this case study is to show that application of fNIR during operator trials with new UAV interfaces may be able to produce an objective assessment of operator cognitive workload, thus providing a vital source of input for evaluating and improving the UAV interface design. In UAV interface development, an increased amount of data displayed on the interface has been shown to improve situational

awareness, but it tends to come at the cost of increased cognitive workload to the operator (Kaber et al. 2000). A balance between performance increase and cognitive workload increase needs to be continually addressed in the development of new UAV interfaces to minimize the risks of operating near the limit of the operator's cognitive capacity as described in Sect. 102.1.1.

An experimental mixed-reality chase view interface was developed for use in direct piloting of UAVs in near-Earth, cluttered environment scenarios. Direct piloting in this case means operation of the UAV through remote control by directly commanding thrust and control surface deflections (aileron, elevator, etc.) through the use of a standard radio 4 channel controller. The chase view interface (shown in Fig. 102.7) integrates both real world "onboard the aircraft" views (onboard camera) with virtual representations of the vehicle and surrounding operating environment. The result is a viewpoint from behind the aircraft such that the extremities of the aircraft are easily seen by the operator and the viewing field is virtually increased. Also, the onboard camera image is stabilized such that the horizon remains level. Aircraft roll is seen directly through visualization of the aircraft motion rather than rolling of the image as experienced from standard onboard camera viewpoints.

A similar approach was originally employed by Drury et al. (2006), supported by their continuing work to define and evaluate situational awareness in unmanned vehicle operations (see Drury and Scott 2008). Their findings indicated that an augmented display improved comprehension of spatial relationships between a UAV and elements of the environment in observational tasks, similar to those performed by payload operators for high-altitude UAVs. Cooper and Goodrich (2008) found

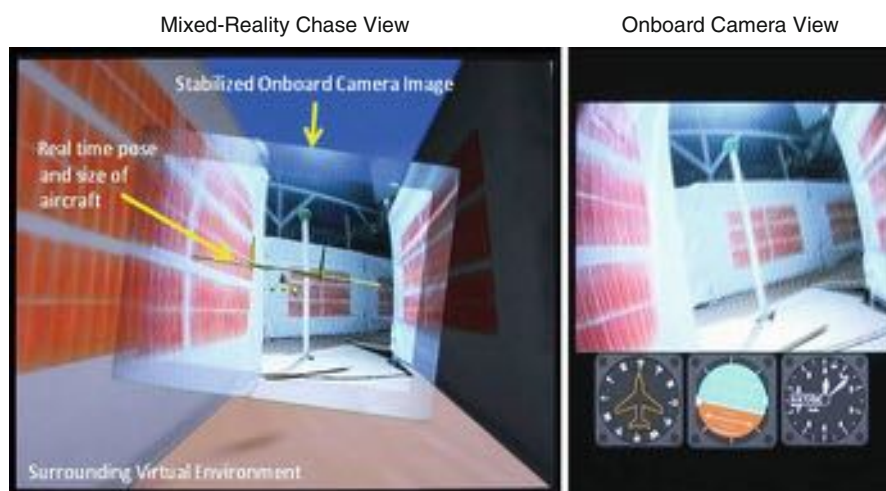

Fig. 102.7 (Left) Screen shot of the mixed reality chase view interface during UAV operation in a cluttered environment. (Right) Onboard camera viewpoint with virtual instruments positioned below the image to relay information about the vehicle state

similar results for search tasks using a mixed-reality system. In their studies, they also found that giving subjects navigation control (i.e., setting waypoints) while conducting the search task helped in flight path recollection, which in turn, improves target localization. These works support the use of a mixed-reality interface in UAV operations for higher altitude missions and waypoint control of the aircraft. Related to this, future applications will also require small UAVs to fly low and in urban/cluttered environments. The present case study focuses on direct piloting of the UAVs in near-Earth environments, where such comprehension of spatial relationships is crucial. We make use of an indoor robotic gantry system, which was developed as a safe means to evaluate factors relevant to UAV operations in near-Earth environments.

This case study addresses the hypotheses: For operating a UAV in a cluttered environment, (1) the chase view will improve an operator's comprehension of the three-dimensional position and orientation of the aircraft with respect to the surrounding environment resulting in more efficient flights (i.e., tighter turns around obstacles), (2) fNIR will detect a higher change in blood oxygenation (i.e., higher cognitive workload) for participants operating via an onboard camera perspective than participants operating via a mixed-reality chase view interface. The narrower viewable field, and rolling of the environment from the onboard camera perspective, results in more cognitive processing for the operator in order to construct an accurate working mental model of the environment and location of the aircraft's position within it.

102.3.2.1 Method

Procedure

A 1:43.5 scale indoor cluttered environment consisting of corridors and obstacles was built inside of a large 3-degree-of-freedom (dof) robotic gantry with a workspace of 18 foot long by 14 foot wide by 6 foot high (shown in Fig. 102.8). The gantry arm was driven through the workspace by the scaled output from the flight simulation software package X-Plane from Laminar Research. A small fixed wing UAV was used as the model for the flight simulator. Henceforth, the gantry arm controlled by the flight simulator is referred to as "the aircraft." Attached to the end of the gantry arm was a 3-dof servo unit that housed a wireless camera and was capable of replicating the yaw, pitch, and roll motions of the model UAV fed to it by the flight simulation software. The wireless camera image was relayed to the operating station and used as the onboard camera perspective and also integrated into the chase view perspective.

Eleven laboratory personnel volunteered as participants during the development of the test methodology. Prior to the start of the study, each subject was given an overview of the experiment and signed a consent form. Six participants flew the aircraft through the environment using only the chase view interface (chase view), and five participants flew the aircraft using only the onboard camera interface (onboard view) (example shown in Fig. 102.8 right). The experiment protocol involved a total of seven sessions per participant, one session per day, and four missions per session. Six sessions involved mission tasks with the fNIR sensor

Fig. 102.8 Flight environment inside the gantry built at 1:43.5 scale. In between the corridor walls is considered the “lower level” of the setup and above the corridor walls where the colored markers sit (and above) is considered the “upper level” of the setup

placed on each participant’s forehead, while session one was used to allow subjects to become acquainted with the aircraft controls and flight environment.

During each mission, participants first operated in the lower level of the environment and were tasked with flying through the corridors following a predefined route. The second part of the mission operated in the upper level of the environment and tasked the participants to search for colored markers and fly over the centerline of the markers in a specific order. Participants provided subjective mental effort and performance evaluation using the NASA Task Load Index (TLX) questionnaire (Hart and Staveland 1988). Each session lasts 45 min to an hour.

Data Analysis and Results

Behavioral performance comes from data such as the participant’s accuracy in positioning the aircraft. From the results shown in Fig. 102.9 left, it was found that chase view participants flew tighter paths around the obstacles (closer distance to the obstacles), while onboard view participants took much longer paths ($p < 0.0001$ for both pole obstacles) (Hing et al. 2011). Figure 102.9 right (error means distance from the centerline of the marker) shows that for the second part of the mission (upper level), the chase view participants were better able to position themselves over the centerline of the markers ($p < 0.02$ ($p < 0.05$ set for significance)) (Hing et al. 2011; Hing and Oh 2009). The data supported the hypothesis that a chase view enhances the awareness of the vehicle’s position and extremities, especially when deciding if the aircraft wing tips have safely cleared an obstacle during a turning maneuver. As stated earlier, this also supports the previous findings by Drury and Scott (2008) and Cooper and Goodrich (2008).

Fig. 102.9 (Left) Horizontal distance (m) of aircraft to the two pole obstacles during turning maneuvers. (Right) Horizontal distance (m) (aka. Error) of the aircraft position from the center line of the marker during upper level flight tasks. Significant distances are highlighted by an asterisk

Table 102.1 summarizes the parameters and results for the analysis of cognitive measures. The NASA-TLX gave a subjective workload assessment for each participant and each session. Chase and onboard views were compared for adjusted weight rating and mental demand using a Mann–Whitney U nonparametric test ($p < 0.05$ for significance) to assess differences between onboard view and chase view groups’ subjective workloads. Monte Carlo permutation tests (10,000 replications) and bootstrapped 95 % confidence intervals of the Monte Carlo tests were calculated. The hemodynamic response features from the fNIR measures (i.e., mean and peak oxy-Hb, deoxy-Hb, oxygenation) were also analyzed. The fNIR measurements were first cleaned of motion artifacts (Ayaz et al. 2011). A linear phase, finite impulse response (FIR) low-pass filter with a cutoff frequency of 0.2Hz was applied to the 16-voxel raw fNIR data for each participant to eliminate high-frequency noise. For oxygenation calculations, a modified Beer–Lambert law was applied to the data to calculate oxy-hemoglobin and deoxy-hemoglobin concentration changes. Analysis was run on all participants. Mann–Whitney U nonparametric tests with view as the grouping variable (with onboard and chase as the levels) was performed across the flights to determine if there were median differences in mean and peak oxygenation for the channels ($\alpha = 0.05$).

The NASA-TLX results are shown in Fig. 102.10. When comparing overall task load score and the mental demand score between chase view and onboard view, no statistically significant differences were found (p values were 0.395 for the overall score and 0.103 for the mental demand score) (Menda et al. 2010). In Table 102.1, the task-weighted workload shows a significant difference for the permutation tests

Table 102.1 Parameters and results of Mann–Whitney U and Monte Carlo permutation tests for key cognitive measures

| Dependent measure | Monte Carlo p value | Mean difference | Exact probabilities $z = (p \text{ value})$ | Bootstrap mean | Bootstrap lower limit 95 % | Bootstrap upper limit 95 % |
|-------------------|---------------------|-----------------|---|----------------|----------------------------|----------------------------|
| Mental demand | 0.004 | 72.359 | 0.854 (0.393) | 72.524 | 17.387 | 122.903 |
| Weighted rating | 0.440 | −2.801 | −1.634 (0.102) | −2.857 | −10.069 | 4.296 |
| Mean oxygenation | 0.020 | −0.386 | −2.001 (0.045) | −0.387 | −0.387 | −0.059 |
| Max oxygenation | 0.029 | −0.386 | −2.367 (0.018) | −0.385 | −0.725 | −0.046 |

Fig. 102.10 (Left) Task load index weighted rating across sessions. (Right) Mental demand rating across sessions

($p = 0.004$) along with bootstrapped confidence interval width not containing zero. Additional testing with a sufficient sample size, as well as tasks that require more mental stimulation, may permit the NASA-TLX to sufficiently distinguish between the view groups.

While the subjective tests showed no significance, the fNIR analysis showed otherwise. The difference of average oxygenation changes for all chase and onboard view groups were found to be significant ($z = -2.001$, $p < 0.045$) (Menda et al. 2010). Onboard View was found to be significantly higher than chase view. These results are shown in Fig. 102.11 left. The difference of maximum oxygenation changes for chase view and onboard view groups were found to be significant

Fig. 102.11 (Left) Average oxygenation changes for chase and onboard view participants. Plot shows Onboard View group's levels are higher. (Right) Maximum oxygenation changes for chase and onboard view groups. Plot shows onboard view group's levels are higher

($z = -2.367, p < 0.018$) (Menda et al. 2010). Figure 102.11 right shows that onboard view had higher maximum oxygenation change when compared with the chase view group. This result suggests that the fNIR approach has potential to be a more sensitive measure of workload than NASA-TLX, since the differences in performance results correlate with the fNIR differences.

These comparisons were performed on channel 4. Activation in the brain area corresponding to channel 4 has been found to be sensitive during completion of standardized cognitive tasks dealing with concentration, attention, and working memory (Ayaz et al. 2012; Izzetoglu et al. 2004). Higher oxygenation in this area is well correlated with higher cognitive workload.

While performance analysis showed that the chase view interface has potential to increase performance, the fNIR data showed its' potential to decrease cognitive workload of an operator directly piloting a UAV in a cluttered environment. The benefit of a lower cognitive workload, as mentioned earlier, is that a pilot would have more cognitive resources available to handle any warnings, system faults, or other unexpected events that might occur during the flight.

102.3.3 Development of Expertise and Monitoring During a Simulated UAV Mission Task

The aim of this case study is to demonstrate that neuroimaging technologies, in this case fNIR, can be implemented to objectively measure expertise development, that is, transition from novice to expert during operator training. This case study can address and test two hypotheses: activation in dorsolateral prefrontal cortical (DLPFC) areas supporting attention, decision making, and working memory

decreases with practice time on task for each individual, and given the same level of task difficulty and the same level of performance, higher levels of activation in DLPFC is associated with less “cognitive reserve,” that is, less capacity to perform at the next level. Similar to aforementioned case study in Sect. 102.3.1, UAV-simulated missions are used for experimental protocols, namely, approach and landing scenarios.

102.3.3.1 Method

Procedure

Participants practiced approach and landing scenarios while piloting a virtual UAV in a flight simulator. The scenarios were designed to expose novice participants to realistic and critical tasks for a UAV ground operator directly piloting an aircraft. The first scenario was a turn-to-approach task, in which the pilot flies through several waypoints on an approach to land at an airfield. The second scenario was a landing task, in which the pilot performs the actual touchdown (Ayaz et al. 2012). In both scenarios, participants were told to fly as smoothly as possible, learn the optimal paths, cope with crosswinds, and operate within certain speed and bank angle constraints (Fig. 102.12).

The experiment protocol involved a total of nine sessions per participant, one session per day. The first session on day 1 was to allow participants to become acquainted with the flight simulator; by the end of this session, they needed to demonstrate basic understanding of flight simulator controls. Study data were collected during the following eight practice sessions. Practice sessions consisted of ten repetitions each of two scenarios (one approach, one landing), a total of 20 flights per session, for a total of 160 trials per participant over the 8 days. Participants provided subjective mental effort and performance evaluation using the NASA Task Load Index (TLX) questionnaire (Hart and Staveland 1988). Each session lasted 2–3 h, with no more than one session per day.

During recruitment and consenting, all participants signed informed consent statements approved by the Human Subjects Institutional Review Board at Drexel University and by the U.S. Army Medical Research and Materiel Command (USAMRMC), Office of Research Protections (ORP), and Human Research Protection Office (HRPO).

Fig. 102.12 UAV simulators on triple panel display running turn-to-approach task screenshots

Data Analysis and Results

UAV fNIR data was preprocessed using the low-pass filters and saturated channel attenuation criteria. fNIR data epochs for the rest and task periods were extracted from the continuous data using time synchronization markers. Blood oxygenation and volume changes for each of the 16 channels were calculated using the modified Beer–Lambert law (MBLL) for task periods with respect to rest periods at beginning of each task (Ayaz et al. 2012, 2011). The main effect for practice level was tested using a one-way repeated measures ANOVA, with participant and practice level designated as fixed effects factors. Geisser–Greenhouse (G-G) correction was used when violations of sphericity occurred in the omnibus tests. Tukey's post hoc tests were used to determine the locus of the main effects with a 0.05 significance criterion. Three practice levels were defined for each participant: the beginner phase included days 2 through 4, intermediate phase included days 5 through 7, and the advanced phase included days 8 and 9 (Ayaz et al. 2012). The Number Cruncher Statistical Software (NCSS) 2007 (www.ncss.com) was used for the statistical tests. The false discovery rate (FDR) approach was used for multiple comparison correction (Benjamini and Hochberg 1995; Singh and Dan 2006).

Ayaz et al. (2012) reported that the NASA-TLX results indicated a significant main effect of practice level (beginner/intermediate/advanced conditions) for mental demand ($F_{2,8} = 17.87$, $p < 0.01$, $\eta_p^2 = 0.817$), effort ($F_{2,8} = 16.32$, $p < 0.01$, $\eta_p^2 = 0.803$), and frustration ($F_{2,8} = 8.60$, $p < 0.01$, $\eta_p^2 = 0.682$). Both mental demand and perceived effort followed a monotonic decrease from beginner to advanced phase (Fig. 102.13).

In the same study reported by Ayaz et al. (2012), behavioral performance for the practice effect was also analyzed. For the approach task, the authors demonstrate that there was a significant monotonic decrease in deviation from the optimal path when comparing practice level (beginner through advanced) for latitude ($F_{2,8} = 18.30$, $p < 0.05$, $\eta_p^2 = 0.793$), longitude ($F_{2,8} = 17.58$, $p < 0.05$, G-G, $\eta_p^2 = 0.815$), bank ($F_{2,8} = 15.80$, $p < 0.05$, G-G, $\eta_p^2 = 0.798$), and heading ($F_{2,8} = 16.41$, $p < 0.05$, $\eta_p^2 = 0.804$) (Fig. 102.14). The analysis for the landing task revealed results similar to the aforementioned approach task, that is, errors for the latitude, longitude, and banking parameters were significant (Ayaz et al. 2012).

For each type of UAV task (approach and landing), the average total hemoglobin (HbT) concentration changes throughout the practice levels (beginner/intermediate/advanced) were analyzed using one-way repeated measures ANOVA and reported by Ayaz et al. (2012). The results indicated that the only significant measurement location was channel #2. Channel #2 is close to AF7 in the International 10–20 System which is located within the left prefrontal cortex (i.e., inferior frontal gyrus). The response was found to be significant for both the approach task ($F_{2,8} = 6.08$, $p < 0.05$, $\eta_p^2 = 0.603$) and the landing task ($F_{2,8} = 7.70$, $p < 0.05$, $\eta_p^2 = 0.658$), see Fig. 102.15. Post hoc analyses confirmed that activation for the beginner phase was significantly higher than the other two phases ($q_{0.05/2,8} = 4.04$, $p < 0.05$) (Ayaz et al. 2012).

102.4 Discussion

An accurate measure of mental workload would help improve operational safety and efficacy in many environments that involve multitasking or sustained vigilance. Deployment of portable neuroimaging technologies to operating settings could help assess cognitive states of personnel assigned to perform critical tasks and thus help improve the efficiency and safety of human–machine systems. Functional near infrared spectroscopy (fNIR) is an emerging noninvasive brain imaging technology that relies on optical techniques to detect brain hemodynamics within the prefrontal cortex in response to sensory, motor, or cognitive activation. In this chapter, three case studies have been reviewed where fNIR technology has been used together with simulated UAV tasks to demonstrate efficacious utility of the technique. The results corroborate with previous studies where we have used fNIR to detect cognitive workload of operators in the DARPA Augmented Cognition Warship command program (Izzetoglu et al. 2004) and in FAA Air Traffic Controllers (Ayaz et al. 2012).

In the first case study, cognitive function assessment during simulated UAV mission task, each participant performed one flight session per day for a total of 18 h over 9 days. The result indicates that fNIR is sensitive to high and low cognitive workload states of a UAV operator in a visual search/vigilance task. The second case

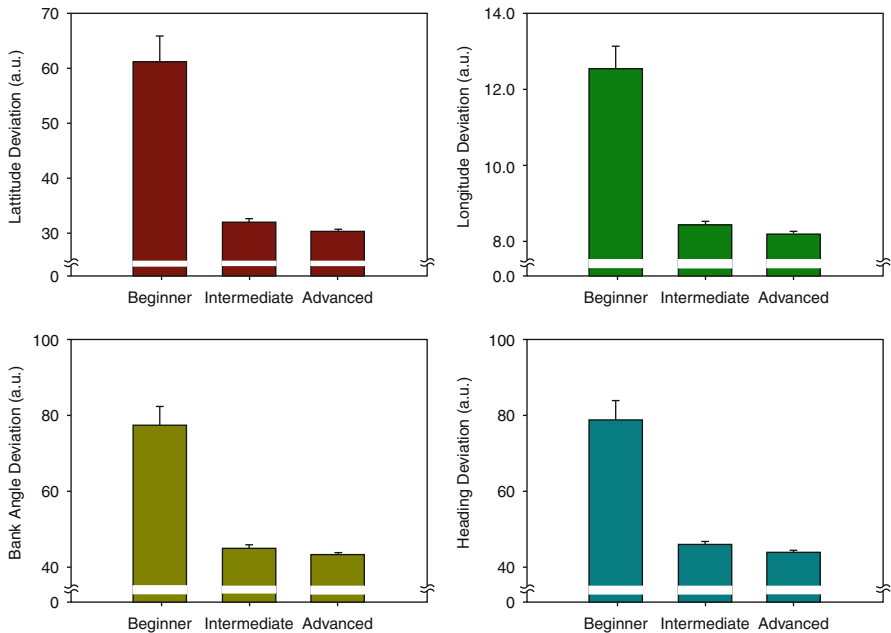

Fig. 102.14 Behavioral performance results for UAV approach task. Deviation from optimal for latitude (*top, left*), longitude (*top, right*), bank angle (*bottom, left*), and heading (*bottom, right*). (5 participants, 10 trials per day, 8 days). Error bars are SEM (©Neuroimage)

Fig. 102.15 Total hemoglobin concentration changes for the UAV approach (*left*) and landing (*right*) tasks (5 participants, 10 trials per day, 8 days) Error bars are SEM

study, the UAV interface development and workload assessment, deployed the fNIR sensor into the evaluation and analysis of pilot performance. Analysis of the fNIR data found that chase view subjects' average oxygenation levels was significantly lower than onboard view subjects, revealing that subjects using the onboard camera view were utilizing more mental resources to conduct the flights. This result is most likely attributable to the narrower viewable angle and rolling of the environment

in the onboard view. Importantly, this study demonstrates that the fNIR signal is responsive to factors that are relevant to situational awareness and affect UAV operator performance and safety. If these results are validated and elaborated by future studies, fNIR could become a powerful tool in monitoring and improving human factors in UAV operations. In the third case study, expertise development and monitoring, the activation changes in the prefrontal cortex were monitored each day in a 9-day series of simulated UAV tasks as participants practiced “landing” and “approach to turn” tasks. Decreases in the fNIR measures, shown in Fig. 102.15, are significant and a valid hypothesis can be derived from the evidence that expertise tends to be associated with overall lower brain activity relative to novices, particularly in the prefrontal areas (Milton et al. 2004). Both practice and the development of expertise typically involve decreased activation across attentional and control areas, freeing these neural resources to attend to other incoming stimuli or task demands. As such, measuring activation in these attentional and control areas relative to task performance can provide an index for level of expertise, and it illustrates how task-specific practice influences the learning of tasks. The differences in activation of the attentional and control regions of the prefrontal cortex may also indicate neural plasticity as a function of task-specific practice (Kelly and Garavan 2005).

It is particularly important to assess and measure operator training and mental workload in situations where performance failures could result in catastrophic losses (e.g., military command and control, air traffic control). Accurate assessment of mental workload could help in preventing operator error and allow for pertinent intervention by predicting performance decline that can arise from either work overload or understimulation (Meshkati et al. 1995; Parasuraman and Rizzo 2007; Parasuraman and Wilson 2008).

In summary, a field deployable optical brain imaging (fNIR) holds enormous potential for research studies and clinical applications that require the quantitative measurements of hemodynamic changes during brain activation under ambulant conditions in natural environments. As such, fNIR has been already deployed in many field settings for objective measurements of cognitive workload, and further studies have been underway to validate objective assessment of the expertise development which will, among other advantages, allow for dynamic interventions in the training process and helping to assure robust performance under adverse circumstances. fNIR application areas include, but are not limited to, the following: brain computer interfaces for cognitive enhancement, neurological and gaming applications, pediatric solutions, education and training, and cognitive aging.

The case studies described here provide important albeit preliminary information about fNIR measures of DLPFC hemodynamic response and its relationship to mental workload, expertise, and performance, in a complex multitasking environment. Level of expertise does appear to influence the hemodynamic response in dorsolateral/ventrolateral prefrontal cortices, at least for some complex tasks. Since fNIR technology allows the development of mobile, nonintrusive, and miniaturized devices, it has the potential to be deployed in future learning and training

environments to personalize the training regimen and/or to assess the effort of human operators in critical multitasking environments.

Human Factors and Training

Fulvia Quagliotti

Kimon P. Valavanis and George J. Vachtsevanos

Human Factors and Training addresses the topic of training of OEMs, military, and other human operators to operate, monitor, and execute a complete mission for all classes of platforms currently available to the military and other sectors.

► **Using Best Practices as a Way Forward for Remotely Piloted Aircraft Operators: Integrated Combat Operations Training-Research Testbed** by Rowe, Conwell, Morris, and Schill centers on work undertaken at the U.S. Air Force Research Laboratory (AFRL) in the Integrated Combat Operations Training-Research Testbed (ICOTT), where training gaps in the RPA community are extensively researched. This is the aftermath of the massive growth and increase of medium altitude, long endurance (MALE) remotely piloted aircraft combat air patrols, which has enforced the need to train RPA operators quickly and effectively. Using a competency-based approach, researchers, engineers, subject matter experts, and warfighters are developing a training research testbed to evaluate curriculum, training methodologies, and best practices in training simulation. The chapter addresses the evolution of training requirements for the RPA community as well as targeted solutions to support RPA training, operational readiness needs, and an exploration into the existing methods and common tools used to understand and evaluate the relative trade-off in training utility associated with alternative training systems. The overarching discussion focuses on methods for providing more rapid and efficient knowledge and skill development for RPA operators.

► **From Research to Operations: The PITVANT UAS Training Experience** by Madrugá Matos, Vieira Caetano, Morgado, and Borges de Sousa presents the PITVANT UAS R&D program training experience, including the different crew positions and responsibilities, the several training phases, and the systems engineering methodology behind all developments carried by the joint team of the Portuguese Air Force Academy and Porto University. The training program is described including theoretical classes, written exams, and practical instruction and evaluation. The process of developing, testing, and validating concepts of operations and the correspondent operational procedures and their training with the involvement of end users is reported. The current operational capabilities of the systems are explained, showing that the PITVANT program has achieved a level of maturity that enables testing and validation in near real scenarios. This leads to the next step in the systems spiral development that should include, in the near future, the possibility of technology transfer to the industry.

Contributions also provide useful information highlighting commonality of UAV training requirements and methods required to reduce operator workload.

Using Best Practices as a Way Forward
for Remotely Piloted Aircraft Operators:
Integrated Combat Operations

Abstract

The growth of medium altitude, long endurance (MALE) remotely piloted aircraft (RPA) combat air patrols increased 660 % between 2004 and 2009 (Gertler 2012). With this massive increase in the U.S. Air Force (USAF) operational requirements, the need to train RPA operators quickly and effectively is in the spotlight. This paradigm change presents an array of warfighter training and readiness issues that require solutions sooner than later. Fortunately,

there are USAF research programs that comprehensively address these types of issues. The work highlighted in this chapter is undertaken at the U.S. Air Force Research Laboratory (AFRL) in the Integrated Combat Operations Training-Research Testbed (ICOTT). In the ICOTT among many platforms, the training gaps in the RPA community are researched. Using a competency-based approach, researchers, engineers, subject matter experts, and warfighters are developing a training research testbed to evaluate curriculum, training methodologies, and best practices in training simulation. This chapter addresses the evolution of training requirements for the RPA community as well as addresses targeted solutions to support RPA training, operational readiness needs, and an exploration into the existing methods and common tools used to understand and evaluate the relative trade-off in training utility associated with alternative training systems. The overarching discussion focuses on methods for providing more rapid and efficient knowledge and skill development for RPA operators. The lessons learned from this research represent a first step to ensuring maximum RPA training effectiveness.

104.1 Introduction

The U.S. Department of Defense (DoD) is projected to spend upwards of \$26 billion on procurement, operations, maintenance, research and development, and test and evaluation of RPAs between 2001 and 2013. Comparing this figure to the \$3.9 billion spent from 1988 to 2000 demonstrates the increased attention being given to RPAs (Gertler 2012). Given this exponential growth, it is no surprise that the use of these aircraft has emerged as one of the most demanded capabilities in the joint forces (Department of Defense 2012). RPAs not only provide information to senior operational decision makers but also directly inform joint and coalition forces operating in the field and in congested urban environments. RPAs provide persistence, endurance, efficiency, mission flexibility, surveillance, and attack capability and have proven to be major players across the spectrum of global, joint military, and law enforcement operations. Unmanned technologies provide a capability that supports intelligence, command and control (C2), targeting, and weapons delivery all while providing situational awareness and keeping the warfighters operating the system out of harm's way. Unmanned technologies provide the greatest strategic utility in contested environments that are considered too high-risk for manned systems such as identification and disposal of improvised explosive devices (Department of Defense Unmanned Systems 2011). The most common operations for RPAs are intelligence, surveillance, and reconnaissance (ISR), strike, meaning the ability to deliver ordnance against a ground target, and combat search and rescue of operational personnel.

The oldest unmanned systems are underwater unmanned vehicles; nevertheless, the most utilitarian unmanned systems in the military operational environment are the RPAs. From the size of insects to the size of fighter aircraft, the RPA has forever changed the game of warfare and is now an integral part of the military arsenal. Generally, a military squadron or battalion operates several RPAs. Depending on the

size of the RPA, the usual components include several aircraft, whose size correlates to the size of the control stations. Larger RPAs such as Global Hawk and Reaper have ground stations that are the size of truck trailers, whereas micro-RPAs may be controlled with a handheld controller similar to a flying toy aircraft and a backpack antenna and laptop for data collection. The system also includes datalink antenna or “dish” that communicates by line of sight to the RPA or via satellite relay to control the aircraft and weapons. Finally there is the sensor payload equipment that controls the sensors and imaging equipment, collects the data, and provides presentation of the data to the sensor operator and/or pilot.

For the largest of the RPA, each aircraft has a pilot and a sensor operator. Larger RPAs have take-off and landing gears, while smaller RPAs have launchers to get the aircraft airborne. Typically, larger RPAs are outfitted with sense and avoid technology to help pilots navigate crowded airspace and autonomous systems that tell the RPA to return to base and land if the command and control system loses communication with the ground station. Some RPAs operate manually, that is, the pilot flies the aircraft while the others can be controlled through preprogrammed flight plans or a combination of both. Larger more sophisticated RPAs can be flown in inclement weather and have sensors suites that can see through fog, smoke, and clouds. The larger RPA can be used in remote split operations where the aircraft takes off and lands closer to theater and is flown from a safe base of operations miles if not oceans away.

Engineers have spent billions of dollars on the development of unmanned systems; however, very little research effort or research funding has gone into training the man in the unmanned system. The explosion of unmanned technologies has exceeded the U.S. military’s capacity to deal with training operators in the traditional ways that the U.S. military train flight personnel. This is especially true in the U.S. Air Force. Former predator training commander at Creech, Lt. Col. Lawrence Spinetta, commented that training U.S. Air Force RPA operators is commonly done in theater. For example, in Southern Afghanistan, RPA pilots work 12 h on and 12 h off for 120 days straight (Mulrine 2009).

In 1996, Air Combat Command, a major command of the U.S. Air Force, put forth its concept of operations for RPAs. At the time of publication, there were three platforms in the U.S. Air Force arsenal: Predator – a medium altitude, long endurance platform; Global Hawk – a high altitude, long endurance platform; and a now cancelled platform called DarkStar. Today, the DoD arsenal contains a myriad of unmanned systems. Similar to the development of weapons systems during World War II, the war on terrorism forced the DoD to develop and field unmanned systems at a rapid pace. Rapid technology changes in the private sector outpaced military acquisition, thus, forcing the department to forego standardization and interoperability in order to exploit technology improvements and field much needed systems (Department of Defense 2010). The rapid acquisition and deployment of these systems created logistical and human systems integration (HSI) gaps.

Public Law 109–364, John Warner National Defense Authorization Act for Fiscal Year 2007, Section 941 indicates that the DoD is to identify the mission and mission requirements for which unmanned systems may replace manned systems. Furthermore, there is explicit preference for unmanned systems in acquisition

programs for new systems, including a requirement under any such program for the development of a manned system for a certification that an unmanned system is incapable of meeting program requirements. In addition, Congress required the Federal Aviation Administration (FAA) to develop policy for greater use of unmanned aerial systems in National Air Space for use in homeland defense and border patrol.

This legislation set the stage for DoD to treat unmanned systems with the same regard as manned systems. However, where training is typically addressed in manned weapon programs such as the Joint Strike Fighter (Enewold and Crowley 2006), it has not been addressed well in unmanned programs. Indeed each of the U.S. military services has been left to define who operates unmanned systems and the final qualifications for operation of the systems (House Permanent Select Committee on Intelligence 2012). RPA operators run the gamut from Army-enlisted operators who engage in a nine-week course after basic training to fully qualified pilots manning U.S. Air Force drones. Congress ordered the FAA to create regulations within 2 years to integrate unmanned flight into U.S. airspace by 2015 (Peterson 2012), but the FAA has yet to announce or publish its official regulations on who can operate RPAs in National Air Space and what qualifications are needed to operate RPAs.

In addition, the GAO addressed in its 2011 military training range report the need for airspace to support training of RPA (GAO Military Training Ranges 2011). In April 2012, the House Permanent Select Committee on Intelligence reported several findings and made several recommendations to Congress regarding unmanned system training. In particular, the report faulted DoD for not having a strategic plan for RPA training and not aggressively pursuing one. The Committee recommended relaxing the U.S. Air Force and U.S. Navy standards for RPA operators from rated pilots to non-rated pilots or trained enlisted, collocate RPA training, and substitute simulation training for live training. Also, the committee recommended to upgrade RPA simulators and eliminate interoperability challenges and increase its investment in simulator training.

In July 2009, the Chairman of the Joint Chiefs of Staff provided policy guidance on the minimum training standards for joint RPA. The policy addresses the five critical skill sets required to operate and employ RPA regardless of the operational environment. The requirements for pilot/aircraft operator vary somewhat based on the type of RPA flown, micro to large airframe, and whether or not the RPA carries weapons (CJCSI 3255.01, 2009). Baseline requirements are the completion of ground instruction including weather, aerodynamics, human factors, operational risk management, and flight regulation for the types of airspace (combat and noncombat) in which the RPA operates and flight training. Baseline flight training requirements include a military-approved training program that provides in-flight and/or simulator training. Simulator training must enable flight crews to demonstrate control of a specific RPA throughout its performance parameters under all operating conditions including emergency and system malfunction conditions. The instruction also spells out currency and certification requirements.

Originally, the U.S. Air Force had required that RPA pilots be manned systems-rated pilots. However, with the increased need for RPA pilots, the U.S. Air Force

implemented two key initiatives. The first created an undergraduate RPA training pipeline with the personnel designator 18X for graduates and 1U for sensor operators. In 2012, 146 pilots graduated this program and 327 sensor operators. The second initiative increased the number of training squadrons (Department of Defense 2012). Undergraduate RPA training is composed of three courses. The first course is an initial flight screening in which RPA pilots learn the basics of commanding an aircraft. The second course is with the 558th Flying Training Squadron at Randolph AFB, Texas, where the students engage in the RPA instrument qualification course. Operators then move on to an RPA fundamentals course, gaining information on grounding in combat operations on a simplified MQ-9 Reaper simulator produced by Intific known as the PRIME Desktop Training System (Simmons 2012; Church 2011).

The Army uses enlisted soldiers to fly RPA under the 15W series. Technicians are Warrant Officers in the 150U series, and maintenance personnel are enlisted personnel under the 15E series. The exception to this is the small Raven operator who is required to complete a 10-week flight course. The 15W operator is qualified to fly the aircraft, operate the sensors, and emplace and displace the system. The 150U, fed by the 15W qualification, provides leadership and expertise in an RPA unit (Department of Defense, Under Secretary AT&L 2012). These Warrant Officers interface with higher echelons and provide safety, standardization, and maintenance programs. Currently the manpower requirement for operators of the Army's RPA fleet is 1,456 (note: Raven operators are not included in this number). By 2015, the Army predicts it will need 2,057 operators not including Raven (Department of Defense 2012).

The U.S. Navy unmanned aviation program is not separated from its Littoral Combat Ship aviation detachments. These detachments maintain and operate MH-60R/S Seahawk helicopters and the MQ-8B unmanned helicopter. Operators rotate between the platforms. As Tritons, a Global Hawk variant, replace the P-3 Orion submarine hunter, the Orion operators will transition to Triton. By 2020, the U.S. Navy will have 866 personnel supporting Triton (Simmons 2012). The U.S. Marine Corps flies the RQ-21A Small Tactical Unmanned Aircraft System (STUAS) and the RQ-7B Shadow. The three active duty and one reserve duty unmanned squadrons, or VMUs, are made up of a headquarters and three RQ-7B Shadow and nine RQ-21B STUAS. The RQ-7B unit is comprised of 51 marines and the RQ-21B of 9 marines. An additional 121 marines makeup headquarters and maintenance personnel within each squadron (Simmons 2012).

The need for well-trained RPA operator is growing. According to the Defense Manpower Data Center, the current U.S. military force with personnel system designations showing warfighters attached to unmanned systems was approximately 2,552 which may include payload operators. The DoD reported that manpower requirements for RPA pilots totaled 1,696 and sensor operators 1,194 with a 338 and 245 manning shortfall, respectively, the highest need being MQ-1 Predator operators. The predicted need by 2015 is a total of 2,060 pilots and 1,454 sensor operators (Department of Defense 2012). In an attempt to address the RPA training gap, AFRL's 711th Human Performance Wing is conducting cross-domain training research to evaluate methods and technologies to maximize communication and coordination effectiveness.

104.2 A Need for Training

Effective and efficient training is crucial for safe and successful mission execution across military domains. Budget restrictions necessitate developing innovative training strategies to compensate for fewer live flight opportunities. This limitation is significantly increased for those who operate RPAs for the military because most of the aircraft are deployed in real-world environments. The Joint Unmanned Aircraft System Center of Excellence supported a study in 2008 assessing this need. This study notes that there is a common concern among the joint military commands regarding the limited opportunities to train for force integration. The report explicitly highlights that RPAs do not operate independently and for mission success must integrate with multiple other players (Department of Defense 2012).

The Global Hawk community has struggled with determining training requirements. Based on discussions between Global Hawk operators and traditional pilots, Cantwell (2009) concluded that there are distinct differences in skill sets used by Global Hawk operators and traditional pilots. Lt Col Christopher Jella, former commander of the U.S. Air Force 18th Reconnaissance Squadron, noted that the long duration of mission and high altitudes of Global Hawk prevent operators from developing skills typically associated with pilots such as interacting with air traffic controllers, transiting controlled airspace, and taking off and landing (Cantwell 2009). Based on the rotation of operators and the duration of flights, Global Hawk operators typically interface with air traffic controllers about once every 2 months. Global Hawk's high level of automation, such as auto-takeoff and auto-land, only requires pilots to monitor the aircraft's autonomous systems, not actually fly it. In fact, according to Jella, the longer an operator is assigned to Global Hawk, the more their airmanship skills fade.

Compared to pilots of traditional aircraft, Global Hawks operators sitting halfway around the world from the aircraft must deal with a host of unusual situational problems when Global Hawk systems go awry. Situational assessment is more complex since pilots cannot feel how the aircraft is handling. Operators know only the information transmitted into the GCS instruments. For example, air turbulence can easily be mistaken for a flight control anomaly. Long mission durations complicate the matter because no one pilot is flying the whole mission; therefore, there is little continuity in the mission scenario. While pilots do debrief during control transition, it is impossible to completely capture the aircraft's performance across an entire mission. Brig Gen H. D. Polumbo, former commander of the 9th Reconnaissance Wing, noted that dealing with a crippled or misperforming Global Hawk requires a highly skilled and experienced airman to recover the aircraft safely. However, what Global Hawk operators do have available is a host of ready expertise that can be called into the cockpit (Cantwell 2009). However, this is a double-edged sword, as the services need to develop the skills of their operators, not have operators rely on the skills of seniors which could lead to a long-term degradation of skills across the community as less skilled operators move up the ranks and replace their seniors.

The tremendous demand for Predator operations, combined with training regimes and simulators not being addressed properly during the acquisition phase of Predator, placed the U.S. Air Force and U.S. Army into an on-the-job training situation in order to maintain operation tempo (Wisher et al. 2011). Cantwell (2009) reported that Predator and Reaper squadrons do not carve time out of their flying-hour program to meet training requirements. In addition, RPA operations and manned aircraft operations are different enough in terms of flight operation that RPA operators question the relevance of many of the flight currencies typically maintained by pilots. Elimination of takeoff and landing currencies, for instance, has caused significant changes to the Predator training syllabus. Less than 50 % of Predator/Reaper pilot skills do not rely on stick and rudder tactics but rather on airmanship and cognitive judgment skills regarding the mission; however, stick and rudder tactics are missing tactile and vestibular cues normally felt by pilots in manned aircraft.

Cantwell (2009) notes that within the USAF, operational tempo prompted Predator/Reaper squadrons to eliminate continuation-training sorties, but the performance gap due to lack of training is an unknown. Predator/Reaper operators fly demanding operational missions such as close air support, air interdiction, support of Special Forces, and killer scout missions in addition to typical ISR missions. Reaper operators employ a host of weapons, including Hellfire missiles and laser-guided bombs, in a multitude of possible scenarios. By contrast, attack and fighter pilots maintain carefully regulated currencies and training requirements for such engagement scenarios (Cantwell 2009).

In addition to operations tempo, restriction to national air space in the U.S. has forced the military service schools to train RPA operators through simulation. In 2012, the services operated more than 250 classrooms of PC-based RPA military training. As the war-time demand for RPA operators has increased, the U.S. Air Force responded in 2010 with its first graduating class of non-aviator Predator pilots and ramped up the numbers quickly (Jean 2010). However, with the war against terror fading, the USAF Chief of Staff will bring a set of MQs back to the U.S. to provide for organic training, with the majority of MQ moving to the Pacific and to South America where commanders need ISR for such missions as drug smuggling. As MQs move back into training operation, the USAF continues to work with the FAA to find suitable options for RPA training in the USA. Dozens of locales are bidding to be one of six spots around the country where drones will be able to fly in the same airspace as piloted aircraft. According the General Schwartz, the USAF's preference is to bring unmanned training out of restricted airspace and into the national airspace in order to train operators close to home (Beidel 2012).

Internationally, the United Kingdom and Italy have developed Reaper/Predator training programs. The Royal Air Force (RAF) embarked on a similar course as the U.S. Air Force by first converting manned system-rated pilots to RPA pilots. In 2009, the RAF implemented the Daedalus Project which included a selection battery and training program for RPA operators and sensor operators. The initial Reaper operator group was sent to Creech AFB for final training where USAF officials conclude that the operators were Predator ready, but not ready for

Reaper (Hoyle 2011). However, by 2012, the RAF concluded that the Daedalus Project had not achieved its goals and the RAF will continue the use of manned system-rated pilots to operate RPA. The UK will deploy the Israeli Hermes 450 in late 2012 and also flies Heron as do Canada and Australia. The Hermes 450 RPA has human factors and situation awareness issues that have to be addressed through training, but the RPA is being replaced with Israeli made Watchkeeper (“Inzpire Develops Human” 2012).

Provided the joint and coalition perspective provided in the previous paragraphs, it is evident that operator training should be able to encompass large teams and teams of teams. It is common for warfighters to work with joint and coalition partners. However, the introduction of distributed players in the real-time war is new and unique to the environment where our warfighters operate. In the following section, the challenges associated with collaborative training are discussed.

104.3 Training for Coordination

“Things began to look up during one shift when we received intelligence that might lead us to the man himself – Osama bin Laden. The source pointed to a tiny village along the Afghanistan-Pakistan border. Bin laden, it seemed, preferred to dwell in places where few other people would go. I headed that way, throttle open, along with a couple of A-10’s, a B-1B bomber, and a dozen marine helicopters” (Martin and Sasser 2010, p. 55). In this excerpt from “Predator the Remote-Control Air War Over Iraq and Afghanistan: A Pilots Story,” Predator pilot Matt Martin discusses one of his many missions while fighting in a war thousands of miles away from where he was. In another excerpt, he identifies the need to coordinate with a joint terminal attack controller, “I was on the radio and in the chat rooms with the on-ground forward air controller, also known as a joint terminal attack controller (JTAC), feeding him live video so he could see what I was seeing. He was ready to grant clearance as soon as I had the opportunity to engage” (Martin and Sasser 2010, p. 51). In these two excerpts, Martin discusses a multitude of ways that the Predator crew is required to coordinate with other team members who are not colocated with them.

Gorman and colleagues (2007) indicate that in cognitively demanding team environments, like RPA control, that teams coordinate to process information at the team level and that effective team coordination is a critical facet of highly effective team performance. In a study assessing a three-person team in an RPA like synthetic task environment, researchers measured team coordination and effectiveness. The researchers reported that perturbations to team coordination caused by mixing team members across team and introducing long retention intervals provide for more adaptive teams (Gorman et al. 2006), where adaptation was defined as successfully handling novel or unforeseen situational roadblocks to effective team performance (Gorman et al. 2006). Moreover, a team team provided with more obstacles (e.g., mixing team members after a long inter-mission retention interval) had an increased ability to adapt to novel situations via coordination flexibility.

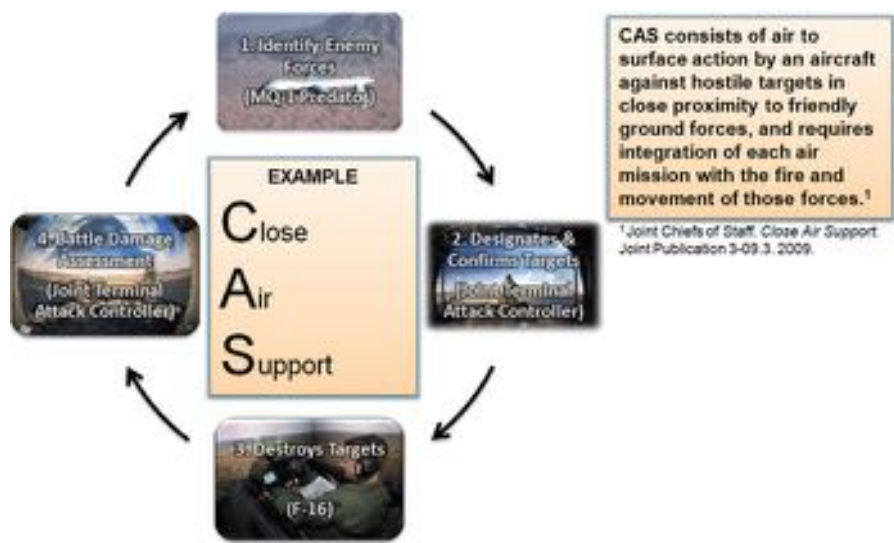

Fig. 104.1 Example of the coordination required for a CAS mission

To demonstrate the need for cross coordination, consider a close air support (CAS) mission. Common in today’s battlefields, CAS consists of air to surface action by an aircraft against hostile targets in close proximity to friendly ground forces and requires integration of each air mission with the fire and movement of those forces (Joint Chiefs of Staff 2009). Accordingly, a CAS mission requires a great deal of planning, coordination, and training for successful and safe execution. Failing to execute a CAS mission could lead to mission failure and even fratricide. Because of their long loiter times and easy deployment, RPAs are often at the forefront of these missions. Therefore, training RPA operators and RPA support personnel to properly coordinate and communicate is essential for mission and military success. Figure 104.1 illustrates an example of the multitude of players that could be involved during a CAS scenario.

104.4 Training Solutions: The Integrated Combat Operations Training-Research Testbed

AFRL is actively looking for training solutions that allow a team of warfighters to train under warlike conditions. The Integrated Combat Operations Training-Research Testbed (ICOTT) combines a family of complimentary trainers to assess training strategies for RPA crews, joint terminal attack controllers (JTAC), and warfighters within an Air Support Operations Center (ASOC). This program strives to provide alternative training strategies and methods for enhancing RPA training by offering solutions that match the level of fidelity required for specific types of training;

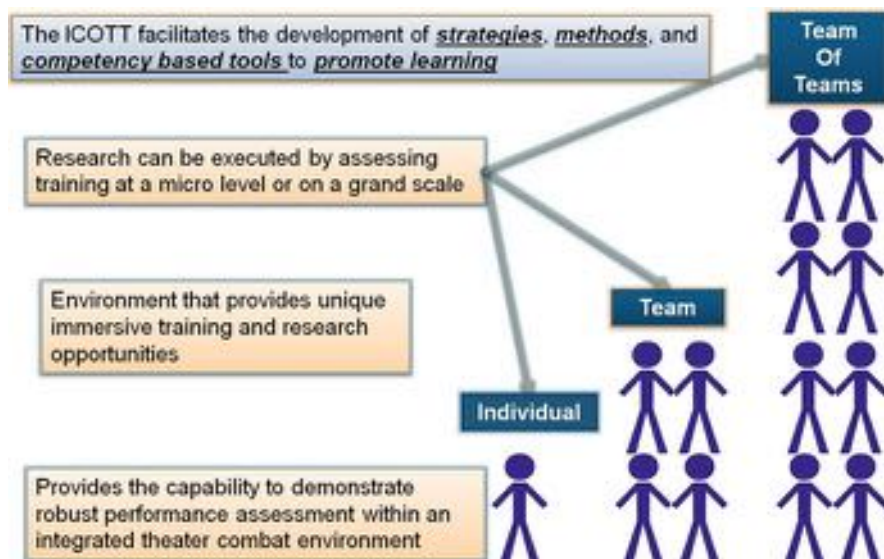

Fig. 104.2 Individual to robust team of team training

thus using training resources effectively and appropriately. In the ICOTT, the research leverages both commercial and government off-the-shelf solutions to build cost-effective, training gap, innovative solutions that allow for the research and development of unique strategies for continuous learning.

In the ICOTT, research can be executed by assessing training at a micro level (e.g., assessing an individual warfighter) or on a grand scale (e.g., assessing a team of teams) as shown in Fig. 104.2. Furthermore, the ICOTT facilitates the development of strategies, methods, and competency-based tools to promote learning within and across the RPA, JTAC, and ASOC operational domains. Findings from the research executed in the ICOTT provide research-driven recommendations for training and assessment in the U.S. Air Force, joint and coalition forces, and in the commercial RPA community. The ICOTT is designed to facilitate a team of teams training experience with interaction in an immersive environment for training research. This testbed provides an opportunity to develop and validate quantitative metrics for measuring these warfighter teams. Furthermore, the ICOTT provides the capability to demonstrate robust performance assessment within an integrated theater combat environment.

The ICOTT is unique because it provides innovative, high-fidelity training that warfighters need. However, at its core, the ICOTT is a research testbed built to assess continuous learning. The research is driven by several research questions, including:

- What are the supporting competencies, knowledge, and skills for effective team and team of teams training?
- What are the training needs, gaps, and opportunities in a networked training environment for JTAC, ASOC, and RPA teams?

- What is the most effective training structure to effectively train a team of teams in the ICOTT that will provide enhanced training capabilities to the warfighter?
- What are the methods and strategies for linking operationally relevant training devices?

Each system in the ICOTT has a unique purpose and function and is able to support Distributed Mission Operations (DMO) (multiplayer networked environments) and in the near future will aid in Live, Virtual, and Constructive (LVC) training research (allowing simulated, live, and computer-generated assets to train together). Each training research system in the ICOTT is illustrated and discussed in turn.

104.4.1 Joint Terminal Attack Controller Training Rehearsal System

The JTAC Training Rehearsal System (TRS) provides an immersive environment to investigate and evaluate training requirements, methods, and future training needs for the JTAC community and is shown in Fig. 104.3. This trainer was developed at AFRL using commercial off-the-shelf (COTS) products and is the only trainer to provide this level of fidelity to JTAC warfighters. This is accomplished by employing physics-based threat generation capabilities with semi-realistic weapon effects. The JTAC-TRS consists of a 5 m 220° field of view dome and includes high-fidelity form fit replicas of the devices that a JTAC warfighter needs to do their job.

The JTAC-TRS is fully equipped with an instructor operator station (IOS) to control the JTAC devices, manage scenario generation, and execute the command and control functions of the system. Training effectiveness is also enhanced through an integrated brief/debrief capability with audio and video playback ability. Remotely Operated Video Enhanced Receiver (ROVER) feed capability integrates full motion video from compatible RPA training systems. JTAC-TRS is Distributed Interactive Simulation (DIS) compatible and is capable of both DMO and LVC operations. These capabilities provide the capability for the JTAC-TRS to work with both live and simulated assets to complete realistic team training events.

104.4.2 Air Support Operations Center Training Rehearsal System

The ASOC Training Rehearsal System (TRS) is a proof-of-concept training research simulator providing theater-level training for ASOC warfighters and is shown in Fig. 104.4. There is little formal training and no existing simulators for warfighters assigned to the ASOC. ASOC TRS aims to fill this gap by incorporating operational command and control systems, computer-generated forces, and replicating the positions and functions of the ASOC through intelligent agent technology. By using intelligent agents as active role players, JTAGSS provides additional training capability and flexibility for this dynamic training environment. The intelligent agent configuration permits realistic computer-generated entities to replace individual ASOC team members with an interactive intelligent agent. Communication between each ASOC position and other command components will be improved by further

Fig. 104.3 Joint terminal attack controller training rehearsal system

developing voice and digital recognition technology. A completed and validated proof of concept will be transitioned to the warfighter to provide the first training system of its kind for ASOC warfighters. Using DIS protocol, JTAGSS is able to network and participate in DMO exercises with other simulators to provide team of teams training, to include the JTAC and RPA simulators in the ICOTT.

104.4.3 Remotely Piloted Aircraft Training Research

The ICOTT RPA training and assessment program provides warfighters and decision makers with research-driven recommendations for training and assessment in the operational and commercial RPA community. The ICOTT is the home of three RPA training simulators: the Reaper Mission Training Device (R-MTD),

Fig. 104.4 Air Support Operations Center Training Rehearsal System

Predator/Reaper Mission Training Device (P/R-MTD), and the Predator Research Integrated Networked Combat Environment (PRINCE).

Both the R-MTD and P/R-MTD are commercially purchased systems and are shown in Figs. 104.5 and 104.6. The R-MTD is presently used to train Air National Guard MQ-9 Reaper pilots and sensor operators. While in the ICOTT, research is being completed to determine what knowledge, skills, and experiences can best be trained using this system. Additionally the researchers at AFRL are developing a competency-based training syllabus that compliments the training that the systems are capable of providing.

PRINCE, shown in Fig. 104.7, is an AFRL built simulator in the final stages of development. The primary purpose of the system is to provide a high-fidelity environment to support ongoing training effectiveness research for standalone RPA crews as well as RPA crews collaborating with other warfighter teams such as JTACs and ASOCs. This game-based system brings the COTS technology to a new level of fidelity by using game-based technology to provide both the simulation backbone and visual system. Gaming software is capable of rendering extremely realistic environments, high-fidelity entities with articulated parts, material-specific infrared radiance data, and very detailed urban environments like the ones found in modern commercial video games.

On top of the game-based technology at the system's core, PRINCE incorporates a highly realistic Ground Control Station (GCS). Just like the live GCS, PRINCE has fully functional heads down display touch screens, a complete tracker display, and peripheral components used operationally, such as Military Internet Relay Chat, mapping programs, and radio connectivity. PRINCE is also DIS capable and is able to interconnect to other DIS systems for distributed training.

Fig. 104.5 Reaper Mission Training Device

Fig. 104.6 Predator/Reaper Mission Training Device

104.4.4 Training Research

The simulators described are a means to an end. Each of these systems is in place to execute training research. Some systems in the ICOTT are commercial and others are home grown; nonetheless, each simulator has a purpose to provide data related to the training effectiveness and continuous learning of warfighters. The ICOTT has capitalized on a training research model introduced by Schreiber and Bennett (2006) during the *Distributed Mission Operations Within-Simulator Training Effectiveness Baseline Study*. During this study, 76 teams of F-16 pilots and air battle managers participated so that researchers could assess the use of Distributed Mission Operations (DMO) to enable warfighter training on higher-order individual and team-oriented skills. The dataset used in this research represented the largest

Fig. 104.7 Predator
Research Integrated
Networked Combat
Environment

DMO effectiveness study known to exist today. During this study, several measures were collected to include objective data from the simulators, multiple participant surveys, subject matter expert ratings of performance, and knowledge structure tests. This study found that DMO training lead to significant improvements in warfighter performance between the pre-training and post-training assessments. The present efforts in the ICOTT are striving to use the findings in this study as best practices to develop a persistent training research program.

104.4.5 Competency-Based Approach: Mission Essential CompetenciesSM

The training research that is pursued in the ICOTT uses a building block or competency-based approach. Training curricula, scenarios, and systems are mapped to the knowledge, skills, and experiences that warfighters are able to provide to trainees. This work is accomplished using the Mission Essential Competency job analysis methodology. This methodology was developed by the AFRL and Air Combat Command and among many things is able to determine training requirements for personnel.

Mission Essential Competencies (MEC) are defined as “Higher-order individual, team, and inter-team competencies that a fully prepared pilot, crew or flight requires for successful mission completion under adverse conditions and in a non-permissive environment” (Colegrove and Alliger 2002, pp. 12). The MEC process results in several outcomes to include MEC statements, supporting g competencies, statements of knowledge and skills, and experiences and is illustrated in Fig. 104.8 (Alliger et al. 2012). The MEC process provides a structured and validated method

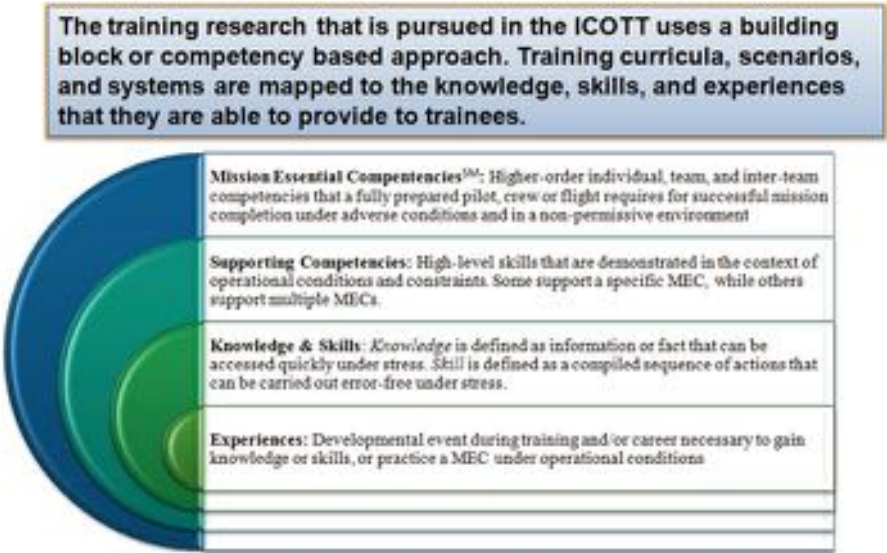

Fig. 104.8 Mission Essential Competency structure

to discover training gaps. Once training gaps are defined, training practitioners are able to engineer and design research focused on filling these gaps.

The MEC-based approach affords researchers the ability to assess training curriculum and programs to rapidly transition these new methods to the warfighters as either permanent or temporary training gap fillers. The ICOTT leverages the MECs to build research programs that are focused on competencies as defined by the warfighter. Using this approach provides a unique research opportunity. Given the present manpower demands and task saturation of warfighters, it is difficult for warfighters to participate in research efforts; however, researchers have found that this limitation can be overcome by providing a unique and valuable training opportunity not available elsewhere to warfighters.

104.4.6 Best Practices: Putting It All Together

The ICOTT uses a circular approach where objectives set the pace of the research, conditions are used to create the materials, and during the assessment stage, lessons learned are fed back to set new objectives. This approach is illustrated in Fig. 104.9.

The ICOTT objectives are set using MEC-based approaches to demonstrate the context of an actual mission using high-fidelity simulation resources. This level of mission reality provides a greater opportunity to have warfighters versus generic research subjects participate in research. Research efforts focus on scenarios that are applicable during wartime conditions, therefore, providing a direct transfer of training scenario for the warfighters.

Fig. 104.9 Best Practices and Processes in the ICOTT

To develop conditions, the ICOTT team is creating a scenario-based training curriculum that provides a building block approach to training similar to the approach taken in the Schreiber and Bennett (2006) study that was previously discussed. This allows for training research exercises that are both realistic and include a high fidelity after action review capability. The ICOTT provides for the capability to execute joint and coalition training and research exercises and allows researchers to assess common architectures to train more efficiently using live, virtual, and constructive systems. The family of trainers in the ICOTT provides the opportunity to develop and validate scenarios and syllabi that can be used across training venues and platforms.

Finally the ICOTT uses assessment strategies to close the loop for training research. To provide the most robust assessment available, the ICOTT warehouses data that in turn allows for the assessment of readiness and proficiency. This provides the ability to determine what has been learned and at what level it has been learned, the frequency in which learning needs to take place, and finally provides the ability to assess the readiness and proficiency of the trainee.

The ICOTT has had success in leveraging applied research methodologies that have been previously validated and vetted. One of the most recent successes include the development of MECs for Predator, Reaper, Global Hawk, JTAC, ASOC, and commercial medium altitude, long endurance RPAs. Presently, researchers are working to develop a MQ-1 and JTAC training research curriculum that will allow warfighter to participate in collaborative research while being provided with unique training that cannot be attained elsewhere. The team is also holding and is exploring additional agreements and partnerships with many members from the academic, commercial, federal, military, and coalition partners.

104.5 Conclusion

As illustrated in this chapter, the requirements for effective RPA training are real. There is a clear requirement for RPA pilots to work in dynamic environments while in realistic distributed locations. One line of research attempting to address some of the team and coordination training gaps for the RPA is the research that takes place in the ICOTT. The ICOTT provides a unique and innovative training-research testbed that enables the comprehensive team and team of teams training research for RPA, JTAC, and ASOC warfighters. Using a MEC-based approach to training and practices previously proven, the ICOTT utilizes scenario-based training across the range of warfighters that are researched in the ICOTT. Successes in the ICOTT have led to achieving accreditation for the JTAC TRS as well as development of MECs for all ICOTT systems and their warfighter users. The ICOTT team is dedicated to a training research mission and provides refined solutions to meet the warfighters' training requirements.

Abstract

The PITVANT Unmanned Aircraft Systems (UAS) Research and Development (R&D) program training experience is described, including the different crew positions and responsibilities, as well as the several training phases. This is done by presenting the systems engineering methodology behind all the developments carried by the joint team of the Portuguese Air Force Academy and the Porto University, together with the PITVANT UAS architecture and main features. The training program is then described including theoretical classes, written exams, and practical instruction and evaluation. In addition, the process of developing, testing, and validating concepts of operations and the correspondent operational procedures and their training with the involvement of end users is also reported. The current operational capabilities of the systems are explained, showing that the PITVANT program has achieved a level of maturity that enables testing and validation in near real scenarios. This leads to the next step in the systems spiral development that should include, in the near future, the possibility of technology transfer to the industry. The PITVANT program is currently on its fifth year of existence, and the several air vehicles have logged about 730 takeoffs adding up to about 320 h of flight, most of which at the Portuguese Air Force Airbase in Ota, which is permanently assigned to the PITVANT program. Several operators and pilots have been trained under the scope of the program, and currently the team of 20 people operates the different PITVANT UAS on a daily basis. The extremely low accident ratio, of about 0.5 %, is a good indicator of the effectiveness of the training schemes that the research team has implemented.

At the end of the program, the team expects that the UAS have reached a level of maturity that will allow industrialization.

105.1 Introduction

This chapter describes the current state of the PITVANT Unmanned Aircraft Systems (UAS) Research and Development (R&D) program, with special focus on training aspects. PITVANT is the Portuguese acronym for Research and Technology Project in Unmanned Air Vehicles (*Projeto de Investigação e Tecnologia em Veículos Aéreos Não Tripulados*). This project, developed under a grant from the Portuguese Ministry of Defense (MoD), is the largest UAS R&D program in Portugal, with a total duration of 7 years, from November 2008 until November 2015. The main contractors are the Portuguese Air Force (PoAF) and the Porto University. Regarding the PoAF, PITVANT is carried out by its higher education school: the Air Force Academy (AFA). The College of Engineering (FEUP) is the lead partner from Porto University.

Prior to the beginning of this project, AFA had already considerable experience in unmanned aircraft design, construction, and testing. The platforms were built for the purpose of in-flight testing of new technologies, such as smart structures, and eventually they became the starting point of the autonomous flight research at AFA. Although they served the first stages of the project quite well, further research

not only demanded extended requirements concerning payload weight and volume, endurance, and performance but also new aircraft concepts. This represented an opportunity to develop and improve skills in aircraft design. Owing to the evolution of optimization algorithms and computational analysis tools in the last decade, air platform-related research has been mostly conducted on multidisciplinary optimization.

FEUP has been designing, building, and operating unmanned underwater, surface, and air vehicle systems for innovative applications with strong societal impact since 1992. FEUP received the Espírito Santo Bank (BES) Innovation National Award for the design of the Light Autonomous Underwater Vehicle (AUV). In the last 15 years, researchers from FEUP have successfully fielded unmanned air, ground, surface, and underwater vehicles in innovative operations in Europe and in the United States of America. These include some world firsts, such as the underwater rendezvous between the Aries and Isurus AUV, respectively, from the Naval Postgraduate School and FEUP, which took place in 2006 in Monterey, California, under a cooperation project between the two institutions.

The AFA/FEUP team is backed up by valuable international partners such as Honeywell, Embraer, Swedish Defense Agency (FOI), University of California at Berkeley, and the Armed Forces University, Munich. End users such as other military services, police forces, and natural disaster response authorities are also involved in the project, in order to provide inputs to the concepts of operations (CONOPS).

Hence, the four main objectives in PITVANT are:

1. To develop/test technologies for UAS
2. To develop new CONOPS for small/medium UAS
3. To test and evaluate the systems and technologies developed in civil/military operation
4. To carry out advanced training of UAS operation teams

To accomplish these objectives, PITVANT follows a systems engineering (SE) methodology. Technologies, CONOPS, and payload are developed/integrated, tested, validated, and matured on smaller and less complex UAS and then move on to larger and more complex platforms. All airframes are developed and built within the project.

Development of a specific training syllabus is not the common practice among academic R&D groups, but in PITVANT this was considered as a main objective. The fact that the PoAF is one of the main contractors, bringing into the project all its knowledge and institutional culture of flight safety, along with the expertise of FEUP in SE, naturally lead the team to the conclusion that a training program supported by strict operational procedures was the only way to perform a high number of flight hours, with a high inherent level of uncertainty, in both the experimental vehicles and in the novel control algorithms, with a low rate of accidents.

To better understand the requisites of training that the PITVANT team must deal with, the road map of development for the PITVANT is depicted in Fig. 105.1.

The first stage of the program addressed the upgrading of the existing remotely piloted aircraft into autonomous flight capable unmanned air vehicles (UAV). This stage included the integration and configuration of autopilots into different

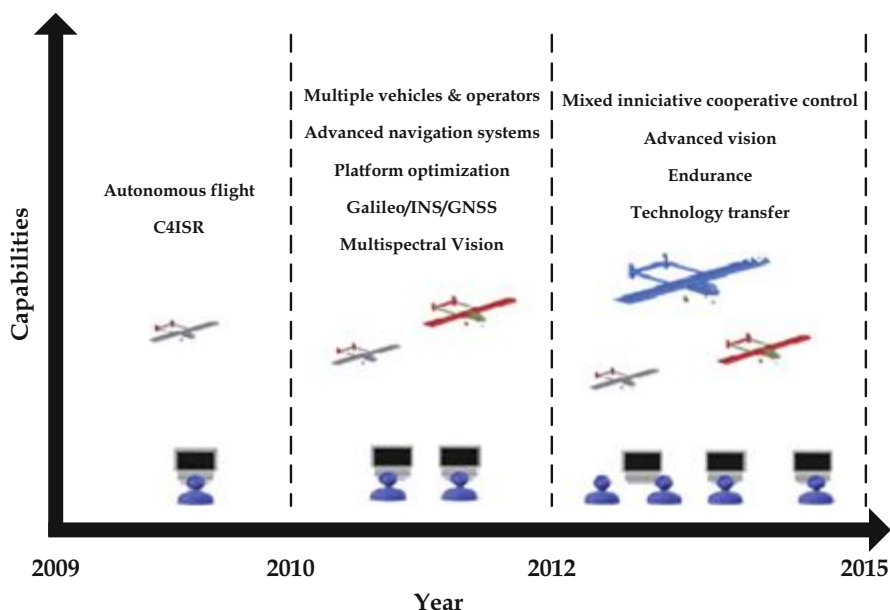

Fig. 105.1 PITVANT development road map

platforms, as well as the manufacturing of improved new platforms, needed for the cooperative control algorithm testing that would take place in latter stages of the program. At the same time, command and control (C2) systems were also being developed. By the end of 2010, the whole process from manufacturing of the platform to autonomous flight was fully developed and matured.

The second stage of the program is now in its final phase and comprises a set of activities that enable the autonomous platforms to perform relevant missions to both civil and military end users. The testing of novel control algorithms for target tracking, obstacle avoidance, and atmospheric thermal currents tracking are some examples of the work developed by the team. Flight testing of these algorithms was only possible due to the experience obtained at the first stage. Multi-UAV operation, characterized by having several UAV operating within the same confined airspace with a centralized C2 structure, was also undertaken, paving the way for cooperative control. Communications are currently being tested, to ensure the necessary range for the endurance tests that follow. Different sensors were integrated into the platforms to provide the data needed for these tests. These include different sorts of stabilized vision sensors, as well as onboard computing systems.

PITVANT's final stage will be devoted to mixed-initiative cooperative control, as well as to endurance tests with larger platforms. Advanced vision systems will allow the UAS to deliver relevant data to end users. By the end of the program, the UAS should be at a stage of development that will allow industrialization.

This chapter is divided in three main sections. Section 105.2 introduces the SE methodology, which is the backbone of the project, and describes the UAS architecture. Section 105.3 focuses on the training aspects. In this section the instruction and training for personnel assigned to different roles within the operational team are described, as well as their responsibilities. The training for maintenance of the systems is not considered in this chapter. The process of CONOPS development is also presented here, as it bears direct impact toward the training requirements. Samples of checklists and procedures that operators must follow for the different CONOPS are also presented. Section 105.4 presents the results achieved by the team to demonstrate how well adapted the training process and operational procedures are to the project goals. This includes the number of personnel trained since the beginning of the program, in-flight statistics and milestones, as well as future goals. Conclusions are then presented to summarize the most remarkable aspects of the systems under development as well as the training program, to highlight flight results and milestones achieved.

105.2 R&D Methodology and Systems

One of the key aspects leading to the PITVANT's good flight results is the use of a SE methodology. The present section will cover the PITVANT's R&D approach from a SE point of view.

The project is divided in two parallel phases (Campos et al. 2010), as shown in Fig. 105.2. The first one is the development of new technologies in a scientific environment. The second one concerns the systems' integration and the operational testing of the developed technologies. A SE approach is applied to both phases, ensuring the correct input-output relation and the maximum effectiveness.

105.2.1 Systems Engineering Iterations

One of the goals of this project is to integrate a wide variety of systems and subsystems into a more complex system, capable of performing autonomous missions in different operational environments. Hence, the concept of system of systems (SoS) will be used to better address the subject, on an SE approach.

The baseline for the definition of the requisites and the functional architecture of each subsystem is defined on the first iteration of the SE process, applied to the SoS. This encompasses the requisites' analysis, functional analysis, and synthesis.

A matrix of design parameters is also developed in parallel, connecting them to the various subsystems as well as the subsystems to each other. This way, should a subsystem need an update, the matrix will indicate the tree influence that specific subsystem has on other subsystems, allowing for the developer to have the information needed to consider compatible updates.

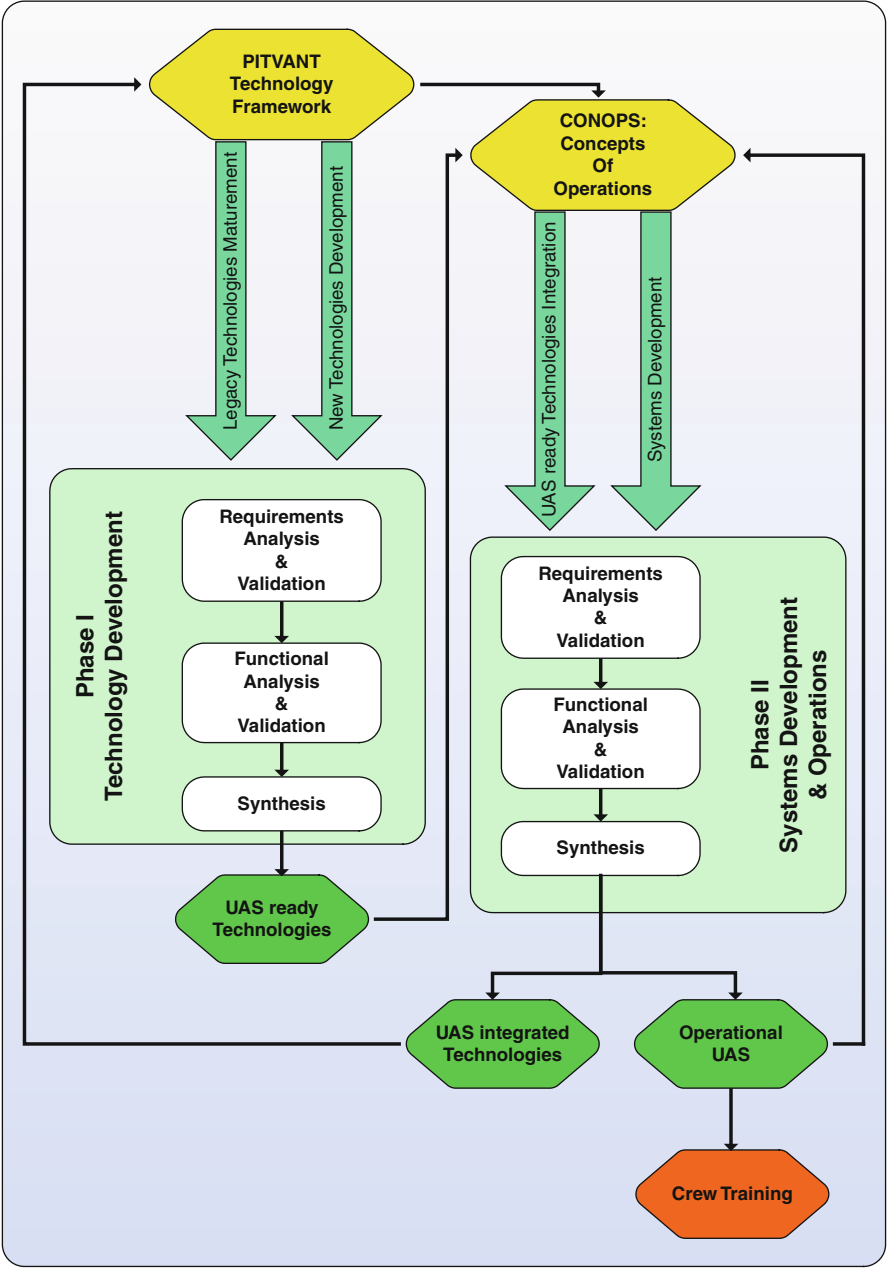

Fig. 105.2 Two-phase SE methodology applied to the PITVANT

Starting with these, seemingly basic, initial definitions, the SE process will be applied to the functional framework in an iterative way, covering all subsystems. At the end of each iteration, a new version should be created, tested, and documented.

The following paragraphs will describe briefly the three most important steps carried out for the system and for each of the subsystems in every iteration.

105.2.1.1 Requirements' Analysis

Referring again to Fig. 105.2, one can see that the requirements' analysis is the first step of each iteration for both phases. The main goal of this step is to define the (sub)system's capabilities, performance, working environments, human-machine interfaces, and, finally, the aspects that affect the development of the system. These considerations have a baseline of requisites that defines the goals and the means of efficiency, further used for the following steps of the process.

105.2.1.2 Functional Analysis

The functional analysis is the second step in the process. Its primary goal is to interpret the requisites and convert them into a functional architecture, dividing each role of the system into sub-roles of the dependent subsystems.

105.2.1.3 Synthesis

This final step defines the physical and the design solutions, identifying the subsystems that are actually capable of satisfying the requisites. Hence, the functional architecture is converted into physical architecture, presenting the first arrangement of the subsystems, their interfaces, and even design restrictions that have already been identified.

105.2.2 Subsystems Development, Integration and Testing

After the synthesis, the designer is able to develop the matrix of design parameters that will serve as the input for the following steps. These are similar to the three steps explained before, applied to each subsystem. Each of the iterations on the subsystems should output the support tools, the integration methods and procedures, as well as the versioning updates.

The development phase of new subsystems culminates with their individual testing being followed by their integration and final systems testing. In order to guarantee that nothing is left aside, the team develops test and integration procedures for each step and version of the subsystem. After passing all tests, training procedures are developed and carried out in an iterative way, to allow the systems to be tested on the field and in-flight, assuring that the test conditions are as similar as possible to the final operational theater.

This step ends with the subsystems' hardware-in-the-loop testing. The new technology and algorithms can be tested in a hardware testbed that is specifically developed for this purpose, simulating the real operational environment as much as possible.

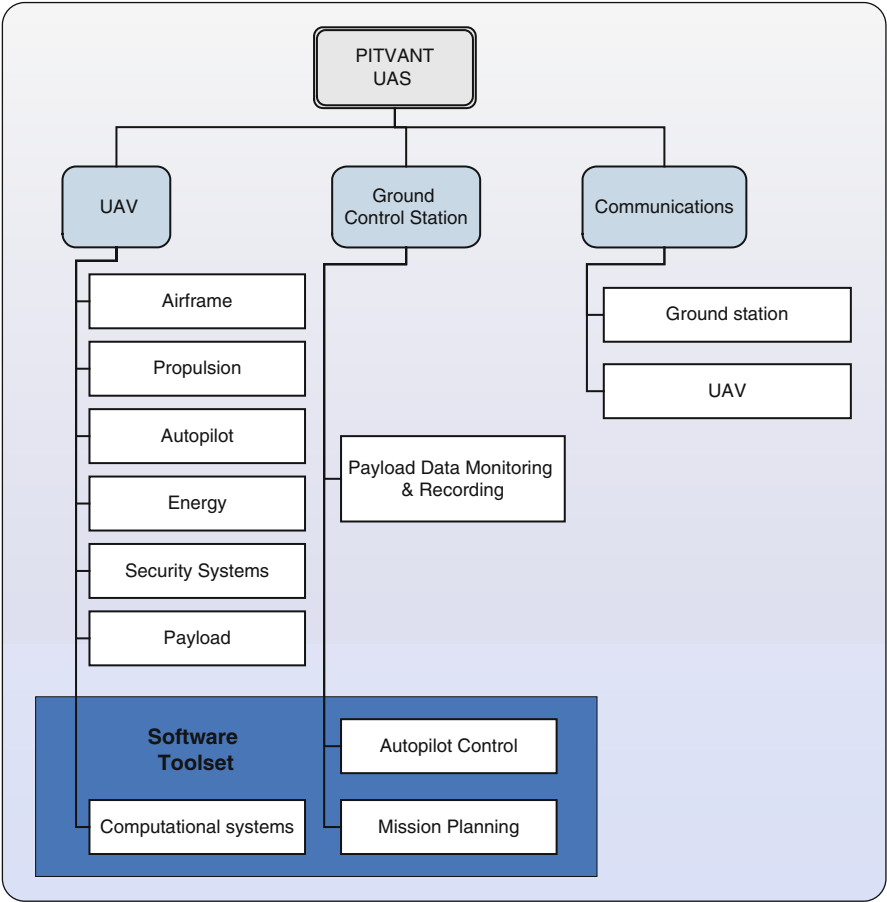

Fig. 105.3 PITVANT UAS system breakdown structure

105.2.3 UAS Architecture

This section presents the PITVANT project’s operational architecture, as it bears a direct impact with training and operational aspects of the UAS deployment in the field. It will cover the three main subsystems presented on the systems breakdown structure (SBS) of Fig. 105.3: UAV, ground control station, and software toolset.

Figure 105.4 presents the UAS functional architecture, for both training or operation environments. As the PITVANT is a research project, the team is always in constant training and procedures’ development: new technologies require new concepts, and UAS technologies require fail-proof safety and airworthiness.

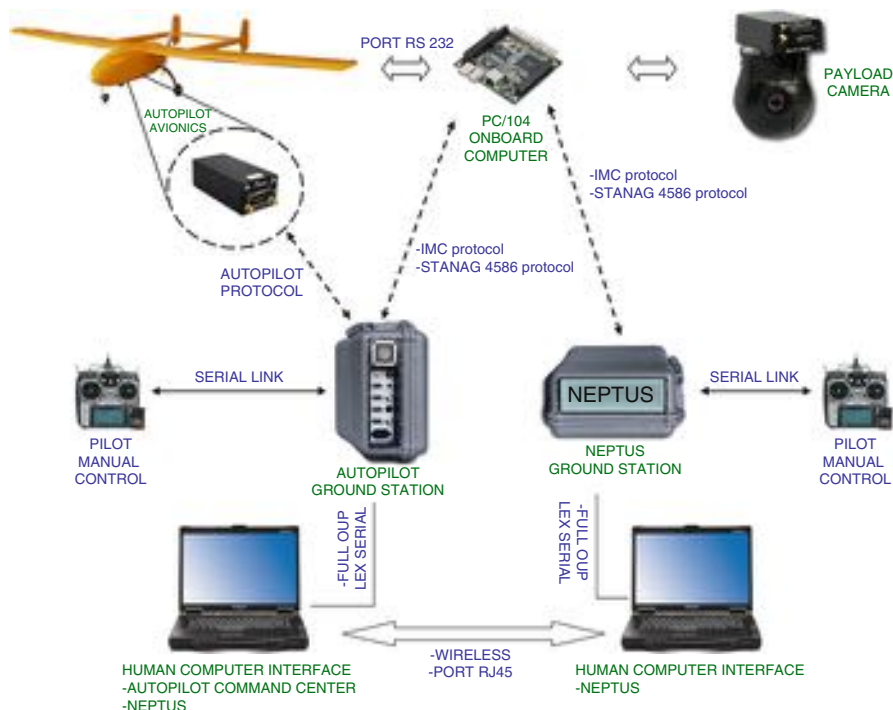

Fig. 105.4 PITVANT UAS functional architecture

105.2.3.1 Ground Control Station

The ground control station (GCS) is composed of the UAV ground station, the off-board control computers, the UAV operator, and the onboard systems' operator hardware, such as receivers, data links, and tracking stations/antennas. The communication between the UAV and the GCS is assured via a dedicated data link to the autopilot via the dedicated ground station (GS). It can have two different configurations, depending on the GCS – fixed or portable. The GS is connected to the operator's computer and the operator interface. The GS is also connected to a pilot console, in order for the pilot to fly the UAV, when in manual mode. Fig. 105.5 shows the portable version of the GCS used in PITVANT.

105.2.3.2 Unmanned Air Vehicles

The PITVANT's objectives lead to the need for developing several platforms for testing of different CONOPS and payloads. The PITVANT comprises different UAV that can be categorized according to the United States Air Force Tier categories. All of the listed UAV were fully designed and built at the AFA Research Center (CIAFA). CIAFA is not an industry-related entity, nor is it an aeronautical company.

Fig. 105.5 Fast deployable campaign GCS

Table 105.1 Summary of the PITVANT’s UAV characteristics

| | Flying wing | Mini-UAV | ALFA | ALFA Extended | ANTEX |
|--------------------|------------------|------------------|-------------------------|-------------------------|------------|
| Wing span (m) | 2 | 2 | 2.4 | 3.5 | 6 |
| MTOW (Kg) | 3 | 4 | 13 | 25 | 130 |
| Payload (Kg) | 0.9 | 1.9 | 4 | 10 | 30 |
| Engine | Electric | Electric | Electric/ combustion | Electric/ combustion | Combustion |
| Endurance (h:m) | 01:00 | 01:15 | 02:00 | 03:00 | 05:00 |
| Max speed (kts) | 50 | 50 | 60 | 65 | 80 |
| Range (km) | 40 | 60 | 130 | 190 | 390 |
| Number of aircraft | 02 | 01 | 07 | 01 | 02 |
| Obs | Hand launched | Hand launched | Catapult launched | – | – |

This fact makes it even more important to have a good training methodology and procedures. The operational teams are instructed in order to be able to operate and maintain all UAV in the fleet. The following sections will cover all UAV types operated in the PITVANT as technology demonstrators and testbeds.

Depending on the UAV configuration, there can be one or more onboard computers in parallel with the autopilot. These computers monitor the tasks the autopilot is not able to perform and can also be used for parallel monitoring or data-link settling and control. Their primary task is to serve as dedicated imagery processors and to allow the tests for the cooperative control of multiple platforms, autonomous target tracking, and obstacle avoidance algorithms. Here, the developers can also implement the software toolset mentioned in the following section.

A summary of the main platform characteristics is presented on Table 105.1.

Tier N/A: Micro/Small UAV

The PITVANT has developed two different configurations of this type of UAV: a flying wing and a conventional airplane configuration, with wing and tail.

Fig. 105.6 Flying wing being launched and in flight

Fig. 105.7 Mini-UAV

Figure 105.6 shows the flying wing UAV subclass. It is a 3-kg maximum takeoff weight (MTOW) UAV. It can be equipped with two fixed cameras and live-stream video links, carrying the autopilot.

The UAV presented on Fig. 105.7 was specially developed for the war fighter in the field. It can be carried in a $0.6 \times 0.45 \times 0.25$ m backpack, set up, and hand launched in less than 5 min.

With 4.5-kg MTOW and a maximum payload mass of 1.900 kg, it can fly for over 1 h at a speed of 15 m/s. It can be configured with a wide range of electro-optic (EO) sensors with a minimum field of view (FOV) of 2° and infrared (IR)-stabilized sensors (FOV down to 12.3°), with digital encrypted video data link with 8 Mbts/s and onboard HD recording. The UAV recovery can be done at the push of a button with three configurable landings, (i) net recovery, (ii) belly landing, and (iii) deep stall, as the main parts separate from each other to dissipate energy. It can be operated in three different control strategies: (i) launch and forget (mission configuration prior to launch), (ii) autonomous flight (control with introduction of references), and (iii) fly by wire. It can also be operated in line or beyond line of sight.

Tier 1: Tactical UAV

In the Tier 1 category, the PITVANT counts with a total of ten UAV, with three different configurations. These differ in size and performance. The smallest within this class is the ALFA, with 5-kg of payload mass for a 13-kg MTOW UAV.

Fig. 105.8 ALFA #05 in flight and ALFA #06 after landing

Fig. 105.9 ALFA Extended

This high-payload small UAV was developed with the main goal of serving as the primary testbed for the first iterations of the subsystems. There are seven UAV similar to the ones presented in Fig. 105.8.

It can also be operated with the same control strategies of the previous UAV, as well as point-to-coordinate fly by camera.

In terms of weight and size, the following UAV in the PITVANT is the ALFA Extended shown in Fig. 105.9. This is an optimized version of the ALFA. It was developed for high-efficiency flights and greater performance. It can carry 9 kg of payload for a total of 25-kg MTOW. This was the first PITVANT UAV to fly with a class C transponder. As it is the first of its class with these requisites and is designed to be the testbed for most of the forthcoming developments, it was painted yellow, to ensure a good visual signature.

The larger platform, the ANTEX, has 5.5-m span and MTOW of 130-kg. It has been developed for medium-altitude medium-endurance missions, such as Intelligence Surveillance and Reconnaissance (ISR), and is intended as a maritime search and rescue asset. The PITVANT has two of these platforms under tests and certification. This UAV is shown in Fig. 105.10.

Fig. 105.10 ANTEX #01

The PITVANT's engineers are developing a newer optimized 7-m span medium-altitude medium-endurance UAV to be used at the latest phases of the project and to be deployed in teams of maritime search and rescue UAV with mixed-initiative cooperative control.

105.2.3.3 Software Toolset

The PITVANT UAS use the Neptus/IMC/Dune software toolset, developed at FEUP, for the development of the UAS command and control applications. This toolset is easily configured for deployment in heterogeneous UAS to carry out mixed-initiative missions. This is because of both the modular design and the use of the publish/subscribe framework for communications.

Neptus is a command, control, communications, computer, and intelligence (C4I) framework. The interactions with human operators are categorized according to the phases of a mission life cycle: world representation, planning, simulation,

Fig. 105.11 Neptus user interface

execution, and post-mission analysis. The planning of a mission is supported by the mission planner. It provides a map editor that allows the construction of a virtual representation of the mission site. Maps are composed of several geo-referenced elements: marks to denote points of interest, geometric figures, surface images (with optional elevation map), generic 3D models, and paths (composed by line segments). For the execution phase, Neptus provides support for the creation of operator consoles that can be configured in terms of displays and controls. An example of such a console is presented in Fig. 105.11. After mission execution, all collected data can be analyzed using the Neptus' mission review and analysis tool. The collected data can be displayed in different ways such as tables, plots, and color maps. This feature is also available for mission replays. Moreover, an embedded web server can also be activated in order to provide web access to real-time mission data and post-mission analysis.

Neptus supports different communications protocols by having a specific communications layer that gives support to message-based protocols, regardless of the chosen transport protocol. It also supports distributed networked vehicles operating in wide areas, through the help of the inter module communications (IMC) message protocol that defines a common control message set, understood by all types of systems (vehicles, consoles, or sensors) in networked environments. IMC provides support for interacting with other autonomous vehicles, such as submarines or surface vessels, and has inbuilt functions that allow communication using the NATO Standardization Agreement STANAG 4586. This important feature makes it

possible to better manage the deployed systems in the field, allowing the operators to have access to information from each other's systems, as UAS or, for instance, unmanned underwater vehicles.

105.3 UAS Team Instruction and Training

This section will focus on the training method and syllabus used in the PITVANT. It will also present CONOPS that the team has developed for the UAS described in the previous section. A sample of the tests the UAV operators, configurators, and flight managers/tactical coordinators have to pass to complete their qualification are included in annex A.

105.3.1 Requisites and Types of Qualifications

The operational team is currently composed of the following positions:

- (a) *Pilot (PIL)* – Person responsible for remote-control flying of the UAV within vision range. This person will be responsible for taking off and landing the UAV in regular test conditions, whenever the mission requires manual flying instead of automatic launch and recovery. The pilot's role is even more important and noticeable in case of in-flight emergencies or subsystems malfunctioning.
- (b) *UAV operator (OP)* – Person responsible for managing the UAV flight, in autonomous mode, and monitoring and controlling the mission objectives in all CONOPS.
- (c) *Systems' operator* – Person responsible for the onboard systems, whether these systems have already been fully integrated in the UAS or are under integration process other than the autopilot. He/she is also responsible for the UAV's collected video imagery, onboard computer behavior, and other data links, as video, parallel telemetry data, or running algorithms. This position can be occupied by an operator if he/she is also a developer of the new onboard subsystems.
- (d) *First-line maintenance (FLM) technician* – These team elements differ in number depending on the UAS and mission being performed. On a regular operation, the FLM is occupied by a single person. This element is responsible for the UAV engine start-up and runway checklists, until the UAV is authorized to takeoff/be deployed.
- (e) *Flight manager (FM)/tactical coordinator (TACO)* – This position is occupied by a senior OP, trained and approved for the position. In case on multiple UAV and air traffic controller-/air command-dependent operations, he/she assures the correct mission performance and coordination of the UAV teams with the land or manned aircraft crews.

- (f) *Configurator* – Responsible for the correct configuration of the UAS in all CONOPS and for all new tested subsystems.
- (g) *Instructor* – The last stage of operational responsibility in the PITVANT. This person is responsible for the correct instruction, training, and evaluation of the operator trainees.

The team's structure reflects the fact that the UAS are under development, therefore the engineers must be a full part of the team, as suggested in Austin (2010). Another key point concerning the training program is the type of UAV operation. Active piloting of the UAV is only performed by the PIL for a very short time, during takeoff and landing, if the CONOPS don't require fully autonomous operation. When in autonomous mode, the UAV flight is managed by the UAV operator, which does not have a direct control over the platform flight dynamics. This means that the UAV operator does not need to be qualified as a manned aircraft pilot, therefore reducing the overall training costs. In fact, the manned aircraft component of the UAV operators training is the most expensive one (Hoffman and Kamps 2005).

Each candidate to UAV operator, pilot, and maintenance technician should fulfill a set of (pre)requisites:

- (a) Possess personal qualities and technical and professional qualifications – Entering the PITVANT's team is difficult, as the candidates are required to possess technical and personal qualities that are evaluated for several years in the PoAF or thoroughly evaluated at FEUP. Since some of the work can be classified, the PITVANT project demands for highly honorable team members. From the PoAF side, the team members can be officers, sergeants, or corporals. Officers are researchers in the CIAFA and can arise to tactical coordinators (TACO), instructors, and configurators. Sergeants can be operators and pilots. Corporals mostly serve as FLM technicians. From the FEUP's side, the team members normally have an engineering or computer science background and go through systematic trials and interviews. After entering the PITVANT, they focus on the engineering and research parts of the project, having the same qualifications as the PoAF officers.
- (b) English level B1, according to the Common European Framework of Reference, equivalent to the NATO Bright Evolution Level 2.0–2.4.

As the PITVANT focuses on developing new technologies and subsystems instead of training the operational teams to be combat ready, the syllabus is adapted to the project's needs, specially addressing safety and systems airworthiness. This is in line with the usual procedures for developing new systems, as the training should be formatted in order to fill the gap between the actual crew skills and the ones required for the systems' thorough operation (Blanchard and Fabrycky 2006).

Table 105.2 presents the time fractions spent in each phase of training and is in line with the findings of the European-funded study concerning the assessment of technology needs for a combat UAV (Ribeiro 2008).

The time percentage for each phase translates into the minimum requirements in terms of simulator, supervised training, number of flights, and flight hours per operator category that are presented in Table 105.3.

Table 105.2 Percentage of time allotted to each training phase

| | | |
|----------------------------|----------------------|------|
| Theory | Principles of flight | 10 % |
| | Operation | 30 % |
| Simulation | | 20 % |
| Supervised flight training | | 40 % |

Table 105.3 Operator categories requisites

| | Operator | Systems' operator | Flight manager/TACO | Configurator | Instructor |
|-------------------------------|----------|-------------------|---------------------|--------------|------------|
| Simulator hours | 10 | 10 | 20 | 25 | 25 |
| Supervised training hours | 10 | 10 | 15 | 20 | 30 |
| Supervised UAS configurations | – | – | – | 20 | 30 |
| Number of flights | 20 | 20 | 40 | 50 | 60 |
| Real-time operational hours | 10 | 10 | 25 | 25 | 35 |

The instruction and training steps described in the following paragraphs are applicable to the positions of operator (both UAS and systems), instructor, and TACO.

105.3.2 Theory

As presented in Table 105.2, the theoretical training comprises principles of flight and operational theory. This is compliant with the STANAG 4670, except for the air traffic control (ATC) procedures and rules of the air. Since PITVANT UAV only fly in segregated airspace, coordination with manned aircraft or ATC is not necessary. However, whenever needed, the PoAF supports the PITVANT operations with their ATC personnel. The principles of flight theory used in PITVANT are adapted from the theoretical knowledge requirements for the Airline Transport Pilot License (ATPL) as stated by the Joint Aviation Authorities (JAA). The topics that are covered are:

- (a) *Principles of atmospheric behavior*
 - (i) Atmosphere
 - (ii) Winds
 - (iii) Rain
- (b) *Fundamentals of aerodynamics for fixed-wing aircraft*
 - (i) Aerodynamic forces and moments
 - (ii) Tridimensional effects
- (c) *Flight stability*
 - (i) Longitudinal static stability
 - (ii) Directional static stability

- (iii) Lateral static stability
- (iv) Longitudinal dynamic stability
- (v) Lateral-directional dynamic stability
- (d) *Maneuvers and flight performance*
 - (i) Propulsion
 - (ii) Gliding flight
 - (iii) Leveled flight
 - (iv) Ascending and descending flight
 - (v) Coordinated turn
 - (vi) Pull-up
 - (vii) Flight envelope
 - (viii) Basics of control
 - (ix) Longitudinal control
 - (x) Lateral control
 - (xi) Directional control

After the first set of courses, the operator trainees proceed to operational-related courses. As presented in Table 105.2, the operational instruction comprises almost one third of the time an operator takes to be certified in UAS. This instruction covers the following subjects:

- (a) Chain of command
- (b) Steps to autonomous flight
- (c) Autopilot user's guide
- (d) Integration guides
- (e) Platforms
 - (i) Characteristics
 - (ii) Capabilities
 - (iii) Flight envelope
 - (vi) Limits
 - (v) Weather conditions
 - (vi) Platform checklists
- (f) Operational procedures
 - (i) Rules of conduct
 - (ii) General terminology
 - (iii) Phonetic alphabet
 - (iv) Critical situations
 - (v) Regular operational conditions (per CONOPS and platform)
 - (vi) Emergency procedures
- (g) Operational checklists for all CONOPS
 - (i) Flight readiness
 - (ii) Preflight checks and rechecks
 - (iii) In-flight
 - (vi) After-flight checks
- (h) Mission planning
- (i) Multiple team coordination

After all theory has been lectured, the candidates are tested. A minimum of 75 % is required in each test. Examples of checklists and procedures that are part of the testing related to the operational theory are presented in Annex A.

105.3.3 Simulation

After the theoretical instruction, the operator trainees go through the simulation training. In this phase, the candidates make use of the theory they have learned in the previous weeks in a mission simulator. The simulator is able to replicate the UAV flight dynamics, most of the operational environment difficulties, as well as some of the CONOPS. It is also possible to simulate turbulence, emergencies, and multi-crew training.

The simulation phase takes about a fifth of the full instruction course. After several hours of training, the operators subject themselves to the instructors' tests. These comprise general knowledge questions, operational/procedure-related questionnaires, and simulator-in-the-loop proficiency tests (execute procedures and checklists under a predetermined time). Operators must achieve more than 75 % approval in order to pass each test.

An example of a test the operator trainees have to pass is shown in Table 105.4.

105.3.4 Supervised Flight Training

Just before being certified to operate as part of the operational team, the operators in training go through supervised flight training. Here the trainees have to perform all tasks in the field, from UAV checks to postflight checks, passing by flight operation. This phase is complemented by a final assessment test that also includes stress reaction and behavior analysis.

Examples of evaluation topics for different flight phases are shown in Tables 105.5 and 105.6.

As mentioned on Sect. 105.3.1, there are several types of operational roles. After being certified as UAS operators for all CONOPS, the operators can proceed with instruction and training to become tactical coordinators and instructors/configurators.

105.3.5 Concepts of Operations (CONOPS)

The PITVANT mixes the R&D aspects of UAV development with their inherent operational nature in the field in a symbiotic environment. The development of new CONOPS takes an important role in development of all SoS in the PITVANT, making it paramount to show the importance and need of the use of UAV for several military and civil missions, in different scenarios.

CONOPS are defined as sets of technologies, procedures, and methodologies that are carried out in a specific operational scenario and conditions, with a predefined system.

Table 105.4 Example of simulator-in-the-loop questions

| Simulator in loop | Pass (V) | No pass (X) |
|---|----------|-------------|
| <i>System's windows</i> | | |
| <i>Aircraft</i> | | |
| Detect autopilot | | |
| Set pilot | | |
| Set active | | |
| What are the previous "set" for | | |
| <i>Ground station (ground station panel)</i> | | |
| Normal "GS serial" state? | | |
| Average power? (~ 4 W) | | |
| Min voltage? (13 V) | | |
| Request communication settings | | |
| Set channel | | |
| Set communication power | | |
| Normal RSSI? | | |
| Meaning of Ant, 3D, 2D, Acq? | | |
| What is the normal state of Ant? | | |
| Meaning of PDOP? (position dilution of precision) | | |
| What is "get spectrum" for? | | |
| <i>System panel</i> | | |
| Request communication settings | | |
| Set channel | | |
| Set communication power | | |
| <i>Telemetry</i> | | |
| What is the normal state of Ant? | | |
| Min voltage? (11,5 V) | | |
| Min servo voltage? (4,8 V) | | |
| Wind reading (where is it?) | | |
| Maximum temperature? (80°C) | | |
| <i>Preflight (meanings)</i> | | |
| Control surface test? | | |
| Control of (D)GPS? | | |
| Zero air data | | |
| Throttle hold and min? | | |
| <i>Mission limits (meanings)</i> | | |
| GPS time out? | | |
| Comm time out? | | |
| Pilot time out? | | |
| Lost comm number? | | |
| Land plan number? | | |
| <i>Advanced windows</i> | | |
| Command loops, substitute for which window? | | |
| Surface calibration (meaning)? | | |
| Sensor config – how to adjust? | | |
| Controller configuration? | | |
| <i>MAP</i> | | |
| Set up layers | | |
| <i>Set custom telemetry</i> | | |

Table 105.5 Before-flight proficiency test sample

| Evaluation topic | Pass (V) | No pass (X) |
|---|----------|-------------|
| Preflight checklist execution in less than 12 min | | |
| Preflight re-checklist execution in less than 4 min | | |
| Random quiz test on the procedures | | |

Table 105.6 In-flight proficiency test sample

| Evaluation topic | Pass (V) | No pass (X) |
|---|----------|-------------|
| Monitor behavior and stress | | |
| Response to malfunctions or emergencies | | |
| Response to simulated: | | |
| –Foreign aircraft incursion | | |
| –Power loss | | |
| –Erratic altitude tracking | | |
| –Others | | |
| Procedure follow-up | | |
| Overall evaluation | | |

105.3.5.1 CONOPS Development Process

As shown in Fig. 105.2, the CONOPS development is included in the SE methodology, as a response to the needs that arise from the development of technologies and subsystems. Another source for the development of CONOPS is the set of inputs from the end users that are participating in the program. A more detailed scheme for the CONOPS development process, linked with crew training, is presented in Fig. 105.12.

Any new test is carefully evaluated and discussed by the team and procedures and checklists are settled, so the operators can train beforehand. A very significant difference from operational systems can be perceived: the PITVANT team is not trained to operate the UAS in one defined way, but the type of operation is constantly evolving. This requires constant updates of the procedures and the improvement of the trained skills.

105.3.5.2 Simulation and Procedures Development Process

The safe operation of the UAS is the high end of all the work and research done backstage. A considerable part of this work is dedicated to the training of new CONOPS and the improvement of the existing ones.

All starts with the simulation of the future CONOPS in a controlled environment, with the inputs of the development team. At this phase, all integrated subsystems must be working flawlessly and must fulfill the requisites. After simulation, the initial procedures are outlined and thoroughly checked by the developer and operational elements of the team.

For some cases, it might be impossible to simulate the full CONOPS without having to actually fly the UAV. For instance, in catapult launch deployment, UAV mock-ups are launched before the real UAV to check for correct functioning of the

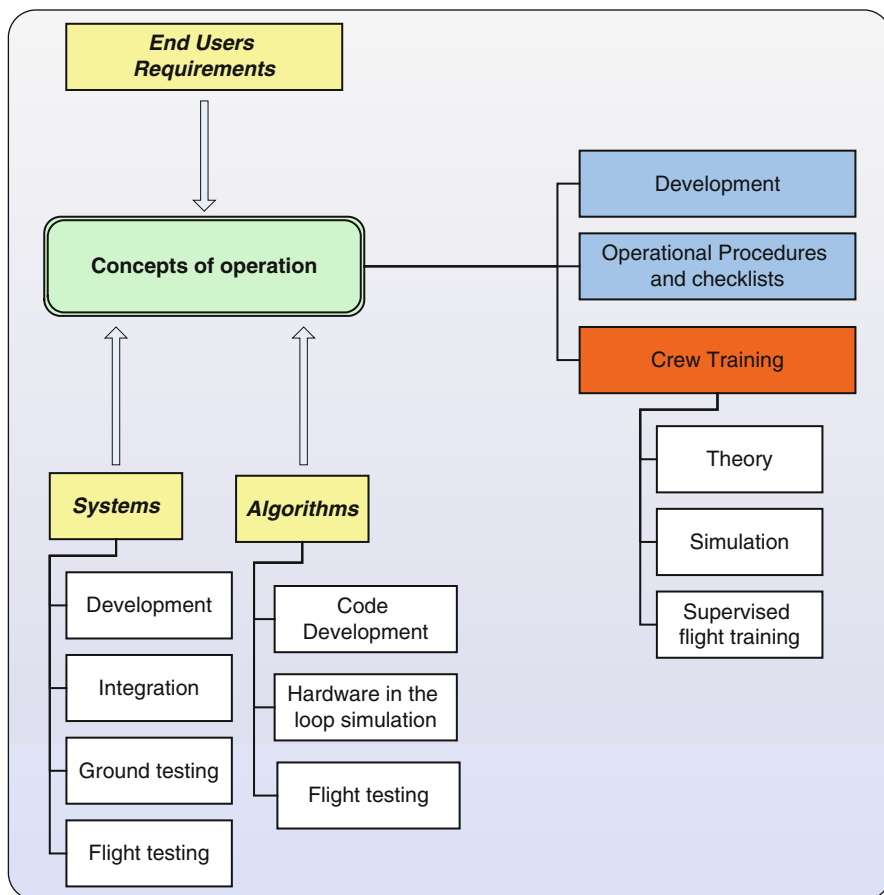

Fig. 105.12 Concepts of operations development methodology

catapult and coupling of the UAV. In the real UAV, acceleration tests are made, to simulate the launch and to detect high-tension points in the structure.

After the development of the operational procedures, checklists are elaborated, and both are executed and updated for an extended period of time, until all subsystems and operators are capable of executing the flight test, assuring the flight safety and airworthiness. Along the iterations, a set of conduct, communication, and emergency procedures are thoroughly tested and updated. This will minimize any collateral damage, should something go differently from what was planned.

105.3.5.3 Operational Testing

As presented on the lowermost blocks of Fig. 105.12, the last step is the operational flight testing. This phase is the most demanding one, despite being the tip of the sword in the UAS field. At this point, all aspects related to subsystems, communication, and operation must be at their final version and well implemented

in the field. By procedure, the senior operators and pilots (instructors) are the ones who carry out the first operational tests. Since November 2008, none of the 730 flights in the 320 flight hours resulted in any damage in the systems or UAV on the testing of a new CONOPS. A summary of the most important CONOPS, including a sample of requisites and procedures, is presented next. To keep this chapter to its intended size, CONOPS D to H are presented without their requisites and procedures.

Day Flight of Single UAV with Autonomous Landing

This operation is characterized by the daylight flight of a single UAV. Within it there are different operational scenarios. It is most commonly used for subsystems' testing and development. In the latest case, the operation will have a higher risk when compared to regular operation with subsystems that have already been fully tested and integrated.

Requisites:

- (i) UAV must be well configured with no error on altitude or indicated air speed (IAS) tracking.
- (ii) UAV must have been previously tested with virtual landing plans with excellent results – no lateral or height deviation from path.
- (iii) UAV must have the autoland path well configured and previously tested.
- (iv) Calibrated static sensor on the landing point, at runway altitude.
- (v) Certificated operator for autoland operation.

Before landing sequence:

- (i) Preflight window or altimeter window: uncheck control to GPS.
- (ii) Confirm touchdown waypoint altitude correct for autoland.
- (iii) Confirm UAV altitude is near altitude of land circuit entry.
- (iv) Request TACO authorization to autoland and inform landing runway.
- (v) Zero air data the barometric sensor to landing altitude.
- (vi) Update barometric reference on the active UAV.
- (vii) Select LAND NOW.

When the landing plan is activated:

- (i) Verify correct flight plan tracking.
- (ii) Inform/report TACO UAV final approach.
- (iii) Monitor flight path accuracy.
- (iv) If flight path track is good and autopilot does not abort.
- (v) When UAV passes decision waypoint, look out to see UAV attitude and altitude:
 - (a) If UAV lands, OP commands the pilot to transition to manual.
 - (b) If UAV reaches touchdown waypoint without landing and altitude offsets below 2 m, OP sets kill engine.
 - (c) Else, OP aborts landing.

Catapult Launch

Catapult launch is used to deploy a UAV without the need of a runway. So far, the PITVANT is using this CONOPS for UAV up to 13-kg MTOW, as shown in Fig. 105.13. This concept is not as efficient in larger UAS as it is on smaller ones,

Fig. 105.13 ANTEX-X02 #03 ready for catapult launch

as the larger normally require airfield landing or heavy launchers that are not suitable to be taken into the frontline. Another aspect is that larger UAVs have more endurance and fly faster than smaller ones making them more suitable for aerodrome operation, as opposed to the smaller ones that can be fitted for landing on unprepared ground.

This CONOPS allows for numerous tactical advantages, such as the deployment of UAV from ships, vehicles, and locations without a runway.

Night Operation

Night operation translates into UAV flights under reduced visibility due to sunset or night. It mainly differs from the daylight flight as it requires full automatic takeoff and landing, instead of the manual control that can be carried out in case of emergency or sudden change of flight conditions, as wind or safety. This CONOPS demands for new procedures and exhaustive training from the operational team.

Requisites:

- (a) GCS light level should be reduced before takeoff.
- (b) Engine final checks are performed by the frontline mechanics (aircraft illumination by a small light).
- (c) Runway lights close to the PIL should be off (40-m radius).
- (d) PIL has to be on a low light level for some time before starting the takeoff run (5 min).
- (e) A light should be near the flight manager/TACO so that the frontline mechanic holding the aircraft can see the hand signals.

- (f) Light or lantern should be used to signal the frontline mechanic.
- (g) If light is on, mechanic should hold the UAV for final checks.
- (h) When light is turned off, the mechanic lets the UAV free.
- (i) Constant update of the static pressure on the ground (for possible emergency landing).

Automatic Target Tracking/Following

This CONOPS is used for automatic target following based on a reference, and it can be added to the previous CONOPS. The reference can either be GPS beacon or video imagery based.

Nowadays it is quite common to have a vision sensor that is capable of following a target that corresponds to a marking on the image. However, in most of the UAS, the operator/pilot has to adapt the UAV flight path to the moving target's behavior. In this case, a tracking algorithm receives the GPS coordinates or image data from the target and automatically adapts the flight path to the target's ground speed and elevation and even corrects for sudden stops or changes in attitude. This can be used to track and follow targets, either friend or foe on land or sea.

This concept was fully developed by request from one of the end users participating in the project. Hence, it followed the development and testing standards mentioned in Sect. 105.2, introduced by the SE methodology. New procedures were developed, and all versions of the target tracking algorithm followed the block diagram in Fig. 105.13.

Intelligence, Surveillance, and Reconnaissance (ISR)

In this CONOPS, the UAV is equipped with vision sensors and real-time video broadcasting subsystems. The communication protocol allows for STANAG 4586 integration with other systems on the ground, sea, or air. For demanding missions, as persistent surveillance of fires or illicit activities, it is possible to equip the platforms with forward-looking or short wave infrared payloads.

The ISR missions must be very well planned and executed in order to ensure that the UAV does not fly in restricted or nonsegregated airspace. Should this need arise, the mission's TACO on the UAS side coordinates the activities with the air traffic controllers in the area. The UAS are also equipped with a class C transponder for this purpose.

UAV Handover

This CONOPS is characterized by the UAV control being passed to another operational team, deployed in the field. It is very useful for having UAV traveling long distances without being affected by communication losses as well as handing over the system to an operational team that will execute a sensitive mission in the field.

Beyond Line-of-Sight

Beyond line-of-sight (BLOS) operations imply the use of satellite communications, instead of the direct radio frequency data links. Sometimes, due to the distance

between the operational team and the UAV, it is necessary to use satellite communications for telemetry, control, and video images.

This CONOPS involves complex logistics and requires a great deal of experience from the operational team, being the CONOPS that requires more training and evaluation of all. This is the last step before operational deployment of the systems in a high-risk or dangerous theater of operations.

Multi-UAV Operation

Multi-UAV operation is an ever evolving CONOPS in the PITVANT. Referring to the last phase of Fig. 105.1, this CONOPS is evolving from two UAVs in the same airspace with separate GCS and operating teams. It is being upgraded and tested to have several heterogeneous/different platforms in the field being controlled by a single operational team. This difficult and highly demanding objective is intended to be one of the final goals of the PITVANT and is the one that uses all of the CONOPS mentioned before.

The extensive list of technology developments, procedures, and training hours should lead to the point where a mixed-initiative (UAV operator) cooperative control of a team of UAV will help the tactical and strategic commands to better decide and fulfill a mission. The applicability of this concept is very wide, going from simple fire surveillance over wide areas to search and rescue or ISR missions.

105.4 Results

Since the project kickoff on November 2008, the team has achieved several important results and milestones. The training program, combined with the careful development of the CONOPS and related procedures and checklists, as described in the previous section, allowed the team not only to grow into a considerable number of trained people but also to log an impressive number of flight hours and sorties for a non-industry-related R&D group.

Flight testing is mostly conducted in the Ota Air Base, now fully committed to UAS testing by the PoAF. A secondary test site is the Santa Cruz Municipal Airfield. Conveniently located near the shoreline, this test site is used for the ISR CONOPS, as it allows flying over the ocean. The PITVANT UAS always fly in segregated airspace. Nevertheless, class C transponder integration and testing was already done, paving the way for integration in controlled airspace whenever the legal framework will allow it and following the recommendations of ICAO Circular 328.

105.4.1 Personnel Trained

The present crew size of 20 people allows the rotation of personnel in order to keep flight operations on a daily basis, in parallel with the scientific and technological developments done at FEUP and AFA. Table 105.7 shows the number of individuals trained for the different roles within the PITVANT team.

Table 105.7 Number of staff trained/in training

| Position | Elements trained | Elements in training |
|------------------------|------------------|----------------------|
| Pilot | 7 | – |
| UAV operator | 14 | 3 |
| Systems operator | 12 | – |
| Flight manager/TACO | 5 | 4 |
| First-line maintenance | 18 | 3 |
| Instructor | 2 | – |
| Configurator | 2 | – |

Table 105.8 Number of sorties, flight time, and mean time between alternative landings per year

| Year | Number of sorties | Flight time (hh:mm) | Mean time between alternative landings (hh:mm) |
|----------------------------|-------------------|---------------------|--|
| 2009 | 98 | 30:50 | 00:43 |
| 2010 | 118 | 44:53 | 02:14 |
| 2011 | 209 | 93:58 | 03:21 |
| 2012 | 278 | 142:00 | 08:54 |
| 2013 (until February 28th) | 27 | 07:59 | N/A |
| Total | 730 | 320:13 | – |

105.4.2 Flight Hours and Sorties

The missions, as the operational part of the development process, are thoroughly planned at the beginning of each year, with most of the primary objectives already defined. Over the years, there has been a considerable increase of mission time and flight hours. Table 105.8 presents the flight hours and sorties per year.

Keeping in mind that PITVANT is an R&D project with operational testing, so far, only three accidents occurred that resulted in the full loss of the UAV and its subsystems. This represents a rate of accidents of approximately 0.5 %. A committee was appointed to investigate the causes for each accident, concluding that the first two were related to failures in the autopilot (which is an off-the-shelf product). The last accident, on September 2010, was a result of a chain of human failures, related to integration of a new subsystem. Once the chain of human errors was identified, the procedures were revised and updated accordingly, resulting in no more accidents so far.

105.4.3 Milestones

The principal milestones achieved by the PITVANT team are presented in the Table 105.9.

Table 105.9 Pitvant milestones

| Year | Milestone |
|------|---|
| 2009 | Autonomous flight |
| | Automatic takeoff and landing |
| | ANTEX-X02 improvements |
| | NEPTUS/IMC operationally used |
| 2010 | Mini-UAV development |
| | ANTEX-X02 extended |
| | Stabilized video sensor subsystems |
| | Night operations |
| | Multi-UAV operations |
| | Automatic target track/follow |
| | UAV handovers |
| | BLOS/satellite operations |
| 2011 | Automatic obstacle avoidance |
| | ANTEX flights |
| | One hundred flight hours |
| | Digital encrypted data links |
| | Successful transponder integration |
| 2012 | Catapult launch |
| | Automatic flight formation of two UAVs |
| | Flight formation of two UAVs over a military parade |
| | Communications test over the ocean (40 Km) |
| | Flying in a GPS-mitigated environment |
| | Three hundred flight hours |

105.4.4 Future Goals

As the PITVANT team is preparing to enter the final stage of the project, steps are being taken to achieve important goals as a wrap-up of all the work and progress done so far.

105.4.4.1 Mixed-Initiative Cooperative Control

This CONOPS was already developed, as described in Sect. 105.3. At this point, the team is ready to operate two UAVs flying in the same airspace. Control algorithms are being developed to allow those UAVs to perform their mission in a cooperative way, allowing for both the human operator and the platform, through the onboard computer, to make decisions along the mission.

105.4.4.2 Maritime Surveillance Operations

Portugal has one of the largest economic exclusive zones (EEZ) and also has search and rescue responsibilities over the Santa Maria flight information region (FIR), one

of the largest FIR in the world. The maritime resources are so important for Portugal, that the government is taking steps toward the definition of an integrated maritime policy (Cunha 2011). In this context, maritime surveillance is an obvious and strategic application for UAS. The largest platforms, ANTEX, are being prepared for autonomous flight, in order to demonstrate to the Portuguese authorities the feasibility of including UAS in the national maritime surveillance effort.

In terms of crew training, there are some challenges related to this operation. Procedures and checklists must be developed for the ANTEX. As new test sites are likely to be used, namely, in Azores and Madeira archipelagos, local procedures must also be developed and trained by the team to keep the accident level as low as it is now.

105.4.4.3 Reliability Program

The flight records of the operation done so far allow for the beginning of a reliability program, as done for manned aircraft. This goal implies a new task for the team members that will be instructed to collect and register specific data to feed the reliability program.

105.4.4.4 Industrialization

As presented along this chapter, PITVANT is an R&D program that combines scientific and technological R&D with intense flight testing, including a detailed training program for the crew. As no Portuguese end user is currently operating UAS, the team intends to reach the end of the project at a level of maturity that will allow industrialization of the UAS developed. This would ensure that all the knowledge gathered during the PITVANT life cycle could be transferred to the Portuguese end users (and other country end users as well) along with the training program, CONOPS, and operational procedures. This is the reason why end users are involved in the project from the beginning, to ensure that their operational requirements are taken into consideration, easing the industrialization of UAS to fit their needs.

105.5 Conclusions

The PITVANT is an R&D project in the area of unmanned systems, following a two-phase systems engineering methodology: the development of technologies and the operational testing and validation of the new systems and concepts. The UAV fleet consists of two micro/small UAVs plus ten Tier 1 tactical UAVs ranging from 13 to 130 Kg of MTOW. The UAS also comprise the GCS and the software toolset that allows for mission planning and flight management, and also support the mixed-initiative cooperative control algorithms.

The SE methodology backed by a well-defined training program has allowed the team to achieve an impressive flight record for a non-industry-related R&D group. From the beginning of the project in November 2008 up to February 28th, 2013, the PITVANT UAS have logged about 320 h of flight in 730 sorties with only three accidents, a rate of accidents of less than 0.5 %. Upon investigation, the first two accidents were attributed to autopilot failure, while the last one was due to human failure. Procedures were revised and updated, and since September 2010 the PITVANT team never registered another accident.

The team members that carry the flight testing are selected and then subjected to a training program that comprises theory, simulation, and supervised flight training. For each phase of the training program, candidates are tested and evaluated. The team includes (i) pilots for visual line-of-sight remote control flying the UAV in manual mode, (ii) UAV operators to manage the flight in autonomous mode, (iii) systems operators for payload data management, (iv) TACO for coordination between two teams and with the ATC, (v) first-line maintenance technicians for UAV preparation before flight, and (vi) instructors and configurators. At this time, the operational team has 20 people, allowing for daily operation in parallel with the scientific and technological developments made at FEUP and AFA. The CONOPS developed so far meet a double objective: to test technologies and systems developed by the team and to answer real requirements of potential end users that are actively participating in the project.

So far, the trained team members have been able to assure the correct execution of the planned missions, through a correct planning of the developments and a good prioritization of the objectives. All missions are carefully prepared, including active logging of the events that occur, in order to debug and improve the subsystems, the procedures, and the training methods. Only this way have the team members been able to considerably increase the number of sorties and tests every year while decreasing the number of failures, emergency landings, and unexpected maintenance.

The team expects to reach the end of the project at a UAS level of maturity that will allow, through a process of industrialization, for the transfer of all the know-how related to the UAS development, technology, architecture, and operation to future end users. If the PITVANT UAS, training program, CONOPS, and operational procedures are put to use in real operations in the future, the PITVANT objectives will truly have been achieved.

105.6 Annex A – Operational Checklists and Procedures: Examples

This annex presents examples of checklists and procedures the operators have to know and execute thoroughly.

Checklists (the checklist's format was adapted to fit the present document)

UAV Operator - Flight Readiness Checklist

| | | | |
|----------------|----------------------|----------|--|
| Mission: | <input type="text"/> | Operator | <input type="text"/> |
| Plane | <input type="text"/> | Pilot | <input type="text"/> |
| Piccolo Number | <input type="text"/> | Date | <input type="text"/> / <input type="text"/> / <input type="text"/> |
| Flight number | <input type="text"/> | Time | <input type="text"/> : <input type="text"/> |

System Checks

Ground Station hardware

| | | | |
|--|----------------------|--|----------------------|
| Power | <input type="text"/> | GPS antenna | <input type="text"/> |
| OI computer connection (RS232) | <input type="text"/> | Handset cable | <input type="text"/> |
| UHF antenna (beware not to connect it on the place of the Iridium sat phone) | <input type="text"/> | Perfect Connection from GCS to pilot handset | <input type="text"/> |
| | | Iridium sat phone | <input type="text"/> |

Ground Station window

| | | | | |
|--|----------------------|------------------------------------|----------|----------------------|
| Verify ground station diagnostic | <input type="text"/> | Set communications power: | [0.01 W] | <input type="text"/> |
| Verify ground station voltage | [>13 V] | Verify ground station GPS 3D fix | | <input type="text"/> |
| Verify communications channel (request) [Ch _____] | <input type="text"/> | Verify ground station GPS PDOP(<3) | | <input type="text"/> |

System panel

| | | | | |
|--|----------------------|---------------------------|----------|----------------------|
| Verify communications channel (request) [Ch _____] | <input type="text"/> | Set communications power: | [0.01 W] | <input type="text"/> |
|--|----------------------|---------------------------|----------|----------------------|

Aircraft panel

| | | | | | |
|-------------------|------------|----------------------|---------------------|------------|----------------------|
| Set pilot address | [SN _____] | <input type="text"/> | Set active aircraft | [SN _____] | <input type="text"/> |
|-------------------|------------|----------------------|---------------------|------------|----------------------|

Pre-flight panel

| | |
|------------------------|----------------------|
| Verify correct vehicle | <input type="text"/> |
|------------------------|----------------------|

System panel

| | | | |
|-------------------------------|----------------------|--|----------------------|
| Verify firmware version match | <input type="text"/> | AP power input (Volt>11.5 V & [3 W<Pwr<5 W]) | <input type="text"/> |
| RSSI: -79 or -71 (3) | <input type="text"/> | Servo power input (Volt>4.8 V & Curr<0,100 A]) | <input type="text"/> |
| Link: 100 | <input type="text"/> | All servos moving voltage: [_____ V; _____ A] | <input type="text"/> |

Main Panel

| | | | |
|--|--------------------------|--|--------------------------|
| Electrical motor - "Engine off" active | <input type="checkbox"/> | Insert lost comm waypoint (WP 80-89) | <input type="checkbox"/> |
| Pre-launch mode active | <input type="checkbox"/> | Insert runway waypoints (WP 96 & 97) | <input type="checkbox"/> |
| Map(s) set up | <input type="checkbox"/> | Insert A2M transition flight plan (Alt 150-200m) | <input type="checkbox"/> |
| Takeoff direction set [_____]° | <input type="checkbox"/> | Insert emergency land plan (WP 90-95) | <input type="checkbox"/> |
| Insert flight boundaries (WP 70-77) | <input type="checkbox"/> | Insert flight paths (WP 0-69) | <input type="checkbox"/> |

Limits panel

| | | | |
|---|--------------------------|---------------------------------|--------------------------|
| Minimum altitude set [_____] m | <input type="checkbox"/> | Comm times out checked | <input type="checkbox"/> |
| Maximum altitude set [_____] m | <input type="checkbox"/> | GPS times out checked | <input type="checkbox"/> |
| Flight timeout set [_____:_____:_____] | <input type="checkbox"/> | Close Throttle uncheck | <input type="checkbox"/> |
| Land if timeout and lost comm checked | <input type="checkbox"/> | Drop Deadman Line uncheck | <input type="checkbox"/> |
| Lost Comm Waypoint Set [WP ____; Alt: ____ m] | <input type="checkbox"/> | Aerodynamic Termination uncheck | <input type="checkbox"/> |
| Landing Waypoint Set [WP ____; Alt: ____ m] | <input type="checkbox"/> | Deploy Parachute uncheck | <input type="checkbox"/> |

Takeoff security settings - Command Loops

| | | | |
|---|--------------------------|---|--------------------------|
| IAS speed reference (min speed + 2 m/s) [____] m/s | <input type="checkbox"/> | Cmd loops: Activate runway endpoint (96/97) | <input type="checkbox"/> |
| Set altitude reference (gnd altitude +100 m) [____] m | <input type="checkbox"/> | | |

Aircraft control Checks (Checked aircraft; Next to the ground station)

Communications flight settings

| | | | |
|--------------------------------------|--------------------------|---|--------------------------|
| Set GS communications power: [0,5 W] | <input type="checkbox"/> | Set Autopilot communications power: [1 W] | <input type="checkbox"/> |
|--------------------------------------|--------------------------|---|--------------------------|

Communications check at distance (About 300m from the ground station). RSSI signal should indicate close to the maximum reading (3)

| | |
|----------------------|--------------------------|
| RSSI: -79 or -71 (3) | <input type="checkbox"/> |
|----------------------|--------------------------|

Communications flight settings

| | | | |
|---------------------------------------|--------------------------|--|--------------------------|
| Set GS communications power: [0,01 W] | <input type="checkbox"/> | Set Autopilot communications power: [0,01 W] | <input type="checkbox"/> |
|---------------------------------------|--------------------------|--|--------------------------|

General

| | | | |
|--|--------------------------|---|--------------------------|
| Select manual control and verify it's displayed | <input type="checkbox"/> | Verify control surface trims. Adjust as necessary | <input type="checkbox"/> |
| Verify control surface movement directions. (Manual) | <input type="checkbox"/> | | |

Control surfaces (Preflight panel - "AP On" mode)

| | | | |
|---|--------------------------|---------------------------|--------------------------|
| Ailerons right: Right aileron up, Left aileron down | <input type="checkbox"/> | Steering wheel right/left | <input type="checkbox"/> |
| Ailerons left: Right aileron down, Left aileron up | <input type="checkbox"/> | Throttle open/closed | <input type="checkbox"/> |
| Elevators up/down | <input type="checkbox"/> | Flaps down/up | <input type="checkbox"/> |
| Rudders right/left | <input type="checkbox"/> | Zero Air Data (1) | <input type="checkbox"/> |

Sensors Telemetry

| | | | |
|---|--------------------------|------------------------------|--------------------------|
| Dynamic pressure (<15Pa with pitot tube protection) | <input type="checkbox"/> | INS test (2): Y acceleration | <input type="checkbox"/> |
| INS test (2): Z acceleration | <input type="checkbox"/> | INS test (2): Pitch up/down | <input type="checkbox"/> |
| INS test (2): Roll right/left | <input type="checkbox"/> | INS test (2): X acceleration | <input type="checkbox"/> |

| | | | |
|----------------------------------|--------------------------|--|--------------------------|
| Telemetry panel | | | |
| Verify Autopilot GPS 3D fix | <input type="checkbox"/> | AGL - Sensor on | <input type="checkbox"/> |
| Verify Autopilot GPS PDOP (<2,5) | <input type="checkbox"/> | AGL - Verify AGL Alt.: "From Sensor" & "Installed" | <input type="checkbox"/> |

| | | | |
|---|--------------------------|---------------------|--------------------------|
| Gains look sensible ("AP on" and "Flying" modes) - Command loops | | | |
| Blow test: 25 m/s + | <input type="checkbox"/> | Yaw damper (online) | <input type="checkbox"/> |
| Roll controller (Bank set to 0 deg/s) | <input type="checkbox"/> | | |

| | | | |
|---------------------------------|--------------------------|------------------------|--------------------------|
| Engine start preparation | | | |
| Fuel tank full/Batteries full | <input type="checkbox"/> | Ignition battery full | <input type="checkbox"/> |
| Refuelling cap on | <input type="checkbox"/> | Pre-launch mode active | <input type="checkbox"/> |

| | | | |
|---------------------------------|--------------------------|-------------|--------------------------|
| Operation team readiness | | | |
| Cellphones off | <input type="checkbox"/> | IM SAFE (5) | <input type="checkbox"/> |

| | | | |
|---|--------------------------|-----------------------------|--------------------------|
| Communications with TACO | | | |
| Flight info to TACO (duration, plan and mission type) | <input type="checkbox"/> | Request Engine Start (TACO) | <input type="checkbox"/> |

| | | | | | |
|---------------------------------------|---------|--------------------------|-------------------------------------|-------|--------------------------|
| Communications flight settings | | | | | |
| Set GS communications power: | [0,5 W] | <input type="checkbox"/> | Set Autopilot communications power: | [1 W] | <input type="checkbox"/> |

| | | | |
|--|--------------------------|---|--------------------------|
| Engine Checks (Aircraft seized) | | | |
| "Engine on" active | <input type="checkbox"/> | Test ground station kill (Commands panel) | <input type="checkbox"/> |
| Request Engine Start (mechanic/pilot) | <input type="checkbox"/> | Test pilot kill | <input type="checkbox"/> |
| Engine start time | : | Check sensor readings for signs of excessive noise due to engine vibration at different RPMs (Gyros readings should be under 20deg/s) | <input type="checkbox"/> |
| Mixture tuning | <input type="checkbox"/> | | |
| Check response to sudden changes in throttle | <input type="checkbox"/> | | |
| Set lower throttle limit (Limits panel) | <input type="checkbox"/> | | |

| | |
|---|----------------------|
| Aircraft readiness to flight (signature) | <input type="text"/> |
|---|----------------------|

| | | | |
|--|--------------------------|-------------------------------|--------------------------|
| Runway Checks (Aircraft rolling to start position of takeoff) | | | |
| Pilot handset memory check | <input type="checkbox"/> | Request Taxi: TACO & Pil | <input type="checkbox"/> |
| Zero Air Data (1) | <input type="checkbox"/> | RSSI: -79 or -71 (3) | <input type="checkbox"/> |
| Remove Pitot tube protection | <input type="checkbox"/> | Autopilot voltage: 11.5 V + | <input type="checkbox"/> |
| Communications power: GS and Autopilot | <input type="checkbox"/> | Start voltage supervision | <input type="checkbox"/> |
| Confirm Takeoff Direction & Runway clear (w/ pilot) | <input type="checkbox"/> | Request Takeoff (inform TACO) | <input type="checkbox"/> |
| Takeoff info to TACO (direction and altitude) | <input type="checkbox"/> | Takeoff warning | <input type="checkbox"/> |

| | | |
|---------------------|---|----------------------|
| Takeoff time | : | <input type="text"/> |
|---------------------|---|----------------------|

In flight Checks (Aircraft flying)

| | | | |
|--|--|---|--|
| Aircraft Flying mode | | Check V-rate [>0m/s] | |
| Navigation mode: INS/GPS or INS/SBAS | | Activate M2A waypoint | |
| Airspeed > Vstall | | Request M2A | |
| Altitude > 70m AGL | | Request TACO to proceed with mission plan | |
| Update Lost comm waypoint for mission safety | | | |

Pre-landing Checks (Aircraft flying)

| | | | | |
|--------------------------------|--|--|--|--|
| RSSI: -93 to -71 (3) | | | Flight info: (IAS, Engine, RPMs, Altitude, Wind) | |
| Link: > 80 | | | Confirm runway clear (w/ pilot) | |
| Autopilot voltage: > 10.5 V | | | Request A2M & checks (inform TACO) | |
| System: Servo voltage: > 4.8 V | | | Activation of runway endpoint or landing path | |
| | | | Request: Downwind, Base leg & Final info | |
| AUTOLAND | Verify GPS (3D fix) and PDOP(<5) | | Landing Warning | |
| | Navigation mode: INS/GPS or INS/SBAS | | Landing time : | |
| | Sensor readings - Gyros (<20deg/s) | | Pre-launch mode active | |
| | Static pressure update | | Electrical motor - "Engine off" active | |
| | Request landing authorization from TACO | | Engine kill time : | |
| | Confirm runway clear (w/ pilot) | | Lower communications power: [0,01 W] | |
| MAN | Activate automatic landing | | Gasoline engine - Turn ignition off | |
| | Motor-altitude supervision (check for flame-out) | | Any Failure / emergency? | |
| | Perfect Connection from GCS to pilot handset | | Emergency landing? | |
| | Request pilot landing direction | | Fill the flight log | |
| | Request landing authorization from TACO | | | |

Procedures

Auto to Manual (A-to-M) Transition

In-flight requirements:

- (a) All A-to-M transitions must assure that the Auto and Manual engine regimes are as close as possible and near the optimum flight speed.
- (b) All A-to-M transitions must be made in leveled flight.
- (c) In “Manual test transition” and “Manual transition for landing” – transition should be carried out at about 600 ft high, 300 ft away horizontally from the ground station, while in downwind, near the optimum flight speed.

Sequence of procedures:

- (a) The OP informs the PIL of the UAV state: attitude, altitude, velocity, and engine percentage input.
- (b) The OP informs the PIL that he can make the transition.
- (c) OP tracks WP 95 or 96 – the one ahead of the UAV.

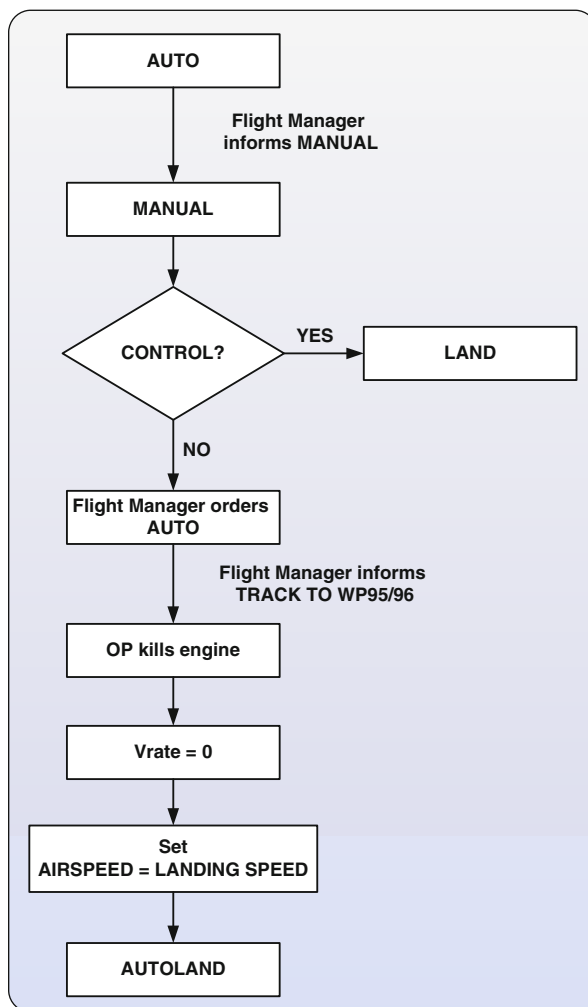

Fig. A1 Procedures for in-flight mechanical emergency

- (d) The PIL activates Manual and reports the transition.
- (e) The OP confirms that the transition has occurred, by checking the console.
- (f) PIL tests the UAV's response to pitch/camber, roll, yaw, and engine (in this sequence).
- (g) The OP should monitor the UAV attitude on the HUD and report if something is out of limits.
- (h) The crew monitors the UAV attitude changes. If no change occurs, OP orders PIL to activate Auto.
- (i) If PIL detects a failure in the transition to Manual, activate Auto immediately.

- (j) If the PIL and OP lose control over the UAV, OP shuts the GS off if ordered by the FM.
- (k) If control is assumed over UAV, initiate land plan.

Emergency – Auto to Manual with mechanical emergency on the UAV (except for elevator Failure)

In-flight requirements:

Before *manual* activation, all operation crew must be well informed of the emergency circumstances and limitations, if the time available for the response is enough.

Sequence of procedures:

- (a) OP requests PIL Manual activation.
- (b) PIL activates Manual, executes the Manual test procedures (3.1), and reports the conclusions to the OP.
- (c) OP informs Manual take over on the console.
- (d) If Manual is not assumed:
 - i OP orders PIL to activate Auto.
 - ii Depending on the response, OP shuts the GS off if mandated by FM.
 - iii FM requests OP to track WP 95 or 96, kill engine, set $V_{rate} = -0,2$ m/s, and force the airspeed to the landing setting.
