UAV Logistics Support

***Fulvia Quagliotti and
Nafiz Alemdaroglu***

Kimon P. Valavanis and George J. Vachtsevanos

UAV Logistics Support refers to UAV lifetime operation support; scheduling issues; delivery of goods and services; maintenance, testing, and fielding of UAVs; design and operation for reliability, safety, availability, and maintainability; logistics for ground station support and mobile UAV platforms; and potentially human operator support.

► **UAV Logistic Support Definition** by Chiesa and Fioriti presents considerations and hypotheses about RAMS characteristics and logistic support options for operational fleets of UAS. At first, an outline of why logistic support is relevant for UAS in comparison with other complex systems is presented, followed by considerations why reliability, safety, and maintainability are relevant aspects for UAS, explaining how such characteristics can be achieved by design. Synthetic considerations regarding transportability, a characteristic strictly connected to safety, reliability, maintainability, and logistic operations, are discussed. It is stated that considering (in addition to technical features) targets, requirements, constraints at the origin of a fleet of UAS, fleet sizing, and related system support (elements and strategies), a useful tool to face such complex problems is stochastic simulation and in particular a Monte Carlo methodology, which is also discussed.

► **UAV Logistics for Life-Cycle Management** by Karaagac, Pakfiliz, Quagliotti, and Alemdaroglu provides the reader with general knowledge on UAV Logistics for Life-Cycle Management, focusing on current logistics challenges and possible

future UAV logistics trends that may improve UAV deployment. Although UAVs do not have a pilot onboard, they require nearly the same logistics support as most manned aircraft. That is, logistics support covers support for all components including the unmanned aircraft and the ground control station. The objective is to design a system with a reduced logistic footprint, enabling fast deployment and high mobility.

Future integration of UAS into the national airspace will require clearly defined rules and procedures for UAV logistics support during every phase of the UAV life cycle, including being proactive in predicting and accommodating possible problems before they become serious issues.

Abstract

The chapter will present several considerations and hypotheses about R.A.M.S. characteristics and logistic support options for operational fleets of UAS.

First, a short review will outline how logistic support is relevant for UAS in comparison with other complex systems. It focuses on how logistic support must be designed and how such a design must be driven up jointly with the system design. The relevance of the scenario in defining logistic support will be discussed.

Next is a consideration of how reliability, safety and maintainability are relevant aspects for all advanced systems, and in particular for UAS, explaining how these characteristics can be achieved by design. The maintenance program will always be defined in the design phase and, consequently the logistic support will also be defined. Several tools useful for these purposes will be presented and shortly described.

Some synthetic considerations will be presented regarding transportability, a characteristic strictly connected to safety, reliability, maintainability and logistic operations, also of particular relevance for UAS.

Other peculiarities of UASs, mainly deriving from the flight segment and ground segment coexistence, will be presented.

Having in mind the targets, requirements, and constraints at the origin of a fleet of UAS, in addition to the technical features of the UAS, the fleet sizing and the related system support (elements and strategies) definition is a very complex problem. A useful tool to face this is stochastic simulation, in particular Monte Carlo methodology. A possible feature of a UAS fleet simulation model will be exposed and discussed.

107.1 Introduction

It is an established concept that in every technique, any complex system can operate for an extended time in a satisfactory way only if it is properly supported by a totality of elements that provide various support tasks, among which are:

- Providing the system (energy supply for operation devices and/or consumables necessary to perform a stated mission).
- Supplying the equipments, spare parts, staff training and technical handbooks to perform the aforesaid operations.
- Supplying the transport of the system, if necessary, and the above mentioned elements (at least the most necessary ones) in cases when the area in which the system works needs to be changed.
- To house, in suitable facilities, the activities, people and hardware involved, as well as, if necessary, the primary system.

With reference to Fig. 107.1, which takes as a typical example of a “complex system” a modern fighter aircraft, it is easy to understand the importance or the critical state of the logistic support system, and this under two aspects:

- The inefficiencies of the logistic support system strongly influence the results obtainable by the primary System.
- The cost of the logistic support system is very high, of the same size of the primary system costs.

In military and advanced industries, a potential cause of criticality has been found to arise as a consequence of placing primary system design before design of the logistic support system; as a matter of fact, in this way, the definition of the logistic support system is bound by the already-defined characteristics of the primary system, while modifications to improve efficacy and efficiency of the logistic support system cannot be made without alteration of relevant performances of the primary system, which could alternatively easily be introduced during the design phase of the system itself. Figure 107.2 shows how the sequential approach, first the primary system design and then the logistic support system, is obsolete,

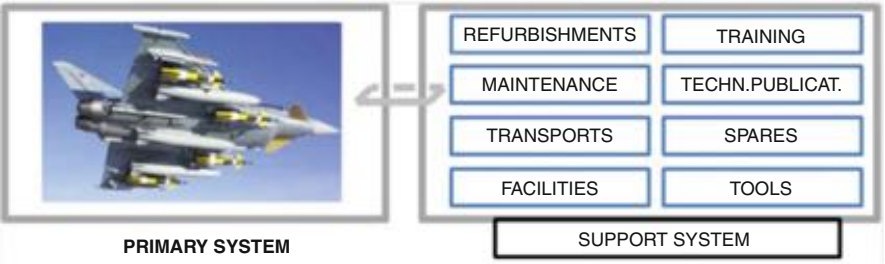

Fig. 107.1 Example of primary system and support system

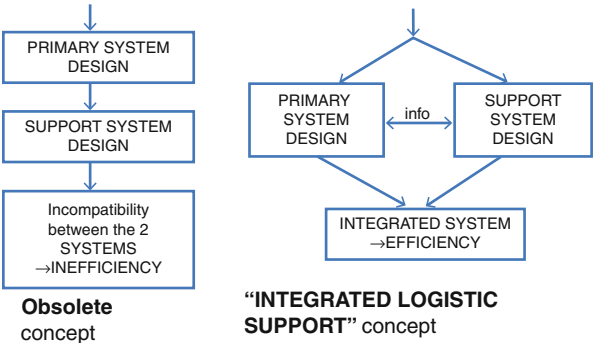

Fig. 107.2 Integrated logistic support (ILS) concept

in comparison with the suitable technique of developing both systems at the same time, with a continuous exchange of information.

The design process is undoubtedly more complex, but the advantage of obtaining an “integrated logistic support-ILS” is extremely more efficient, and this completely justifies the increased engagement in the design phase (Chiesa and Gianotti 1996).

Figure 107.3 points out that the importance of the logistic support system for any complex system is certainly valid for UAS as well, as they are typically complex systems; in particular, the concept of ILS is fundamental, even if it is not easily realized in a new field, at present in an evolving phase, and with peculiar characteristics. In the next section (Sect. 107.2), peculiarities of this system will be briefly discussed.

107.2 UAS Operational and Logistic Scenario

To achieve the best logistic support for any product or complex system involves a range of subjects, methodologies, and means to carry out in the best way everything

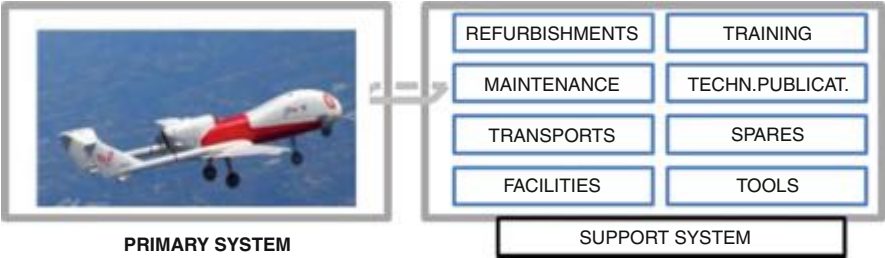

Fig. 107.3 UAS and related logistic support system

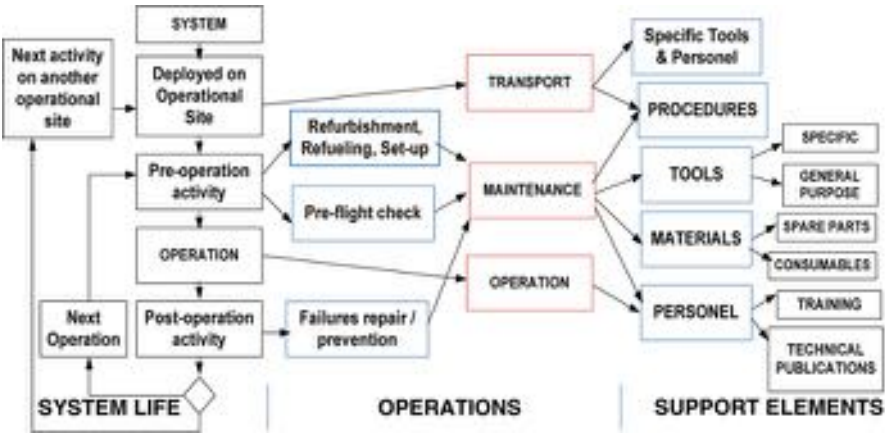

Fig. 107.4 UAS operational life and logistics

that is necessary to allow the product to perform continuously during its lifetime; Fig. 107.4 shows the key criteria for a UAS system to work correctly:

- (a) It must be moved to the place where it performs;
- (b) It must be prepared before starting working or, in particular, before starting a mission; the suitability to perform a mission must obviously be checked before the starting of the same mission.
- (c) It must be operated (or “piloted”) during its performance.
- (d) It must be checked after an expected period of performances to prevent a deterioration; in other words, possible failures are to be corrected or, better, prevented and addressed in advance. In this way, the product is ready for a new cycle of functioning after a necessary preparation.

The result of the support logistic includes operational system deployment in the intended environment, planning of efficacy and maintenance, and all else necessary for operation: staff (for guiding and maintenance), tools (particular for the system and of “general purpose” or “standard”) and equipment (consumable and spare parts).

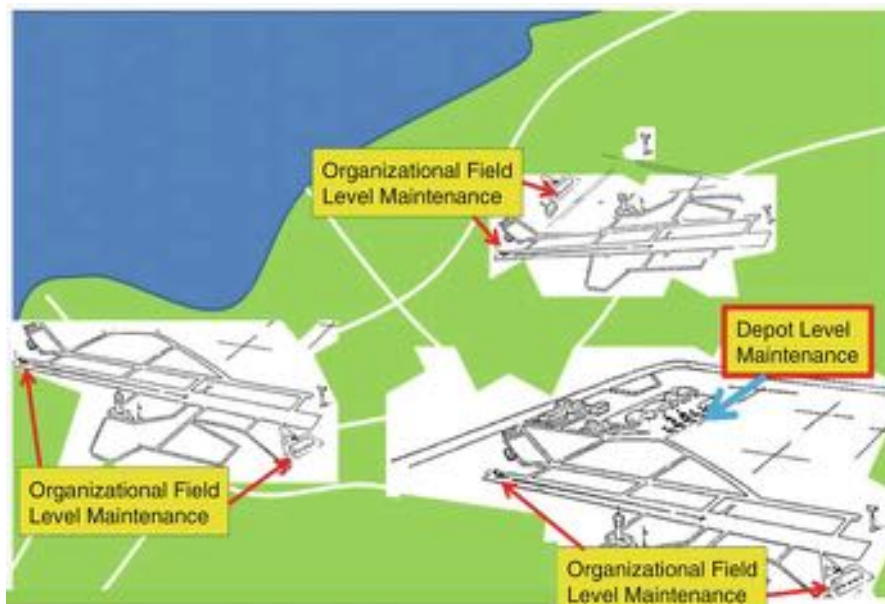

Fig. 107.5 Multi-bases operational and logistic scenario

Figure 107.4 highlights other problems, for instance, that operations as well as maintenance staff must be properly trained and supported by suitable technical handbooks; it is also clear, even if not shown in the figure, that staff, materials and equipment must be kept in dedicated facilities and that the system must be managed and information (internal and external) must be exchanged with a special computerized system.

Next, Fig. 107.5 shows how the operational and logistic scenario can get complicated if the UAS system is (as is very probable) deployed in a vast region, with more than one operation base.

Indeed, this fact offers the opportunity of optimizing the logistic processes, in particular maintainability, by diversifying the typology of activities on the various bases.

This requires organization of the whole maintenance process on many levels, depending on the difficulty of operations. In Fig. 107.5, for example, a possible subdivision of maintenance operation of a UAV fleet on two levels is shown: the “Organizational Field-Level Maintenance” scheduled for all the bases and the “Depot-Level Maintenance” scheduled only for a lower number of bases (in Fig. 107.5 the example of a single base).

In particular, whereas the more general and frequent activities (i.e., refurbishment and, generically, flight setting activities, as well as before and after flight controls) are carried out in all the bases (with reference to Fig. 107.5), which are sites of organizational field-level maintenance, the more complex, and usually less

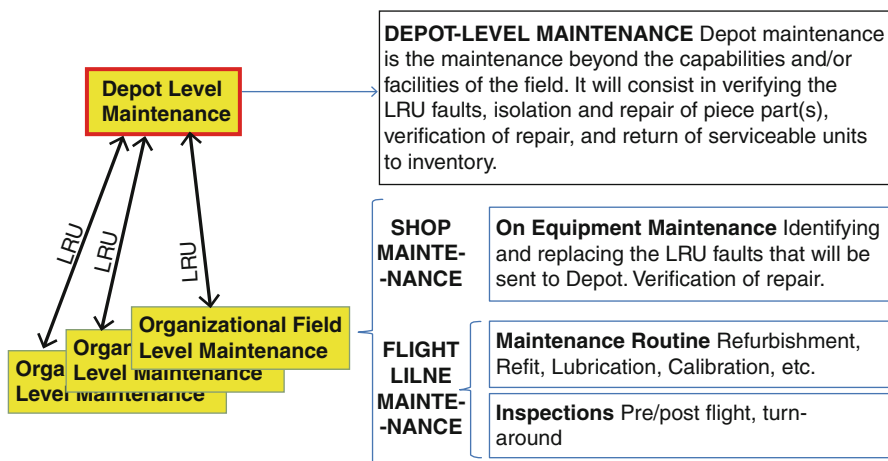

Fig. 107.6 Maintenance levels

frequent operations are carried out only in a lower number of bases (one only in Fig. 107.5).

This fact makes basically uneconomical to deploy at all bases the resources (staff, tools and facilities) for specialized operations, as these resources would be underutilized.

In particular, as to maintenance, in “organization field-level maintenance” the aircraft’s broken units LRU are replaced with other correctly working units; in this way the following advantages are obtained:

- The aircraft downtime is strongly reduced, with a quick replacement of the broken LRU with a working one; the operation is carried out by a staff with generic training that can easily replace any kind of LRU, while the indication of which part of the LRU is out of order is usually given by an automatic diagnostic system.
- The operation of repairing the unloaded LRU, which are generally specialistic and complex activities, are delegated to depot-level maintenance, where specialized resources are conveniently utilized as they receive LRUs from all the bases, whereas if they are included at all the bases they will be utilized in a reduced way.

The aforesaid advantages that derive from organizing maintenance on more than one level (as the scheme in Fig. 107.6 shows) are considerable (so that LRU costs and time of transports to and from the depot maintenance level are minimized), but it is clear that all these considerations are influenced by the fact that the system project has already foreseen the level maintenance organization, in particular by providing the above mentioned automatic diagnostics, and that the project is modular, that is with LRUs ready to be easily removed and reassembled.

It is clear then that the optimization of maintenance and, consequently, the logistic support system has as main assumption, which cannot be overlooked, the

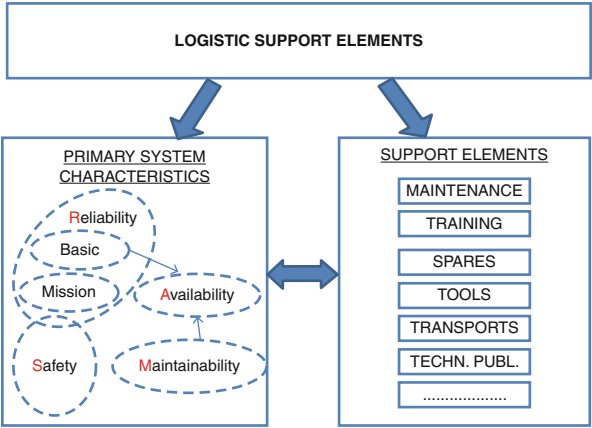

Fig. 107.7 Logistic support components: primary systems characteristics and support system elements

primary system project and its logistic support as carried out at the same time from the ILS point of view.

After such a short characterization of complex system logistic and an operative scenario depicting a possible system for a UAS fleet, Fig. 107.7 shows again the support elements already seen, along with primary system characteristics like reliability and maintainability.

A very preliminary peculiarity of these two characteristics could be considering reliability as indication of how the system tends towards failure or not, and maintainability as an indication of increased or decreased ease to be placed under maintenance.

It is evident that such characteristics are basic for the definition of logistic support, and this explains why, in Fig. 107.7, they are indicated as “elements” of logistic support; in the same figure it is said in advance that reliability and maintainability are characteristics strictly linked to others, like availability, mission reliability, and safety.

These extremely important characteristics are to be treated together, as is seen in the following section. In the same Fig. 107.7 the explanation of the acronym R.A.M.S. is shown.

107.3 UAS Support Systems Elements

R.A.M.S. refers to “Reliability, Availability, Maintainability, and Safety.” Considering these topics together is widely accepted due to their strict relationships, as for instance:

- The stochastic nature of safety binds it with reliability, as the probability not to suffer any failure in any part of the system; so on the basis of these

probabilities (the reliabilities of each component) and how the components are interacting, safety, mission reliability, and basic reliability are derived. Safety is understood as the probability of having no failure (or in many cases “groups” of concurrent failures of various components) to prevent the fulfilment of critical functionalities; mission reliability means the probability of having no failures (or groups of concurrent failures) to prevent the fulfilment of functions needed for the mission success. Finally, basic reliability or simply reliability includes all the possible failures occurring on the system.

- Basic reliability obviously affects the entity of maintenance needed to delete the effects of failures as they occur, so the time required for the maintenance itself; maintainability also, being the feature of a system to receive maintenance actions more or less easily, is a concurrent issue in defining such time. It seems clear the binding between reliability, maintainability and availability, being this last a feature depending on the time spent under maintenance by the system.

Having demonstrated that reliability, availability, maintainability and safety are linked together, there is still “unavailability,” by which we mean that availability does not depend only on maintenance, that is, the system is not available not only when it is under maintenance, but also when unavailability is imposed by operational needs, in particular due to transports in case of clearing in other sites. In the field of maintenance, availability is also dependent not only on maintainability but also on the maintenance organization, on its sizing, on the skills of maintenance personnel, on technical documentation, on the tools used, on the amounts of spare parts available and, where needed, again on the transport activities.

This leads to the concept of logistic support systems and of the multiple elements that are part of it; clearly, the logistic support system is a particular to the system and it is affected greatly by its features of reliability and maintainability, and even, for the needs of “transportability,” on the division into different modules (to be easily integrated or separated) that the system has to include. A basic step is to understand that all the features imposed on the system by design, as already seen for reliability, and all the maintenance operations and logistic support systems, such as technical publications and the skills of maintenance personnel, are all features that affect safety.

Figure 107.8 shows synthetically the concepts explained.

Discussing the relevance of the above described features, it is worth notice how safety, apart from obvious ethical reasons, is the basis of certification and is thus a needed condition within any system, particularly in aeronautics, while reliability, maintainability, availability and logistics affect operational capability and, heavily, costs (purchase and operational costs) of a system, so affecting its effectiveness and efficiency.

This topic will be investigated at a deeper level in the following, but for now we point out that the competitiveness needed to develop successful aerospace systems today clearly show how strong an attention has to be placed on it.

The state of the art in the field of R.A.M.S. and logistics is defined by some consolidated results reached in previous times (Chiesa 2007); in particular, the following points can be reiterated:

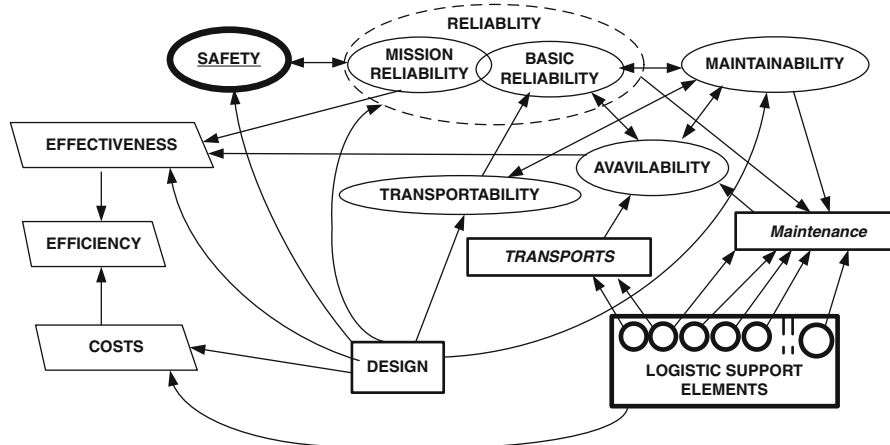

Fig. 107.8 Relationships between R.A.M.S., logistic support elements, design and other related issues

- Safety, reliability and maintainability are design features, as their respective values, in a given product, are derived by the design of the product itself;
- The logistic support system has to be designed not subsequently but at the same time as the primary system design, in such a way that the two systems will be developed with no problems of compatibility between each other, and in such a way to achieve the highest level of efficiency (this is the concept of Integrated Logistic Support – ILS (ILS Army Regulation 2007))
- Particularly with reference to maintainability (MIL-STD 471 and 472) it is worth notice that in this field a particular development was obtained with the techniques of automatic diagnostics (Johnson 2005, Keller et al. 2001, Xiaoyang 2012), with their own processes in both HW and SW; as a direct consequence, the feature of “testability” has increased in relevance, encompassing both the testability the easiness of the System to be tested (MIL-STD 2165 and MIL-HDBK 1814); the relevance of testability is such that sometimes, instead of R.A.M.S., R.A.M.S.T. acronyms can be found, in order to show the importance of testability, which is considered a self-grown discipline and not only a branch of maintainability.

107.3.1 R.A.M.S.

Returning to a deeper level of investigation it's useful before showing how R.A.M.S. disciplines can be developed in design phases to notice how all of these disciplines are “crossing characteristics,” features for which nearly all components of the system concur to define their own level. A direct consequence of this is that in the design team of a system only specialist designers of all part components are able to, and have to, design the part components under their responsibility in order to

satisfy R.A.M.S. requirements, while at the same time they have to satisfy specific “crossing characteristic” requirements with respect to other parts and the system as a whole, such as overall weight or overall cost; the activity of specialist designers has therefore to be addressed, driven, and supported by discipline specialist that, in order:

- Provide specialist designers the requirements, for their own part components, in the various R.A.M.S. disciplines;
- Control continuity of designs of the various parts are developed with respect of the above mentioned requirements;
- Provide specialists supports for what concerns the aspects of various R.A.M.S. disciplines, in particular for what is related to the improvements whose needs was put in evidence by the control activity above mentioned, but also for planning and execute demonstrations of R.A.M.S. level reached at the end of design development.

This organizational strategy is shown in the following Fig. 107.9.

In order to complete the overview of “design to R.A.M.S.” it can be useful to recall some of the techniques currently in use today; in particular:

- In the field of prediction techniques it’s worth remembering MIL-HDBK 217 “Reliability Prediction for Electronic Components” and several data bases (among which is RAC - Reliability Analysis Center) for mechanical design to reliability (Dudley 1997).

Other techniques, even for the other R.A.M.S. disciplines beyond reliability, are available in the exhaustive set of MIL rules (MIL-HDBK 217F N2), at least for the activities concerning design development. On the contrary, for what concerns the early design phases, in which taking care of R.A.M.S. aspects is not easy due to the still poor definition of the design, but yet extremely useful since the features achieved by the future product through the conceptual design phase will tend to be maintained, some methods, developed mainly in academic environment (Chiesa 2007), are available.

- Analysis Techniques: in the reliability field, a great relevancy is held by F.M.E.A. (failure modes and effect analysis, MIL-STD-1629A), used in various shapes, starting from the original definition MIL, later on relevantly readapted in several cases. For what concerns safety, the most known technique is probably F.T.A. (faults tree analysis), often mentioned together with F.M.E.A., as complementary techniques (Fig. 107.10), one being based on a bottom-up approach, the other being top-down, while, in particular if there is an aim to catch the effects on Safety of the installations of the systems on the cells, the “Qualitative Safety Techniques” are worth to be mentioned, of which a clear example is given by the “Safety Specification” of ESA (European Space Agency) and yet other methodologies determined by the academic world (Chiesa 2007).

As a further consideration on safety, it has to be kept in mind that, for unmanned air vehicles, the fact of not carrying crew or passengers onboard leads to a major concern not only on that failures that may cause a crash, but above all care must be taken to avoid damages for people on the ground. In particular, the concept of ELS (expected level of safety) was elaborated, such as:

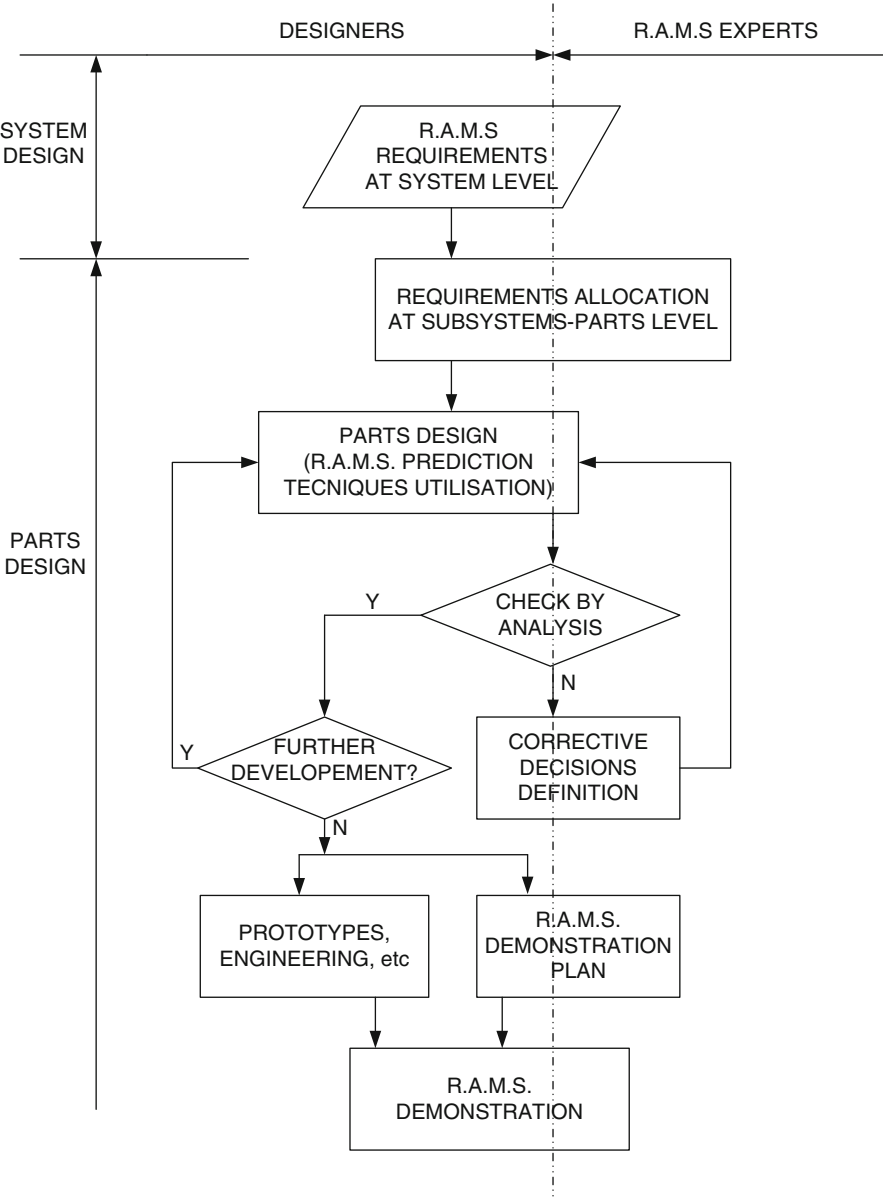

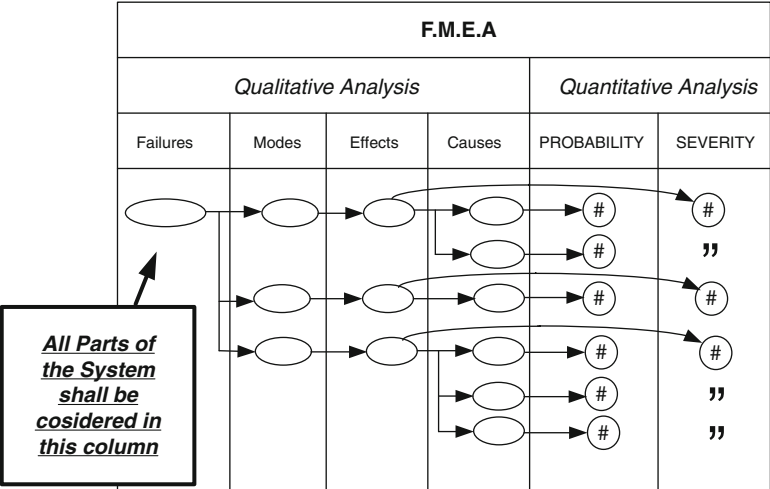

Fig. 107.9 Task distribution in R.A.M.S. oriented design

All Parts (Componets) are considered, with their various possible modes; for all the effects on System are analyzed
→ **BOTTOM - UP APPROACH**

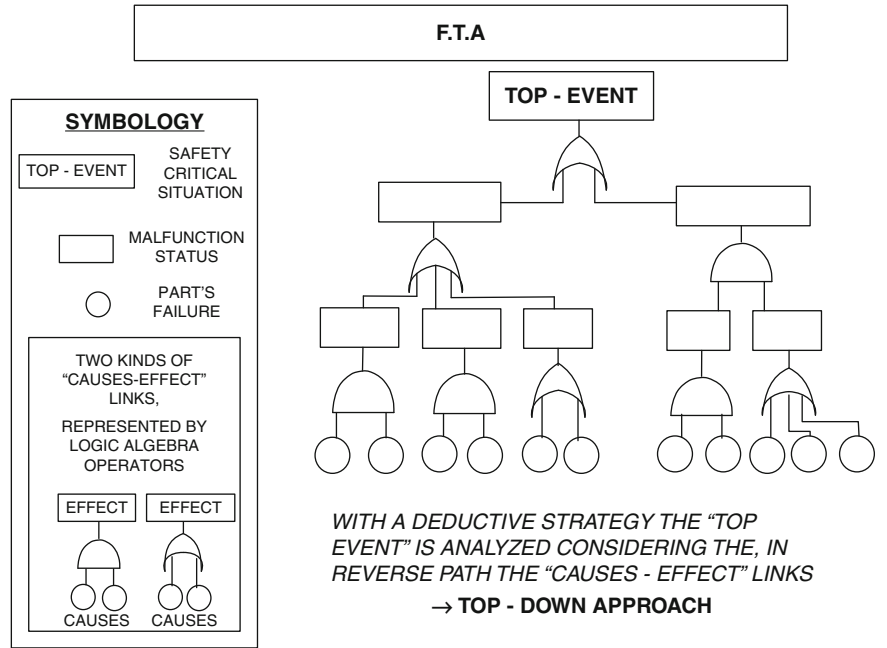

Fig. 107.10 F.M.E.A. and F.T.A. approaches

$$ELS = \frac{A_{\text{exp}} \rho P_{\text{pen}} (1 - P_{\text{mit}})}{MTBF},$$

where,

- $(1/MTBF)$ is the failure rate of safety, so the estimated rate of “crash”
- A_{exp} is the territorial area damaged by the crash
- ρ is the population density of the area on which the UAV is operating
- P_{pen} is the probability for people to be hit by debris, even if they are protected by houses, buildings or vehicles in which they eventually find themselves in the timeframe when the crash occurs.
- P_{mit} is the probability that crash effects are decreased by systems of safe flight termination (i.e., ballistic parachutes, autonomous guidance systems on uninhabited places, and so on)

This point of view, particularly innovative, requires a great attention.

A brief consideration of the following phases of design leads us to consider how in the phases of construction of a product (production, but also prototype realization) R.A.M.S. features have to be taken into account; before all else, it has to be recognized that, as already mentioned before, the design is assumed to be oriented to R.A.M.S. features, for which the most critical issue is that, through production, there should not be an unacceptable decrease in the values achieved by design. This is particularly relevant for reliability, as design choices for maintainability (such as, accessibility, systems of automatic diagnostics, modularity, use of connections “quick connect/disconnect”) and partially design choices for safety (in particular for redundancies, and installation choices, in spite of already mentioned qualitative safety) result in design “macro-choices” that cannot be overcome by construction; on the contrary, reliability of equipments and installed devices (with clear effects on safety, mission reliability, and basic reliability) can be reduced with respect to design levels for integration mistakes, rough handling, etc. There is a clear need for attention to avoid, or at least decrease, this reduction of reliability caused by construction process; a very useful tool for this is the “process FMEA,” that is FMEA applied no more on all the “part components” of the product but on all the consequent operations in the processes of construction and production.

107.3.2 Logistics

As to the logistics aspects, they are focused on developing, as already mentioned, in an as far as possible way, designs integrated with the system development (I.L.S. concept Jones 2006, see Fig. 107.11), that is called “System Support.”

The system support is constituted by the integration of the various elements concurring to the system support, that is:

- Support and maintenance tools and instruments
- Technical publications
- Personnel training
- Spare components and consumables

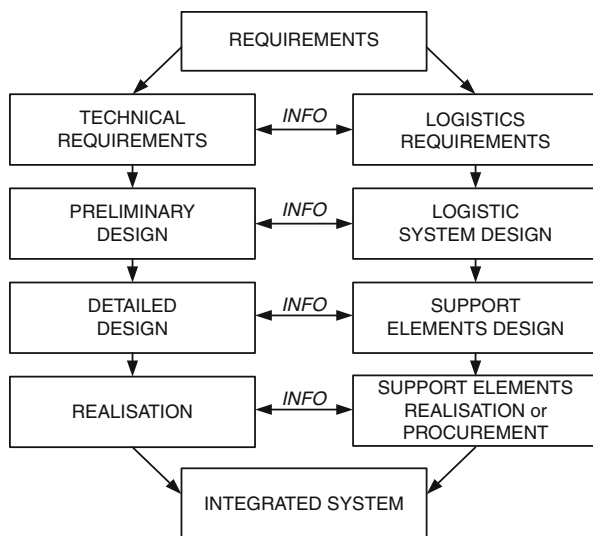

Fig. 107.11 From requirements to integrated system, meaning product and logistic support system

- Facilities
- Management procedures and SW
- Transportation

This list, purely indicative and not exhaustive, helps understanding as system support is constituted by various and heterogeneous elements, including elements such as “personnel,” “HW,” “SW,” in which there is a concurrence of human factors, technical and economic management aspects, with strict interfaces with the main system, in particular for the levels of reliability and maintainability and the operational needs; there is a strong evidence of the amount of resources included and so of costs, usually in the same order of magnitude of the main system.

Another important and challenging task is to define and refine the sizing of the system support and how it has to be performed. The currently common strategy puts on the first place the definition of a maintenance program deriving the requirements of the system support (in both qualitative and quantitative terms) from maintenance tasks that are defined (as tasks and frequency) by just defining the maintenance program: this is a list of the various maintenance tasks that have to be foreseen to prevent anomalies and failures (preventive maintenance) or to repair occurred failures (corrective maintenance). It's clear that for tasks of preventive maintenance, which can be either “routine tasks” such as refuelling, cleaning, lubrications, controls, servicing, etc., or scheduled replacements of parts or components, or periodical controls on parts, there is not only a need to define the nature of the tasks, but also to define the frequency and a time schedule.

An obvious consequence is that the definition of the maintenance program becomes a very important task to be executed with great accuracy and in the most favourable timeframe; these two aspects are examined in detail in the following.

Currently, the definition of the maintenance program can be performed in the best way possible by using the RCM approach (reliability-centered maintenance) (MIL-STD-2173) with the use of techniques such as, to recall the most well-known, MSG-3 standard. This methodology was developed, in the last decade, by a critique of the traditional approach, which essentially considered the various parts-components of the main system, defining for them the maintenance tasks estimated as the most useful. The key flaws of this strategy were:

- A certain difficulty in imagining the failure modes of the various parts, in particular those due to interactions of more than one parts, to define the most suitable maintenance action, preventive or corrective;
- A complete separation from the design activities (often already completed previously, that is opposite with respect to ILS approach)
- The subjectivity of the decisions taken

In summary, the RCM approach prescribes the following guidelines:

- Define a maintenance program based on FMEA statements; for each one of these an eventual maintenance task has to be decided; please note that in this way the first two criticalities of the traditional approach are deleted, avoiding the separation from the design and using FMEA, thus providing an completed activity where problems, such as failures due to multiple part interactions, have already been solved (moreover, they have been solved by whomever seems to be the most appropriate person to do so);

Use an appropriate decision logic to decide, for the various FMEA points, if a maintenance task has anticipated; this decision logic practically eliminates the threat of subjectivity; it is constituted by a series of decisional diagrams that force the writer of the maintenance programs to ask him/herself the correct question in the correct order, avoiding the mistake of not considering one or more solutions eventually possible; it has to be noticed that the decision logic is organized in a way to guarantee first of all, safety, and then to minimize costs. A further contribution brought by MSG3 is to provide a very good and exhaustive “traceability” of how and why the various decisions, leading to the maintenance program, have been taken. Finally, it has to be noticed that the decision logic can lead, for each point of FMEA, to foresee servicing or scheduled checks (to decide if a part is to be removed or not) or scheduled substitution of parts or even decide to wait being ready for, eventual, corrective maintenance; it has to be noticed, on this point, that, in case a failure involves problems of safety and no preventive maintenance tasks result possible, the decision logic puts as the only alternative a need to redesign.

In Fig. 107.12, the RCM methodology is summarized; in particular, the figure illustrates how the RCM inputs are the whole failure modes reported by FMEA. For each of them the decisional logic is applied; the figure shows that the decision logic is spread on two levels, the first of which classifies the failure mode from the point of view of criticality on the system, and the second responds with different strategies, depending on the result of the first level, and chooses the more convenient

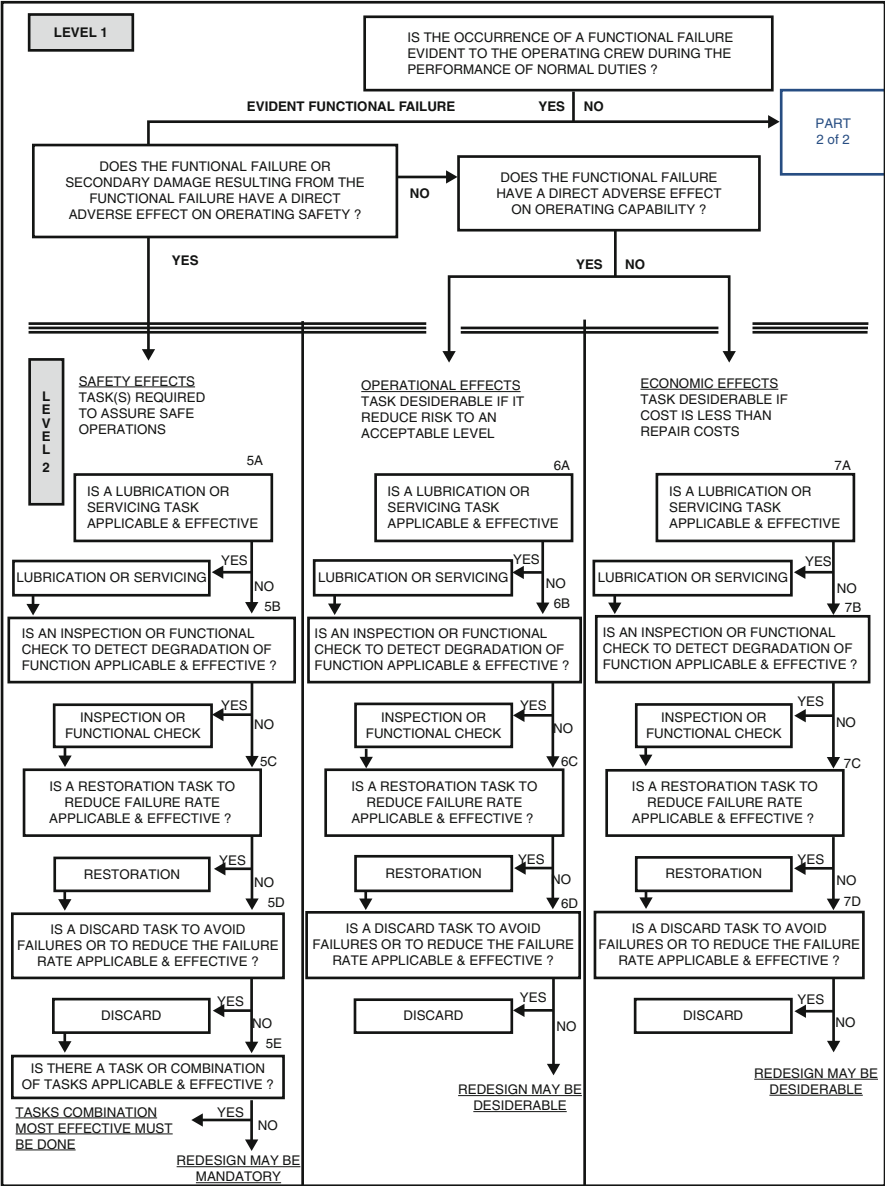

Fig. 107.13 Example of a system logic diagram

led to the sequence (apart from obviously possible iterations and feedback on the previous activities) shown in Fig. 107.14, fully agreeing with ILS approach.

In order to complete the overview on the currently available instruments, the already mentioned Fig. 107.14 points out three more, the L.S.A. – Logistic Support

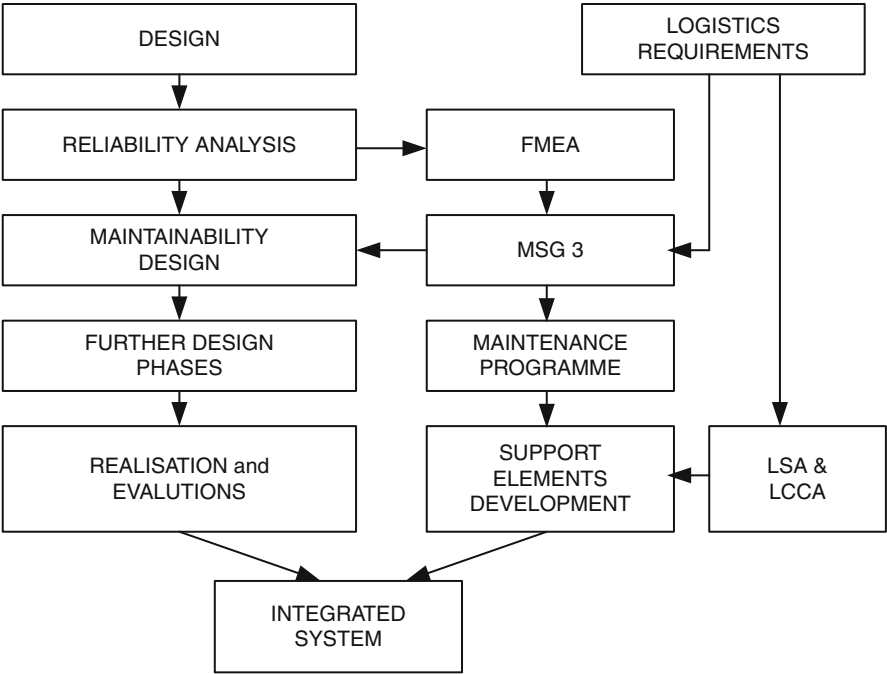

Fig. 107.14 Activities in integrated logistic system definition

Analysis (MIL-STD-1388-1A), the L.O.R.A. – Level Of Repair Analysis (MIL – STD 1390D) and L.C.C.A. – Life Cycle Cost Analysis (Blanchard 1978).

The first one, the LSA, is in summary a guideline for the development of ILS, pointing out the several data that have to be produced and put in evidence in the so called LSAR (LSA reports). The related MIL standard or other equivalent regulations list all activities to be done, during an integrated logistic system development in order to avoid any weakness in logistics definition. To give idea of high level of detail that LSA requires, in Fig. 107.15 the logistic requirement considered at every phase of the development are shown.

The second tool indicated in Fig. 107.14 is, on the contrary, a quite specialised tool, very useful in definition of procedures describing how a maintenance task has to be driven up, if the task involves the identification of a failed part; in such a case, the LORA, as Fig. 107.16 (MTain Inc. 2011) shows, indicates if the part has to be discard or has to be repaired, and, in this case, provides a definition of the maintenance level in which the repair has to be performed. As the figure shows, the LORA forces the maintenance planner to make the economically more convenient choices.

Finally, the third tool indicated in Fig. 107.14 is the LCCA (life cycle cost analysis) that plays the role of optimisation driver for the whole integrated logistic system development process.

Fig. 107.15 Logistic support requirements in logistic support analysis

It is logical to think about life cycle cost concept, with the famous allegory of the “iceberg,” illustrated in Fig. 107.17, that defines all the cost components to be considered during the life cycle of the system, and it is extremely pertinent to other complex systems and with long life cycles. The LCC concept is useful in order to establish a standard, clearly defined and accepted definition of the very many costs items (Blanchard 2003). The LCCA (life cycle cost analysis), operated in a standard way by evaluating LCC for the various alternatives that grow through the development of the ILS, becomes a very good instrument for decision making and, as already said and as illustrated in Fig. 107.18, a precious optimisation tool.

107.3.3 Transport and Transportability

In a preview of the development of future advanced systems, in particular ones comprehensive of UAS, it appears mandatory to pursue a minimization of logistic footprints and of costs in general. The obvious choices use the best that state of art can provide in fields of R.A.M.S. and logistics, but there is another topic on which studies and researches have to be addressed; the transports.

Considering Fig. 107.4, it is clear that, for UAS, deployment in different sites can happen many times during operational life. The scenario (the related relevance has been discussed) can be considered as geographically variable if the UAS has to be deployed, when requested, far from its usual operational site; in this case, it is clear that the logistic support, or a part of it (for example the first level of maintenance), has to be moved; further considerations about this aspect will be presented in the following point. As the transport will be, probably, not specific for UAS, the compatibility with the available transport system has to be pursued

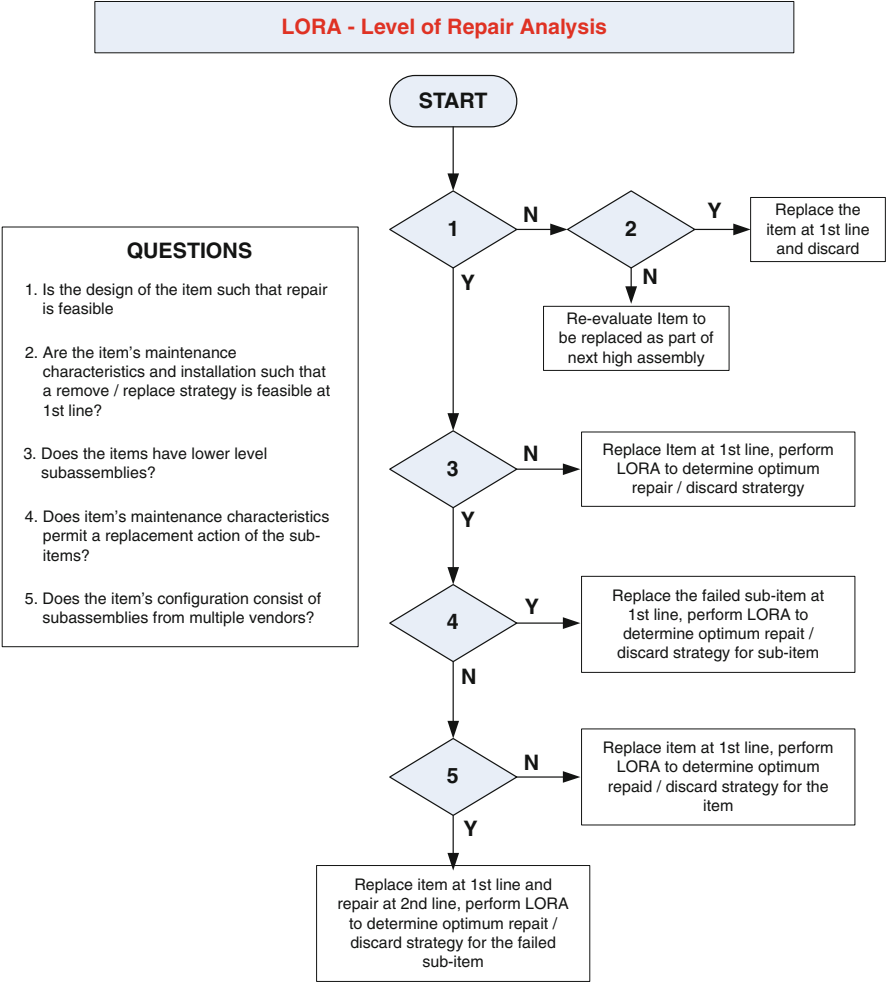

Fig. 107.16 LORA – level of repair analysis

during logistic support elements definition. Similar considerations can be done for moving the GCS (ground control station) of the UAS.

The problem can be interesting when speaking of the aerial vehicles, i.e., the UAVs; in this case, an interesting trade-off analysis to be performed is whether it is better for the UAVs themselves to reach the new operational site in flight, versus being transported by transport system, as happens for GCS and support elements. Please note that the first alternative is usual for manned aircraft, but the second could be better for UAVs, but only if they are “designed to be transportable.”

But what does “design to be transportable” mean? Concisely, it means that the UAV can be easily and quickly disassembled and reassembled, and that the various

Fig. 107.17 LCC – life cycle cost allegoric representation

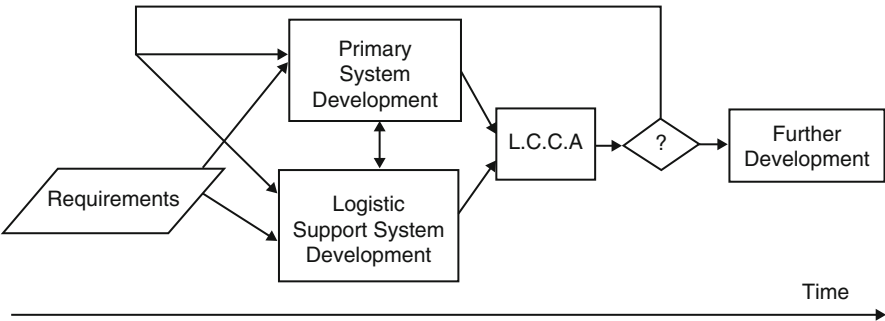

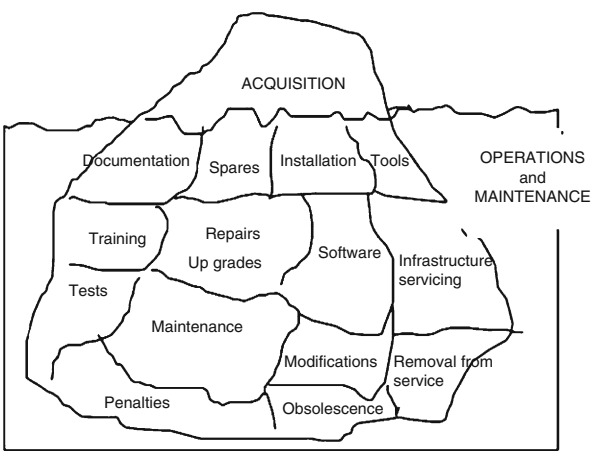

Fig. 107.18 L.C.C.A. – life cycle cost analysis as optimisation tool of ILS development process

parts in which the aircraft is disassembled can be easily stored, in particular in containers with standard dimensions (compatibles with the transportation systems) and of very few kinds (better if the same containers utilised to transport the system components other than UAVs).

So the optimization of the break-down of the vehicles becomes of primary relevance, and has to be defined in the early phases of design, taking into account that, apart from the fact that it concerns many technical aspects, such as layout of assembly line and thus the entire process of manufacturing, and also affects maintainability and logistics, for UAS (much more so than for manned aircraft) there is the question of being stored in containers for transportation by means of ground or sea path.

Figure 107.19 shows the concept of vehicle breakdown. It is important to understand that the vehicle breakdown has to be defined early in design, due to the following reasons:

- The whole project of development and the following detailed design are highly affected by the kind of decomposition, in terms of design and structural sizing,

Fig. 107.19 Concept of aerial vehicle break-down

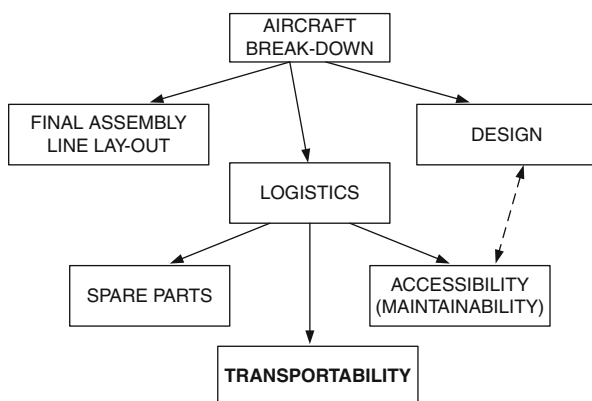

Fig. 107.20 Transportability

but also of design of systems that would have to be split in several “segments” into which the aircraft will be divided and, as it will be discussed later, these choices should be studied with care.

- The breakdown will be functional, and so it will affect some other activities and features of the vehicle that will affect on their own side effectiveness and costs of the system; all of these considerations are displayed in Fig. 107.20;

In this figure it can be noticed how the division of the aircraft has impacts on logistics for several aspects, among which is “Transportability,” that is, the attitude of a system to be transported by means of air, sea, or ground paths. It seems evident that this feature, generally not important since it is relevant only for the assembly tasks (transport of segments of vehicle from the production site to the final assembly site), or carrying segments to be used as spare parts for great maintenance or repair campaigns, it nevertheless takes on a great relevance for UAS. In fact, transport not by air but by means of ground paths are quite usual for unmanned vehicles, both for operational reasons linked to transfer flights, and because, differently from “manned” vehicles the aircraft requires a ground control station which may also be in the process of being moved itself.

Table 107.1 Load factors during transportation

| Medium/mode | Longitudinal load factors, g | Lateral load factors, g | Vertical load factors, g |
|-----------------------|------------------------------|--------------------------|--------------------------|
| Water | $\pm 0,5$ | $\pm 2,5$ | $+2,5$ |
| Air | $\pm 3,0$ | $\pm 1,5$ | $\pm 3,0$ |
| Ground | | | |
| Truck | $\pm 3,5$ | $\pm 2,0$ | $+6,0$ |
| Rail (bumping shocks) | $\pm 6,0$ to $\pm 30,0$ | $\pm 2,0$ to $\pm 5,0$ | $+4,0$ to $+15$ |
| Rail (rolling) | $\pm 0,25$ to $\pm 3,0$ | $\pm 0,25$ to $\pm 0,75$ | $+0,2$ to $+3,0$ |
| Slow-moving dolly | $\pm 1,0$ | $\pm 0,75$ | $+2,0$ |

This fact makes it necessary to consider, during the design of the vehicle, the sizes and shapes of the containers needed to contain the segments in which UAV has to be split, and to conclude that “designed to be transportable” requires an integrated study of the vehicle breakdown, and consideration of the features of the various transporters considered, both their transport capability (weights and volumes) and the environment in which the elements (UAV and GCS) will be hosted; see the following Table 107.1 for example:

From this short consideration, it is clear that a global strategy to define the vehicle breakdown will have to be implemented in the design of future UAS. Such a strategy will have to foresee a strict integration of design activities involving the features shown in Fig. 107.20, in a way that all the needs will be satisfied as much as possible. Particularly interesting is the need that the division of the various systems that have to be distributed in the various segments has to be optimized by means of the choice of the positions on the vehicle (and so on the various segments) of the devices; among other criteria, the following ones can be noted:

- To minimize the number of lines (cables, pipes, etc.) to be interrupted when separating segments;
- The parts of a system on the same structural segment shall be as much as possible complete from a functional point of view (with the purpose to allow eventual testing operations on those system parts separately).

The whole transportability strategy has to be considered during the primary system development and in a collaborative way with it, exactly as already seen for other elements of the system support, and so the “transportability design” (a concise example is given by Fig. 107.21) will be a relevant aspect during the operative way of the system (see again Fig. 107.4).

107.3.4 UAS Logistic Peculiarities

Further logistic peculiarities of UAS derive from the coexistence of two different segments, one concerning flights, and one concerning the ground.

As Fig. 107.22 shows, the link between the flying segment and the ground one is a fundamental element that must always be present in every phase of the mission;

Fig. 107.21 Example of transportability design

even in the cases when the system has a high ability for operating autonomously, the possibility of setting the link between aircraft and the GCS must always be present.

In comparison to traditional aircraft, for which the loss of the link with other “systems of the systems” elements represents only a reduction of efficiency and/or efficacy, as such piloted aircraft have enough decisional autonomy to complete the mission or at least to return safely to the base, for UAS the loss of the link is considered a serious problem.

The more complex UAS systems (such as Global Hawk, Predator A and B) can carry further problems from the logistic point of view, when deployed far from the usual base. In fact they are made up from a ground segment (GCS, ground control system) that controls one or more UAV (normally 1 to 4). The GCS in its turn is

Fig. 107.22 Flight segment
– ground segment Link

made up from a LRE (launch and recovery element) station and a MCE (mission control element) station (Austin 2010).

The LRE station is utilized for the taking off and landing operations, and it is usually located in the same base where the flying segment operates. The communication established between LRE and UAV is a LOS (line of sight) link and it usually extends for a range of 200 nautical miles, in consideration of the Earth's bending and the UAV altitude. On the contrary, the MCE controls UAVs during all the remaining of the mission. Unlike the LRE station, the MCE is not bound to operate from the same base as the flying segment, so it can be positioned in any place on the Earth. Indeed, the link between the MCE station and the UAV (one or more) is a BLOS (beyond line of sight) link, by means of satellites or carried out by means of radio relay ground stations, and it is possible that the control station MCE is positioned in the main base of the UAS, while the UAV and LRE are deployed in the operation site, which could be located even in another continent (Fig. 107.23).

In fact, from the R.A.M.S. point of view, the link can be considered as an element that is in series with the other UAS segments. During some phases of the mission, such a link can be redounded, as can happen when the UAV communicates with an LOS link and is not performing landing or take-off phases, as the reliability block diagram in Fig. 107.24 shows. In more advanced UAS systems, the critical situation following the loss of the link can be compensated by setting up a waypoint in advance in the UAV mission computer, which must be reached autonomously when this failure occurs, and on which the UAV will stay until the link is restored.

Please note that the link reliability depends on components that can also be external to the UAS system and that are different according to the LOS or BLOS link.

In particular, the LOS link depends on the reliability of the UAV receiver/transmitter, and also on the control station, as well as the ether electromagnetic waves transmission that can be deviated by obstructions or jammed by atmospheric perturbations. In case of BLOS transmission, besides the above mentioned elements, satellites or the ground radio relay ground stations must be taken in consideration.

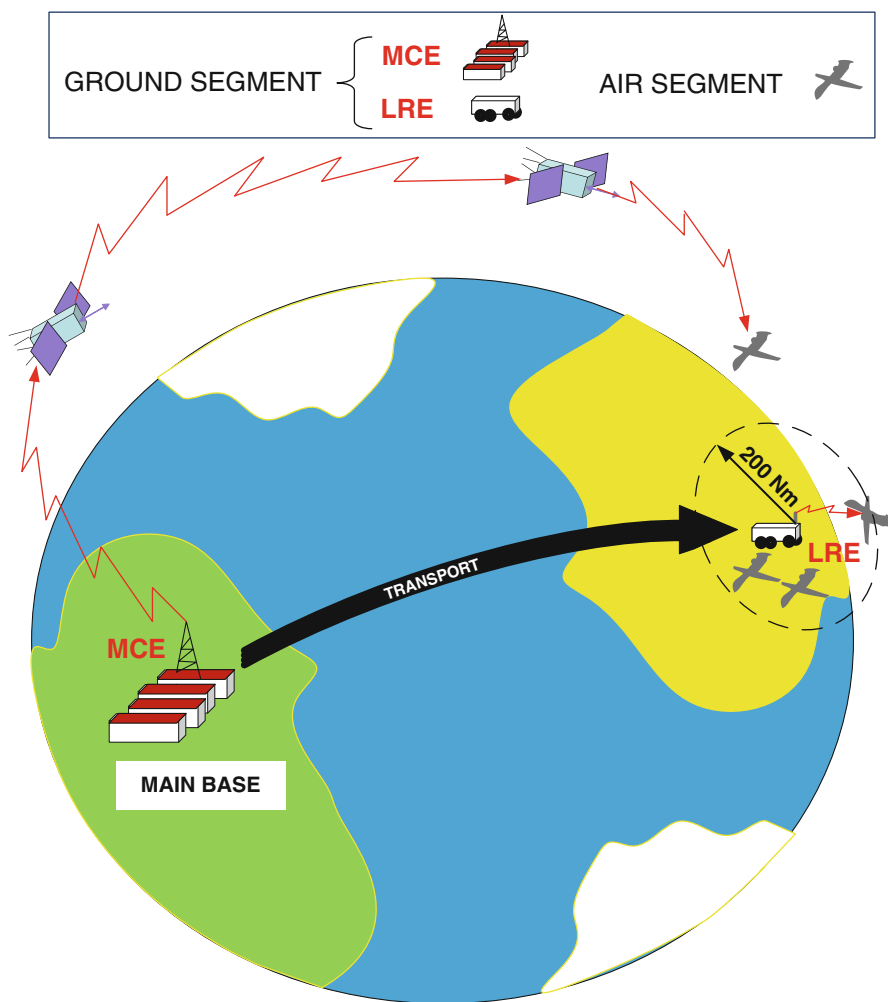

Fig. 107.23 Deployment in far settings

Other UAS peculiarities that produce effects on the RAMS characteristics are analyzed in the U.S. DoD “UAV Reliability Study” document (Unmanned Aerial Vehicle Reliability Study UAVs Design 2004). In consideration of the necessity of low acquisition cost for such systems, many failure causes derive from the choice of low reliability equipment, little redundancy of subsystems, and design inaccuracy. Other failure causes are more related to UAV design peculiarities, and are:

- Rain infiltration in the avionic bay: for simplicity of manufacture, in the absence of a cockpit, and in order to improve maintainability, UAVs generally have avionic equipment spread on a single stub plane between the nose of the fuselage

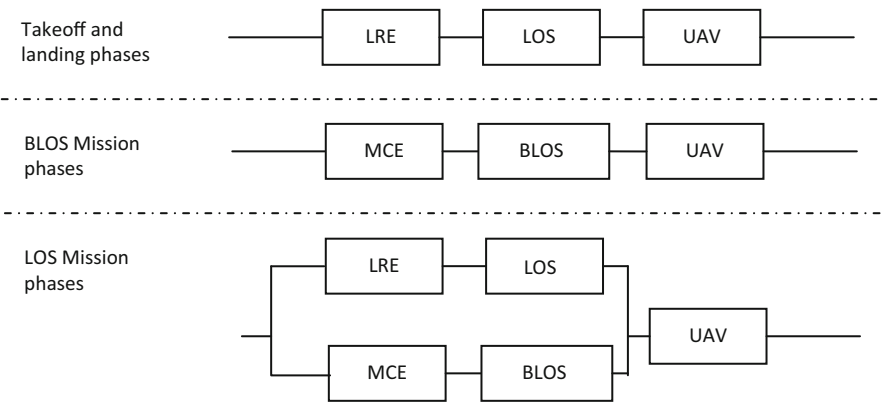

Fig. 107.24 Link between UAV and ground segment reliability block diagrams

Fig. 107.25 UAV avionics installation

and the wing cross. All the fuselage over the stub plane is a single removable fairing that is not easily sealed because of its size (Fig. 107.25).

- Low wing load: existing surveillance UAVs are designed to have a high aerodynamic efficiency and operational altitude, and these facts cause a low wing load. This fact, in addition to a low cruise speed, leads to a high sensitivity to gust. The flight in turbulent air may cause a reduction of sensor accuracy, possible loss of satellite link and flight control loss when the turbulence is so high that the flight control system is not able to restore the flight level (i.e., safety conditions).

In a case such as the one shown in Fig. 107.23, the logistic support of the UAS system, at least the one called “organizational field level maintenance” would be physically separated (part with UAVs and LRE, part with MCE) with reduction of possible synergies that, on the contrary, would be possible in operating and maintaining all the parts of the system in the same base. The synergies that would be lost could be: the transport with the same means utilized for spare parts, the

utilization of the same maintenance staff, and the utilization of part of the system operating team for other activities.

In addition, the UAS system shows peculiarities also for the maintenance and system operation staff. The UAS system needs a high number of operators; for instance, for the REAPER system (4 UAV, LRE and MCE), about 170 people would be employed (Deptula 2009). In comparison to traditional aircraft, it is necessary to attend to the maintenance not only of the flying segment, but also of the GCS; which means considering the GCS complexity, as it is to operate in autonomous way, with autonomous power generation, and with multiple piloting and control (up to 4 UAVs contemporarily). Moreover, in view of the single pilot that drives the traditional aircraft, it is necessary to consider, for UAS systems, not only the person that operates it, but also the staff that operate the sensors and the satellite link, and the staff that plans the mission, sometimes in real time. In future times, the staff can be reduced by increasing the decision autonomy.

It is necessary also to take into account that missions can last up to 30h, and teams of operators taking shifts during the mission are needed.

107.4 Integrated Logistic Definition

R.A.M.S. analysis and logistics have an extremely relevant impact on any aeronautic systems, and this is particularly true while talking about UAS.

In general, for future UAS achieving a satisfactory level of safety, apart from obvious deontological reasons, has to be considered as a mandatory condition, since it is mandatory to obtain flight permission; this fact is particularly true for UAS devoted to operation in a civil field. In this ambit, a very interesting aspect could be to focus attention on the aforesaid concept of ELS, considered especially when the plan crashes on ground; in particular, research activities are desirable in order to accurately assess, in design phases, values such as A_{exp} , P_{pen} , and P_{mit} ; while for this last, the problem will be simply to estimate the probability of success of various kind of safe flight termination systems that will be surely equipped on the various UAVs; for the other two parameters, a methodology of estimation would have to be elaborated. An initial idea for a reliable assessment, not only statistical, for A_{exp} and P_{pen} is being able to find a correlation between those values and design choices, which would be set according to a strategy such as the one described in Fig. 107.26. Useful ideas and methodologies can be, at least partially, taken from methodologies for studies of “survivability” that are usual for flight vehicles. We also see some synergy with “safety zonal analysis,” previously already assessed.

Safety, in design phase, shows very strong interactions with reliability and, in general, with the large field known as “R.A.M.S. techniques”; the relative dependence between safety and logistics is also strong, and can be reviewed as logistics depend from design through reliability and maintainability.

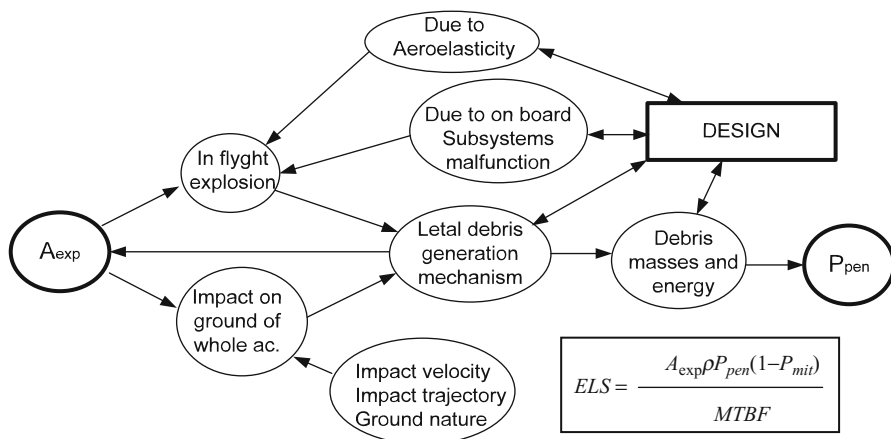

Fig. 107.26 Relationships between parameters of ELS

$$ELS = \frac{A_{exp} \rho P_{pen} (1 - P_{mit})}{MTBF}$$

The development of an integrated logistic system for UAS, in addition to the peculiarities examined for transportability, could be similar to the one used for other aircraft based systems; this is partly true, and it is demonstrated from the fact that methodologies like ILS, FMEA, RCM, LSA, LORA, LCCA are perfectly usable for UAS; a peculiarity of UAS is that the potential for use in generally not well defined and quickly changing places is extremely easy to waste. In addition, as UAS are still in a development phase, with a poor statistical data background, it has been observed that in many case traditional methodologies have stressed serious limits of applicability.

In such a situation, although the methodologies and the tools described before are to be considered generally valid, the uncertainties due to a lack of knowledge of quantity levels and/or provisional and nonstandard utilizing procedure, the possibility of having on hand a good simulation model of the system and of the operation and scenario, with in their evolution in time, is very important for evaluating possible alternatives, as well as for having a view of different results derived from different situations not predictable in advance. The model must obviously be precise enough to point out the differences of parameter values and/or qualitative differences (i.e., operative and logistic or, more generally setting procedures) that are not possible to be reliably evaluate in advance (Chiesa and Kostandinidis 1987; Chiesa and Olivero 1985).

A simulation tool must be able to simulate the operational environment mentioned above, and as a result forecast the right size for the considered UAV fleet and for their related logistic support (always in terms of operating bases and maintenance needs).

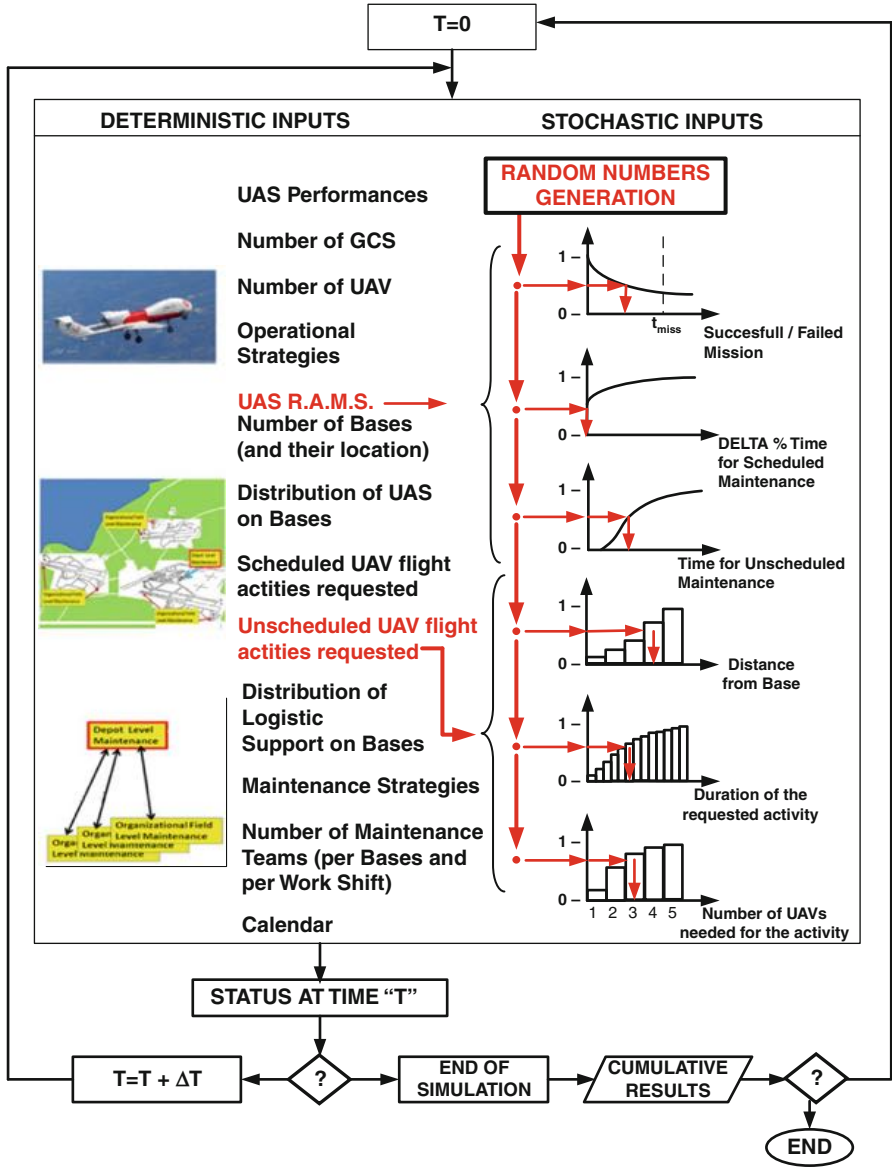

Fig. 107.27 Simulation model

Such a model must be able to consider as inputs all available data concerning the system, the scenario and the operations, summarized in Fig. 107.27. In this figure, it is shown that “inputs” can be of several kinds:

- *Deterministic Data*, that is data on which it is possible to assign an extremely precise numerical value, i.e.: number of UAV present, number of bases active

and number of GCS, number of maintenance teams present in each base for every work shift scheduled (shifts can be different day and night and between weekdays and holidays), calendar, with working days and holidays, for long enough period of time to include a planned operational cycle or a year, for instance for land monitoring systems, where seasons effects can be seen (i.e., summer engagement against bushfires mainly, winter engagement against bad weather damages), scheduled activities (for times and for activity extent, i.e., number of hours flown by a certain number of UAV) that are, in case of land monitoring systems, under seasonal influence, for instance different kinds of crop control.

It is necessary to consider not only numerical but more complex data like operative “procedures” (for instance when UAV of a certain base are requested to operate in another, they fly or are transported by land means) as well as maintenance ones (for instance, in the case that only one maintenance team is available and two aircraft need support, two options are possible: the first to be repaired is the one that can be more quickly reestablished, versus “the first arrived the first served”)

- *Stochastic Data*, that is, data depending on high randomness, for instance when a certain mission is successful or not, the time occurring for an unscheduled maintenance operation, the possible increase of already foreseen time to complete a scheduled maintenance operation, the possible arise of a flight activity necessity (for instance, for land monitoring systems again, a sudden flood) as date, length and strength, and number of UAV wanted to be in flight contemporarily. In Fig. 107.27 it is shown how the randomness of such events can be simulated, obviously by knowing the statistical distribution (that, as to RAMS characteristics, brings to the knowledge of parameters MTBF and MTTR) and matching to them the random numbers automatically generated; this technique is widely utilized and it is known as “Monte Carlo method” (Fishman 1996; Chiesa et al. 2010).

Please note, as Fig. 107.27 shows, that the data inputs set have to be updated at every simulation step, i.e., following the advancing time, and it is shown that at every time the status of the system is calculated, obviously on the basis of inputs data and of previous status.

The calculation of the new system status is operated by the part of the software that makes up the real system simulation model. To understand the working simulation model well, Fig. 107.28 shows a possible organization of it, based on the verification that, at time T , UAV takeoff is requested (for scheduled activities or for an arising request of nonscheduled activity, or to continue an activity already started).

All the UAV and all the maintenance teams taken into account in the simulation are now examined, by verifying the condition that has already been defined in the previous simulation step. Afterwards, they can be modified (or not), in relation to a possible request for takeoff, and the UAV status is “available,” the same UAV passes to the status “perform a new mission” (in reality “it will be taking off, starting the new mission”), while if a UAV is in the status “needs maintenance” it can pass to the status “under maintenance” only if at least one maintenance team is “available” (and consequently such a maintenance team passes to the status “working”). Please also

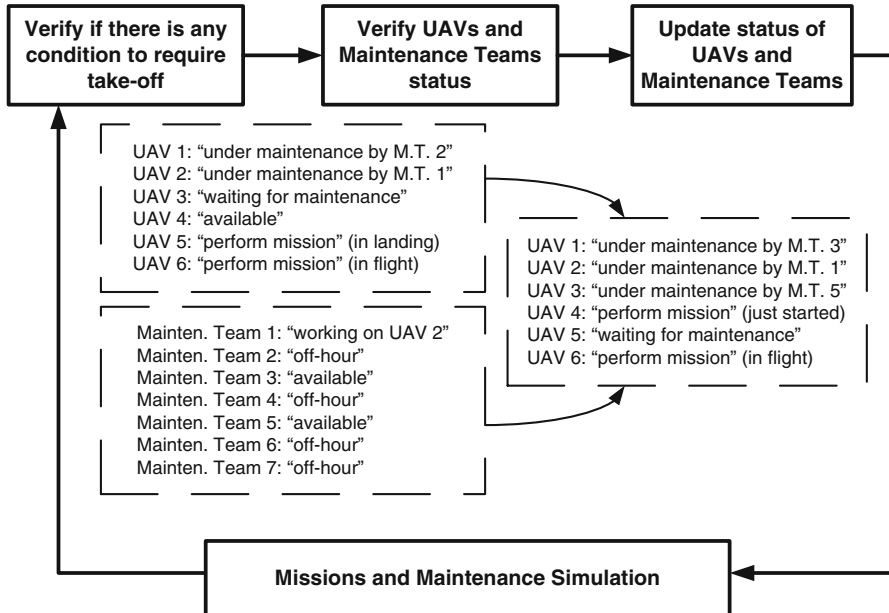

Fig. 107.28 Main loop flowchart

note that a UAV in status "under maintenance by team 'i'" can change its status if the aforesaid Maintenance Team "i" passes to the status "off-hour"; the transit could be to the status "under maintenance by team 'j'" or to "needs Maintenance" in the case that no maintenance teams were available. In particular, the dashed boxes in Fig. 107.28 show examples of these situations.

The model simulates the "active" status (not the "available" and the "waiting for Maintenance" ones) of the UAV (for those in status "under maintenance," considering also the maintenance team working on such UAVs). For both UAVs, with a possible active status ("perform mission" or "perform maintenance"), the simulation, during the step, can cause a changing of status; the possible changes are:

- From status "perform mission" to status "perform mission" if the mission has not been completed.
- From status "perform mission" to status "waiting for maintenance" if the mission is completed.
- From status "perform mission" to status "emergency re-entry" if a failure occurrence has happened.
- From status "under maintenance by maintenance team 'x'" to a status "available" if the maintenance activity has been completed in the time (casually) generated when it had started. At the same time, the status of maintenance team "x" becomes "available" unless it has reached the status "off-hour" at the same time.

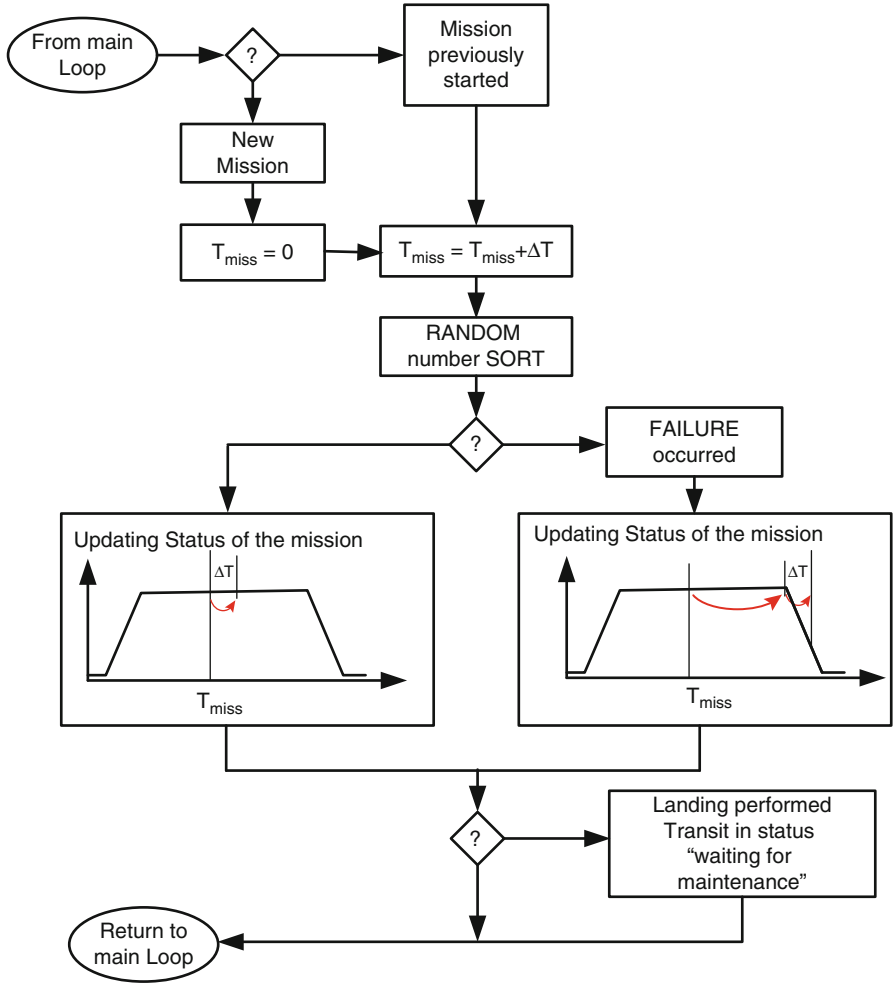

Fig. 107.29 Flowchart for “perform mission” task

- From status “under maintenance by maintenance team ‘y’ ” to a status “waiting for maintenance” if the maintenance activity has not been completed while the status of “maintenance team ‘y’ ” has become “off-hour”

In Fig. 107.29, the logic of the routine “perform mission” is shown as an explanation.

Back to Fig. 107.27, it is shown that the time will increase until a determinate value, for instance the accomplishment of a certain operational cycle or the end of a calendar year, if important effects of season become considerable; at this point, the results are disposable, but they are not immediately utilizable as they are incidental; that means deriving from the “random” numbers generated during the simulation. The problem can be solved by repeating several times the simulation

Fig. 107.30 Monte Carlo methodology output

Fig. 107.31 Simulation results – example

and considering the average of results obtained from the several simulations. If the average value among several simulations is considered, this value varies in relation to the number of effected simulations; for the first simulations, high oscillations of such an average result will be noticed, and these oscillations will gradually reduce with the increase of the number of simulations done, until the result stabilizes.

In Fig. 107.30, a typical “output” of an application of Monte Carlo methodology is shown; several lines are observed, every one of which represents the evolution of the average result of various simulations; this result trends to a stabilized value with the increase of the number of simulations done. The different lines refer to different “runs” of the Monte Carlo methodology; they are different only because of the different generation of random numbers; it is interesting to observe that they tend to stabilize not on a single value but on a very close one, offering the possibility of a result (stabilized results average) with a relating “confidence level.”

As previously said, the Monte Carlo simulation instrument can be extremely useful to define a complex system, as a UAS-based operative system certainly is. A well-realized and flexible model can obviously simulate the results obtainable by the system with its different configurations; for example, the number of UAVs and their performance and logistic characteristics could be changed; different distributions of the ground bases and/or different deployment of UAS and logistic resources on the same bases could be considered, as well as the utilization of different numbers of maintenance teams, with different work shifts and different operational and/or maintenance procedures; finally, different probabilities of events that require system unscheduled activities could be simulated.

The useful results obtained for every simulated solution are the expression of efficacy and efficiency of the same solution; possible results could be: number or flight hours/number of hours required (index of System efficacy), of UAVs utilization, percentage of maintenance teams utilization and so on. An example of results obtainable with a Monte Carlo simulation model applied to a system based on UAS is shown in Fig. 107.31.

| Abstract | |
| Although an Unmanned Aerial Vehicle (UAV) does not require a crew onboard, it is a kind of flying platform, which requires nearly the same logistics support similar to the most manned aircraft. UAV system is a system of the systems. Thus, UAV logistics support should cover the required support for all sub-systems of the UAV system including unmanned aircraft and, ground control station. | |
| UAV logistics support system depends on many different parameters including the type of the UAV system, its operational requirements, and its operational environment. It should be a system with a reduced logistic footprint, enabling a fast deployment and high mobility. | |
| Because of urgent operational requirement for the UAVs, traditional UAV design procedures weren't followed, and first prototypes were deployed for operations without enough consideration for logistics. So, mishap rate and sustainment cost of the initial UAVs was very high because of insufficient logistic consideration during design phase. Immature UAV systems have required many modernizations and upgrades. | |
| UAV logistics support system depends on many different parameters including the type of the UAV system, its operational requirements, and its operational environment. For a small hand-launched UAV system, relatively little logistics support is required, while larger UAV systems mostly need more logistics support. | |
| UAV logistics support should be considered during every phases of the life cycle. Logistics support efforts should be proactive to predict the possible problems before they become serious issues. | |
| The goal of this chapter is to provide the reader with general knowledge on UAV Logistics for Life-Cycle Management with the logistics challenges faced by the UAV pioneers and the possible future UAV logistics trends which improve UAV employment. | |

108.1 Introduction

Although a UAV does not require a crew onboard, it is a kind of flying platform, which requires nearly the same logistics support similar to the most manned aircraft. Improving the overall efficiency and readiness of UAV systems for all purposes, including military, civil, and commercial employments, is critical. A well-established and operated logistics system serves to increase the efficiency and readiness of the UAV system while decreasing the acquisition and sustainment costs for customers.

UAV system is a system of the systems. The employment the UAV system requires the contribution of each subsystem. One small failure or problem for a subsystem of the UAV system may impede the overall success of the operation at a certain level or completely stops the system. Thus, UAV logistics support should cover the required support for all subsystems of the UAV system including unmanned aircraft and ground control station.

UAV logistics support system depends on many different parameters including the type of the UAV system, its operational requirements, and its operational environment. It should be a system with a reduced logistic footprint, enabling a fast deployment and high mobility.

In a traditional acquisition, a system would be designed to meet certain requirements, and then a prototype would be built and tested before production of the operational vehicle. But, under some circumstances, the need to field a functional system may be greater than the need for a system that meets all requirements. According to a RAND Report [1] this has been the case for some current UAVs, whose prototype vehicles were quickly pressed into actual service, even as the overall production process was being accelerated; test, evaluation, and real-world operations were taking place concurrently. USAF UAS Flight Plan [2] states that the lack of any substantive logistics planning during acquisition has resulted in large contractor logistics support (CLS) expenditures, postproduction engineering studies, and modifications that could have been mitigated with a more rigorous approach.

Lessons learned during operational employment of the UAVs have been applied to later versions of such UAVs. So, mishap rate and sustainment cost of the later version UAVs have been decreased to reasonable numbers. Although there has been some important progress, this problem still exists for the newly developed UAVs in many countries. On the other hand, retrofits and upgrades created many different versions/blocks of the same UAV while creating different logistics support packages (mostly spares) for the same fleet of the UAV.

UAV operations resemble those of manned aircraft in many ways. The similarities include aerial platforms, professional personnel, use of airspace, requirement for aviation logistics support, and training. Although a UAV does not require a crew onboard, it is piloted or directed by a pilot or an operator from a ground or airborne control station. Thus, a UAV is a kind of flying platform, which requires nearly the same logistics support similar to the most manned aircraft.

For logisticians, basic support for UAV systems is the same as for manned aircraft. However, there are some fundamental differences between manned and unmanned systems that affect the UAV logistics support system. Here are some important characteristics that are unique for UAV systems:

- Critical importance of ground systems and payloads.
- Complicated system availability tracking because of the role many different subsystems.
- Fault isolation is more complex, requiring robust onboard diagnostics.

These unique characteristics and associated implications require a different approach than that of manned platforms in some areas of life-cycle management,

especially when engaged in requirements generation, systems engineering, product support planning, and management [2].

For a small hand-launched UAV system, relatively little logistics support is required, while larger UAV systems mostly need more logistics support. Like manned aircraft, UAV systems require dedicated logistical support, which includes the equipment to deploy, transport, launch, enable communications, and sustain the UAV system according to U.S. Army UAS Roadmap [3].

Since UAVs have only been employed by armed forces with quite a few examples of civilian and experimental UAV usages so far, UAV logistics support section is mainly based on military sources. But, UAV logistics support procedures, which are explained in this chapter, would be adapted to civil and commercial UAV employments that are expected to expend in mid-term future.

108.2 Logistics Principles

UAV systems require a logistics approach similar to manned aircraft. According to U.S. Marine Corps MCWP 3-21.2 Aviation Logistics document [4], the logistics planners and the entities responsible for the acquisition should consider the seven principles of the logistics:

- *Responsiveness*: Providing the right support at the right time and at the right place. UAV system could be deployed to anywhere easily in a relatively short time and operated efficiently with its logistics support system. The logistics system should provide necessary support in reasonable time. It should also respond to unpredictable failures.
- *Flexibility*: Adapting logistics support to changing conditions. A UAV system may be used for different purposes in any environment around the world. UAV logistics system should adopt itself to the new condition without a decrease in the logistics support and system operation efficiency.
- *Attainability*: The ability to acquire the minimum essential logistics support to begin operations. UAV logistic support package should not be a burden or impediment for the efficient employment of the UAV system. If the UAV logistics footprint is increased because of high level of spares and/or redundant tools/personnel, the mobility of the UAV system decreases while increasing its sustainment cost.
- *Survivability*: Ensuring the functional effectiveness of the logistics infrastructure in spite of degradation and damage. UAV systems will have to monitor their own health by using built-in tests (BIT) and will either have to notify the ground station of any failures or, in the case where data communications are not possible, will have to be preprogrammed with decision criteria on whether or not to continue with the mission [5].
- *Sustainability*: Ensuring adequate logistics support for the duration of the operation. UAV logistics support system should provide the necessary support while enabling required level of UAV system availability and reliability for operations with reasonable acquisition and sustainment costs.

- *Economy*: Effective employment of logistics support assets. UAV support equipment and maintenance procedures should be similar to those of other UAV types and manned aircraft in order to increase interchangeability and commonality while decreasing the acquisition and sustainment costs. It will be beneficial if UAVs use similar consumables and spares to that of manned aircraft.
- *Simplicity*: Avoiding unnecessary complexity in preparing, planning, and conducting logistics operations. Although UAV systems have many different complex systems and new sophisticated technologies, their logistic support should be as simple as possible.

108.3 Logistics Life-Cycle Management

There are many different acquisition process models; most of them are very similar. The United Kingdom Ministry of Defense’s acquisition process has six phases: concept, assessment, demonstration, manufacture, in-service, and disposal/termination. The U.S. Department of Defense’s acquisition process for a requirement has also six phases. The U.S. Department of Defense’s acquisition process [6] with the relevant procedures will be used as a basis in the following parts of the chapter of UAV logistics support with also considering the United Kingdom Ministry of Defense’s acquisition process [7].

The U.S. Department of Defense’s acquisition process for a requirement starts with the Materiel Development Decision. It consists of an identification of a capability gap, a description of related risks, and a recommendation of whether or not to enter the acquisition process or use a nonmateriel solution. Materiel Development Decision is followed by life-cycle phases.

Figure 108.1 depicts the life cycle phases for an advanced UAV system on a time scale and provides a general understanding how the phases take place. The durations

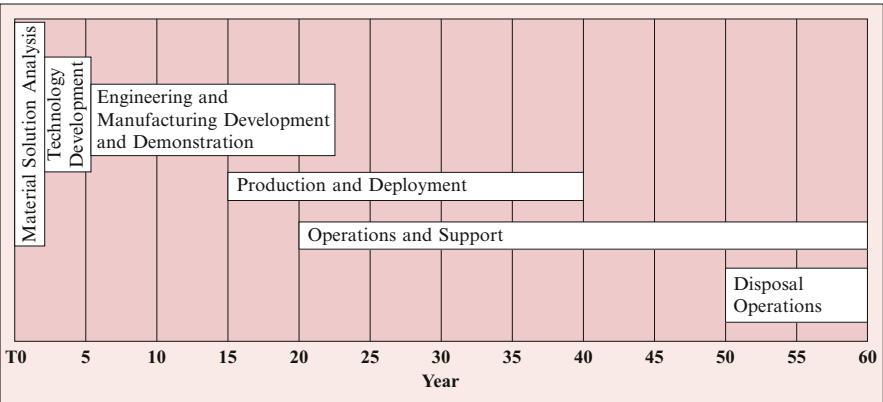

Fig. 108.1 Life-cycle phases

of the total life cycle and the phases depend on the type of the UAV system and the urgency level of the UAV system requirement. For an urgent operational requirement, UAV system development and production may be done in a couple of years, and of course, this simple UAV system could be in the inventory for a relatively short period of time. On the other hand, a complicated UAV system, which is similar to advanced manned aircraft, requires the same life-cycle approach like most manned aircraft.

Life-cycle sustainment planning shall be considered during Materiel Solution Analysis and shall mature throughout Technology Development. A Life-Cycle Sustainment Plan shall be prepared during Technology Development Phase. The planning shall be flexible and performance oriented, reflect an evolutionary approach, and accommodate modifications, upgrades, and reprourement. At every phases of the life-cycle support, logistics support efforts should be proactive to predict the possible problems before they become serious issues.

Logistics Life-Cycle Management System may be adopted for all types of acquisitions. For example, a user, such as a small Army with a requirement of a couple of UAVs, does not need to follow the first three phases of the life cycle. So, logistics support strategy/package would be prepared during Production and Deployment Phase.

108.3.1 Integrated Logistics Support (ILS)

Integrated logistics support (ILS) is an integrated and iterative process for developing materiel and a support strategy that optimizes functional support, leverages existing resources, and guides the system engineering process to lower life-cycle cost and decrease the logistics footprint (demand for logistics), making the system easier to support [6].

From the earliest stages of the systems development, the acquisition strategy and life-cycle sustainment plan will ensure that the requirements for each of the elements of ILS are properly planned, resourced, and implemented. These actions will enable the system to achieve the operational readiness levels required by the customers at the time of fielding and throughout the life cycle.

ILS is a comprehensive discipline that is applicable to all acquisition activity through life. However, the cost-effective application of ILS requires that there is a balance between benefit and cost. Research shows that over the whole life cycle of a product, the cost of acquisition is small compared to the cost of support, both financially and in unavailability of assets during operations. Reliability and maintainability have large implications on the overall cost of ownership. Thus, investment during development or production in these areas will be saved many times over the whole life of the product [8].

Although there are many descriptions for UAV classes, the NATO UAV classification described in the relevant NATO Strategic Concept [9] is the most widely accepted one. UK Joint doctrine Note 2/11 [10] acknowledges that many platforms

may well share characteristics across classes. The type of the UAV system has a critical importance on the logistics support system including ILS:

- *Class I:* These are typically hand-launched, self-contained, portable systems. Payloads are generally fixed electro-optical/infrared (EO/IR), and the system has a negligible logistics footprint.
- *Class II:* These UAVs are typically medium-sized, often catapult-launched, mobile systems. They do not usually require an improved runway surface. The payload may include a sensor ball with EO/IR, a laser range finding or designation capability, synthetic aperture radar and ground moving target Indicator (SAR/GMTI), and signal intelligence (SIGINT) pod. It has a small logistics footprint.
- *Class III:* These are typically the largest and most complex UAVs, operating at high altitude with, typically, the greatest range, endurance, and transit speeds of all UAVs. Payloads may include sensor ball(s) with EO/IR, multi-role radars, lasers, SAR, communications relay, SIGINT, automatic identification system (AIS), and weapons. Most Class III UAVs will require improved areas for launch and recovery and may be piloted from outside the joint operations area via a satellite control link. The logistics footprint may approach that of manned aircraft of similar size.

108.3.1.1 Supportability Analysis

Supportability analysis is the principal tool of ILS. It is the primary means by which the objectives of ILS are achieved and its activities consist of a series of analytical tasks which [7]:

- Influences the design of the product to take account of logistic support considerations
- Identifies support issues, readiness requirements, and cost drivers as early as possible in the product life cycle
- Defines logistic support resource requirements for the life of the product
- Creates the cost-effective physical logistic solution
- Creates the necessary data for logistic support and project decision-making, through life
- Creates the necessary information for logistic support and project decision-making.

108.3.1.2 ILS Elements

The ten ILS elements listed in Fig. 108.2 are described in the following part with using Defense Acquisition University information [6] and U.S. Army Regulation 700–127 Integrated Logistics Support [11].

108.3.1.3 Design Influence

Design influence is a systematic approach to the integrated, concurrent design of products and their related processes, including manufacture and support. This approach is intended to cause developers, from the outset, to consider all elements of the product life cycle from conception through disposal, including quality,

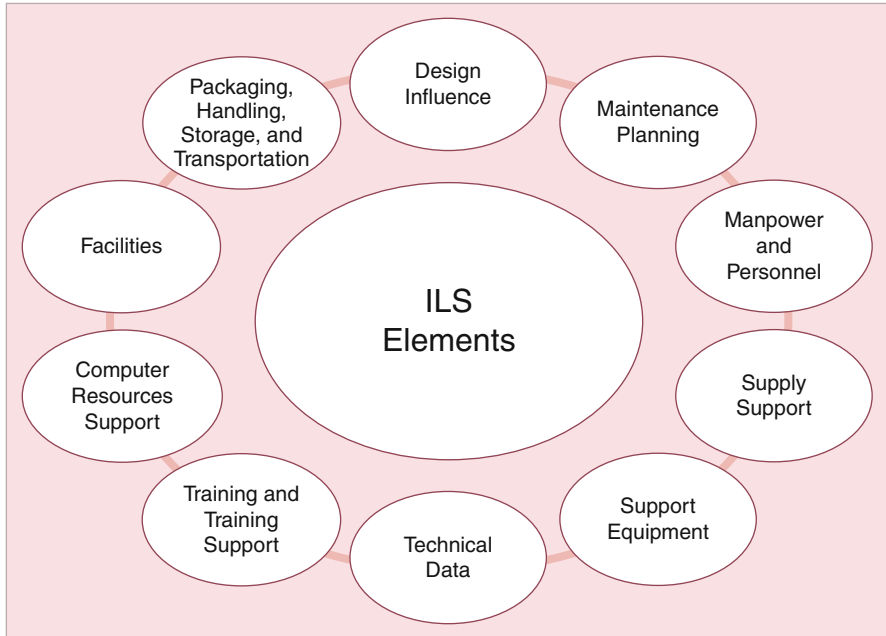

Fig. 108.2 ILS elements

cost, schedule, and user requirements. Logistics design influence acknowledges the inherent characteristic of design in recurrent logistics fundamentals. It seeks to imprint these logistics fundamentals into the end-item design as part of the system configuration and performance parameters.

108.3.1.4 Maintenance Planning

Maintenance planning is the process conducted to evolve and establish maintenance concepts and support requirements for the life of the system. It includes the following:

- Describe the maintenance concept for the system including all levels of maintenance. Identify trade-offs to be performed and maintenance considerations peculiar to the system.
- Identify maintenance tasks required to sustain the end item at a defined level of readiness, including all critical and high tasks.
- Describe the general overall support concepts. Identify proposed or actual skills; tools; test, measurement, and diagnostic equipment (TMDE), support equipment, and so on, to be available at each level of maintenance. Include analysis of possible design for discard of components and repair parts.
- Indicate strengths and weaknesses of each support alternative and the effect of the support concept on the system design, system readiness objectives (SRO),

acquisition and operations & sustainment (O&S) costs, and on affected ILS elements.

- Summarize known or planned interservice support, host nation support (HNS), interim contractor support (ICS) or life-cycle software support (LCCS), and contractor warranties. Identify proposed solutions to potential problems that may result during transition to organic support.
- Include information about planned organic depot maintenance.
- For systems being acquired for multiservice use, address the feasibility and desirability of centralized repair and supply support by a single service, the predominant user in a geographical area, or the one with centralized support capability.

108.3.1.5 Manpower and Personnel

It is the process of identifying and acquiring military and civilian personnel with the skills and grades required to operate and support a materiel system over its lifetime at peacetime and wartime rates.

The overall objective of ensuring that during equipment definition and procurement, full account is taken of the capabilities and limitations of the military and civilian personnel required to operate and maintain the equipment or facility in-service.

108.3.1.6 Supply Support

Supply support includes all the management actions, procedures, and techniques used to determine requirements to acquire, catalog, receive, store, transfer, issue, and dispose of secondary items. This means having the right spares, repair parts, and supplies available in the right quantities, at the right place, at the right time and at the right price.

The objective of supply support is to identify, plan, resource, and implement management actions to acquire repair parts, spares, and all classes of supply to ensure the best equipment/capability is available to support the warfighter or maintainer when it is needed at the lowest possible life-cycle cost.

The process includes provisioning for initial support, as well as acquiring, distributing, and replenishing inventories. This encompasses provisioning for initial support and all end-to-end replenishment supply support and supply pipeline plans and activities. Supply support must be distribution based rather than inventory based and proactive rather than reactive.

During all phases of Life-Cycle Management System, reliability improvement developments should be continuously considered, which may result in a decrease in malfunctions leading to a decrease in spare part quantities.

108.3.1.7 Support Equipment

Support equipment includes all the management actions, procedures, and techniques used to determine requirements for and to acquire the fixed and mobile equipment needed to support the operations and maintenance of a system.

The objective of support equipment is to identify, plan, resource, and implement management actions to acquire and support the equipment (mobile or fixed) required to sustain the operation and maintenance of the system to ensure that the system is available when it is needed at the lowest life-cycle cost. Support equipment consists of all equipment (mobile or fixed) required to support the operation and maintenance of a system. This includes, but is not limited to, ground handling and maintenance equipment, trucks, air conditioners, generators, tools, metrology and calibration equipment, and manual and automatic test equipment. During the acquisition of systems, program managers are expected to decrease the proliferation of support equipment into the inventory by minimizing the development of new support equipment and giving more attention to the use of existing government or commercial equipment.

108.3.1.8 Technical Data

Technical data is all scientific or technical information, equipment publications and technical drawings associated with the system, and its operation, maintenance, and support. Technical data for all support equipment are also included under this ILS element. Although computer programs and related software are not considered technical data, any documentation about computer programs, software support, and output reports is considered technical data.

Technical data are used to provide the necessary information to manufacture and support the system after deployment. The Technical Data Package (TDP) may include engineering drawing and specifications, process descriptions, and documents that define physical dimensions, material composition, performance characteristics, manufacture, assembly, and acceptance test procedures.

Technical manuals information may be presented, according to prior agreement between the contractor and the customer, in any form or characteristic, including hard printed copy, audio and visual displays, electronic imbedded media, disks, other electronic devices, or other media. They normally include operational and maintenance instructions, parts list, and related technical information or procedures exclusive of administrative procedures [12].

The manuals will be drafted in the Engineering and Manufacturing Development and Demonstration Phase and amplified in the Production and Deployment Phase. ICAO Annex 6 [13] require that the operations manual shall be amended or revised as is necessary to ensure that the information contained therein is kept up to date. All such amendments or revisions shall be issued to all personnel that are required to use this manual.

108.3.1.9 Training and Training Support

Training and training support consists of the processes, procedures, and techniques used to identify requirements for and to acquire programs of instruction, training facilities, and training systems/devices needed to train/qualify military and civilian personnel to operate and maintain a system proficiently. This includes institutional training, on-the-job training, new equipment training, sustainment training, and individual/crew training.

The goal of training and training support is to plan, resource, and implement a cohesive integrated strategy to train military and civilian personnel to maximize the effectiveness of the doctrine, manpower, and personnel, to fight, operate, and maintain the equipment throughout the life cycle.

As part of the strategy, plan, resource, and implement management actions to identify, develop, and acquire training aids devices simulators and simulations to maximize the effectiveness of the manpower and personnel to fight, operate, and sustain equipment at the lowest total ownership cost.

Training is the learning process by which personnel individually or collectively acquires or enhances predetermined job-relevant knowledge, skills, and abilities by developing their cognitive, physical, sensory, and team dynamic abilities. The “training/instructional system” integrates training concepts and strategies and elements of logistic support to satisfy personnel performance levels required to operate, maintain, and support the systems. It includes the “tools” used to provide learning experiences such as computer-based interactive courseware, simulators, and actual equipment (including embedded training capabilities on actual equipment), job performance aids, and interactive electronic technical manuals.

All UAV systems should be developed with the maximum use of personalized learning management, simulation-enabled computer-based training and virtual instruction. Training for support equipment should also be a part of the training package.

108.3.1.10 Computer Resources Support

Computer resources support is all the management actions, procedures, and techniques used in determining requirements and acquiring hardware, software, facilities, documentation, personnel, and manpower required to develop and sustain computer resources for operation and maintenance of a system, including planning and support requirements for post-deployment software.

Computer resources support element evaluates the operational and support capabilities of the various computer resource systems. The evaluations will center on the overall operational and support concepts of computer resources, the effectiveness of computer resources, quality and accuracy of data, and man/machine interface. The computer resources support evaluation will include evaluation of the built-in test (BIT) system, all computer resources that interface with the test article, all off-equipment computer resources the maintainer may interface with to complete a task, and all test article systems involving computer resources [14].

As the primary end item, support equipment, and training devices increase in complexity, more and more software is being used. The expense associated with the design and maintenance of software programs is so high that one cannot afford not to manage this process effectively. It is standard practice to establish some form of computer resource working group to accomplish the necessary planning and management of computer resources support. Computer programs and software are often part of the technical data that defines the current and future configuration baseline of the system necessary to develop safe and effective procedures for operation and maintenance of the system. Software technical data comes in many

forms to include, but not limited to, specifications, flow/logic diagrams, computer software configuration item definitions, test descriptions, operating environments, user/maintainer manuals, and computer code.

108.3.1.11 Facilities

Facilities consist of all the management actions, procedures, and techniques used to determine requirements for and to acquire the permanent and semi-permanent real property assets needed to support operation, maintenance, and storage of a system and its support equipment.

The objective of facilities is to identify, plan, resource, and acquire facilities that will allow storage, maintenance, and training to maximize the effectiveness of a systems operation and logistic support system at the lowest life-cycle cost and enable responsive support to the warfighter by identifying and preparing plans for the acquisition of facilities.

Facilities consist of both semipermanent and permanent real property assets for the support of a system. Studies that define location, types of facilities, facility improvements, space needs, security requirements, environmental requirements, and equipment are also considered in facilities. This element includes new and modified facilities for supply storage, equipment storage, ammunition storage, maintenance, etc.

Although nearly all of the UAV systems are mobile systems, most of them require some infrastructure such as hangars, aprons, taxiways, runways, buildings, communication lines, and electricity. The facilities for support equipment should also be a part of the facility requirement. Moreover, facilities for the storage of hazardous material such as lithium batteries required for UAV operations must be planned.

108.3.1.12 Packaging, Handling, Storage, and Transportation (PHST)

The PHST concept describes any anticipated special considerations for the packaging, handling, storage, and transportability required for deployment and sustainment of the system as well as the process for determining these requirements. The operational environment conditions (temperature, humidity, etc.) and potential for use of hazardous materials must be considered.

Transportation of a UAV system will range widely from the one or two man-carried backpacks of a small UAV to a strategic UAV system with a requirement of strategic airlift. Since the strategic airlift platforms are very rare at the moment, the air transportation of the UAV system requires special consideration. Transportation of the UAV system from main base to the operational deployment location should be planned carefully.

A typical medium altitude long-endurance (MALE) UAV system like ANKA, Heron, MQ-1B Predator, or MQ-9 Reaper consists of 4 UAV platforms, one or two ground control station, one or two ground data terminal, some support equipment, and an important amount of spares. These systems and equipment should be packed properly for the air transportation. Strategic airlift is required for the deployment of such UAV system. Although the required airlift capacity depends on the type of the

UAV system, typically two to three An-124, IL-76, or C-17 sorties, and six to seven C-130 or C-160 sorties are sufficient.

108.3.2 Performance-Based Logistics (PBL)

B.D. Coryell [15] states that PBL means different things to different people, but principally it is defined as establishing a contract or agreement with a logistics provider for a specified level of performance for an item at a system, subsystem, or component level. This level of performance can be achieved by a contractor, the government, or a combination of both.

According to Defense Acquisition University document of Performance-Based Logistics: A Program Manager's Product Support Guide [16], PBL is the purchase of support as an integrated, affordable, performance package designed to optimize system readiness and meet performance goals for a weapons system through long-term support arrangements with clear lines of authority and responsibility. Simply put, performance-based strategies buy outcomes, not products or services.

The application of PBL can provide numerous benefits. The most visible benefits of PBL are in the operational portion of the program life. PBL should reduce logistics costs and footprint, increase system reliability, and mitigate obsolescence [15]:

- *Reducing logistics cost and footprint:* PBL will get the best capability return on the funds available in the Defence Forces to support weapons systems. In other words, incentive-oriented agreements should reduce product support costs through reduced infrastructure, reduced obsolescence, and reduced provisioning and data requirements. PBL will provide more visibility and control over operations and support costs which will ultimately improve the ability to manage program resources. With this visibility and control, PBL should create a reduction in the overall demand for logistic support and reduce the logistics footprint.
- *Increasing system reliability:* Incentive oriented agreements will improve weapon system availability and provide warfighters with increased operational readiness. The provider is provided incentives to ensure that set levels of system support performance are achieved. If the contract is correctly incentivized, the items, components, or subsystems that configure the weapon system will be designed to fail less. The PBL supplier then has the financial incentive to continuously improve performance because it has a bottom-line impact. This in turn will improve customer satisfaction. PBL will result in confidence in the warfighter that the system will provide the required performance capabilities when needed in combat.
- *Mitigating obsolescence:* PBL provides a powerful tool for mitigating obsolescence and making continuous modernization a reality for legacy weapon systems. PBL clearly fulfills the need for continuous modernization and obsolescence mitigation. Because it provides incentives for private industry to continually improve reliability and the performance of the managed system. In this manner, private industry conducts research and development and acquisition activities

in-stride with performing their contracted logistics support contract. Consistent with evolutionary acquisition practices and the spiraling of technology as it matures, the PBL contractor can leverage research and development efforts for spirals into legacy component system reliability.

The essence of PBL is buying performance, instead of the traditional approach of buying individual parts or repair actions. It is important to note that, although the fundamental concept of buying performance outcomes is common to each PBL arrangement, the PBL strategy for any specific program or commodity must be tailored to the operational and support requirements of the end item.

A key component of any PBL implementation is the establishment of metrics. Since the purpose of PBL is “buying performance,” what constitutes performance must be defined in a manner in which the achievement of performance can be tracked, measured, and assessed [16]. U.S. DoD Momerandum [17] lists the following criteria to be used for PBL performance objectives:

- *Operational availability*: The percent of time that a system is available for a mission or the ability to sustain operations tempo.
- *Operational reliability*: The measure of a system in meeting mission success objectives (percent of objectives met, by system). Depending on the system, a mission objective could be a sortie, tour, launch, destination reached, or other service- and system-specific metric.
- *Cost per unit usage*: The total operating cost divided by the appropriate unit of measurement for a given system. Depending on the system, the measurement unit could be flight hour, steaming hour, launch, mile driven, or other service- and system-specific metric.
- *Logistics footprint*: The government/contractor size or “presence” of deployed logistics support required to deploy, sustain, and move a system. Measurable elements include inventory/equipment, personnel, facilities, transportation assets, and real estate.
- *Logistics response time*: The period of time from logistics demand signal sent to satisfaction of that logistics demand. “Logistics demand” refers to systems, components, or resources (including labor) required for system logistics support.

There is no “one-size-fits-all” approach to PBL. Similarly, there is no template regarding sources of support in PBL strategies. It comprises a combination of public (organic) and private (commercial) support sources. Finding the right mix of support sources is based on best value determinations of inherent capabilities and compliance with statutes and policy. This process will determine the optimum PBL support strategy within the product support spectrum, which can range from primarily organic support to a total system support package provided by a commercial original equipment manufacturer [16].

According to University of Tennessee and Supply Chain Visions’ White Paper [18], PBL may be implemented at four levels:

- *Level 1 – Component*: The lowest level of PBL implementation is at the system component level, such as aircraft tires. At this level the “performance” purchased is the consistent and timely delivery of needed components. The scope of support

responsibility for the contractor is generally narrow – focusing primarily on supply chain activities.

- *Level 2 – Major subsystem:* At level 2 the scope of support and corresponding performance outcomes broadens, and the customer/operator-contractor relationship begins to become more collaborative. The focus is not just on delivery speed, but on broader improved material availability, which necessitates enlarging the scope of support to include not only supply chain activities but also encompassing repair processes, engineering and technical support, configuration management, and even minor modifications and process improvements. One of the best examples of a major subsystem PBL is the GE F404 Aircraft Engine.
- *Level 3 – Platform availability:* At this level the scope of support is the buying warfighter performance. The warfighter doesn't think in terms of employing components or subsystems; their focus is on the availability and readiness of weapon system platforms – an aircraft, a ship, or a tank – the tools of combat capability. Consequently, this level of PBL transfers even more responsibility for management of support activities to the contractor. One example of a level 3 PBL is the Lockheed Martin and U.S. Air Force Total System Support Partnership (TSSP) program involving the F-117 Nighthawk.
- *Level 4 – Mission:* While level 3 PBLs optimize weapon system availability for the warfighter, what the warfighter ultimately needs in combat is not only for the system to be available to perform its mission but to successfully complete the mission. One of the best examples is the Army Shadow Tactical Unmanned Aerial Vehicle program.

108.4 Logistics During Materiel Solution Analysis Phase

The purpose of Materiel Solution Analysis Phase is to assess potential materiel solutions. During Materiel Solution Analysis Phase, ILS issues, supportability deficiencies, and opportunities for improvements and efficiencies are evaluated.

Prior to the Materiel Development Decision, supportability objectives must be clearly defined. System supportability objectives provide the basis upon which product support capabilities are evaluated. They include design, technical support data, and maintenance procedures to facilitate detection, isolation, and timely repair and/or replacement of system anomalies.

The goal is to ensure product support capabilities, requirements, and risks are considered early and throughout the acquisition continuum, in order to minimize support costs, provide end users with required resources, and attain materiel availability objectives.

To facilitate an evaluation of product support capabilities, from concept through fielding, required system reliability, planned maintainability, and supportability methods, practices, and processes must be clearly defined and integrated with the systems engineering process. Additionally, the concept of operations must be

defined to provide the basis for assessing system requirements and overall product support capabilities, as well as the initial definition of the system maintenance and support concept for sustainment.

Life-cycle sustainment planning and execution should seamlessly span a system's entire life cycle, from Materiel Solution Analysis to disposal. It translates force provider capability and performance requirements into tailored product support to achieve specified and evolving life-cycle product support availability, reliability, and affordability parameters.

108.5 Logistics During Technology Development Phase

The purpose of Technology Development Phase is it to reduce technology risk and to determine the appropriate set of technologies to be integrated into the full system. It is an iterative process designed to assess the viability of technologies while simultaneously refining user requirements. The Technology Development Phase begins when a materiel solution has been endorsed in the end of the Materiel Solution Analysis Phase.

Logistics support goals for the Technology Development Phase are to refine sustainment objectives and requirements, demonstrate system feasibility and mature technology, and design in sustainment and establish Product Support Package requirements.

The objective of the Technology Development Phase is to reduce technology risk. From a sustainment standpoint, this means designing critical supportability aspects into the system and developing the system support package.

A sustainment concept should be prepared in the Materiel Solution Analysis Phase. At the beginning of the Technology Development Phase, the data gathered while developing the sustainment concept should be used to establish sustainment requirements. The sustainment concept should also feed the design of the product support package. The Product Support Package has two major components:

- The Maintenance Plan and Requirements describe the management approach for developing and implementing the maintenance plan.
- Product Support Package Elements include an overview of technical documentation (paper and electronic), Test/Support & Calibration Equipment, Manpower & Training/Computer-Based Training, supply support, packaging, handling, storage and transportation, facilities, and computer resources support.

The program manager should develop a product support strategy for life-cycle sustainment and continuous improvement of product affordability, reliability, and supportability while sustaining readiness. The support strategy is a major part of the acquisition strategy which includes design, technical support data, and maintenance procedures to facilitate detection, isolation, and timely repair and/or replacement of system anomalies. This includes factors such as diagnostics, prognostics, real-time maintenance data collection, and human system integration considerations.

108.6 Logistics During Engineering and Manufacturing Development and Demonstration Phase

The purpose of Engineering and Manufacturing Development and Demonstration Phase is to develop a system or an increment of capability, complete full system integration, develop an affordable and executable manufacturing process, ensure operational supportability with particular attention to minimizing the logistics footprint, implement human systems integration, design for producibility, ensure affordability, and demonstrate system integration, interoperability, safety, and utility.

During Engineering and Manufacturing Development and Demonstration Phase, Product Support Plan is developed. Product (or logistics) Support Plan is a document that outlines how product support and sustainment of a weapon system will be managed over its life cycle. Product support is the package of support functions necessary to maintain the readiness and operational capability of weapon systems, subsystems, and support systems. It encompasses all critical functions related to weapon system readiness, including materiel management, distribution, technical data management, maintenance, training, cataloging, configuration management, engineering support, repair parts management, failure reporting and analyses, and reliability growth.

Logistics support model is to be defined at System Development and Demonstration Phase. The source of the support may be organic or commercial, but the product support plan's primary focus is to optimize customer support and achieve maximum availability at the lowest total ownership cost.

UAV platform may incorporate a modular design for flexible payload configuration. The configurable pods and payload bays can house a wide array of sensors and weapons. Fault isolation within UAV system must mostly be accomplished by using built-in test (BIT).

The design of the UAV systems should consider the climatic extremes ranging from high temperatures in arid regions, through frigid temperatures with associated ice and snow, to tropical climates with high relative humidity and excessive rainfall.

108.7 Logistics During Production and Deployment Phase

The purpose of Production and Deployment Phase is to achieve an operational capability that satisfies the mission need. Operational test and evaluation shall determine the effectiveness and suitability of the system. During the Production and Deployment phase, the system should achieve operational capability that satisfies mission needs. It has two main stages: Low-Rate Initial Production and Full-Rate Production and Deployment.

Low-Rate Initial Production (LRIP) is intended to result in completion of manufacturing development in order to ensure adequate and efficient manufacturing capability to produce the minimum quantity necessary to provide production-representative articles for testing and evaluation.

Full-Rate Production and Deployment should be based on the results of testing initial production articles and refining manufacturing processes and support activities which indicate the product is operationally capable, lethal and survivable, reliable, supportable, and producible within cost, schedule, and quality targets.

During Production and Deployment Phase, all documentation is finalized, necessary training of personnel for maintenance and operations are accomplished, and Product Support Package/Performance-Based Logistics (PBL) is implemented.

108.8 Logistics at Sustainment (Operations and Support)

Logistics plays a crucial role at sustainment phase, which takes place between acquisition to disposal phase. In logistics point of view, sustainment is the longest part of the ILS. This period lasts 10–30 years up to requirements, economy, and technological trends. During this period UAV systems are required a perfectly coordinated and regularly manipulated logistic system.

The purpose of logistics at sustainment is to execute a support program that meets materiel readiness and operational support performance requirements and sustains the system in the most cost-effective manner over its total life cycle.

During sustainment, logisticians execute a support program that meets materiel readiness (availability) and operational support performance requirements and sustains the system in the most cost-effective manner over its total life cycle. When the system has reached the end of its useful life, it shall be disposed in an appropriate manner.

System modifications are initiated whenever necessary to improve performance and reduce ownership costs. The users conduct continuing reviews of sustainment strategies, utilizing comparisons of performance expectation as defined in performance agreements against actual performance measures. Sustainment strategies are revised, corrected, and improved as necessary to meet performance requirements.

108.8.1 Supply

Supply is an essential part of logistics for all kind of systems. In maintenance point of view, its necessity comes from the requirement of material flowing, because maintenance process can't occur without it. In aviation supply plays a crucial role, and also UAV systems pursue this rule. This section of logistics deals with acquisition, packaging, shipping spares, and meeting them with technicians.

To supply all the equipment for an Unmanned Air System (UAS) rapidly is required to establish a reliable and robust supply mechanism. Operational requirements, especially expected flying hours, declare the time toleration for spare packages. In order to manage products and ensure high levels of equipment availability with an online asset management tool which tracks complete UAS flying hours, life expired and obsolete parts are replaced in a timely manner that fits in the mission cycle. Emergency logistical support is also maintained through the level of

spares management and rapid distribution system. The supply materials may be consumables or replaceable components. Reg Austin defines them as follows [19];

- Consumables: Depending upon the size of the system and the quantities required, lubricants, cleaning materials, batteries, and fuel may be carried within the Control Station (CS) especially if the CS vehicle uses the same type of fuel as the aircraft. Otherwise, for larger systems or for safety reasons, fuel will be carried in a separate vehicle or browser.
- Replaceable components: These kinds of components are listed in the Maintenance Manuals, and the replenishment of these to the UAV system's operating base is required from the logistics support organizations.

To supply all of the required equipment rapidly, a robust and well-defined chain must be established. This chain is generally called as supply chain. A supply chain is a complex logistics system in which raw materials are converted into finished products and then distributed to the final users. It includes suppliers, manufacturing centers, warehouses, distribution centers, and retail outlets. At this point reflection of the supply chain on the supply process of UAVs is inspected. Not only the regular periodic maintenances but also the unplanned repairs require spare materials. Establishing a supply-flow method is a crucial target for logistic planner. For this purpose an effective and optimal supply chain must be planned before sustainment and applied during sustainment. In planning phase the following factors are taken into account, and also this list may increase or decrease according to the requirements:

- Flying hours: The expected flying hours of UAV in a year, also this includes consecutive flying hours
- Number of the UAVs and ground assets: The number of UAVs and ground assets achieved during procurement and probable loss and additive assurance amount during sustainment
- Percentage of availability during life cycle: The amount of available UAVs and ground assets in a definite period of time during life cycle
- Probable service life: Expected life cycle of UAVs and whole related assets (ground assets, avionics, payloads, etc.)
- Obsolescence program: To put probable expired and obsolete parts on a time table

By using the aforementioned requirements, an analysis is conducted, and an application plan is prepared. This plan must support all the maintenance levels. Additionally this plan should meet the readiness requirements of UAV system. After preparing the plan, it is applied to practical life. A supply chain is established, and related stakeholders are connected to the chain network. An example of UAV system supply chain is shown in Fig. 108.3.

108.8.2 Maintenance

Maintenance is most critical and time-consuming part of logistic activities during the life cycle of all kind of systems. Within the airline industry, it has been estimated

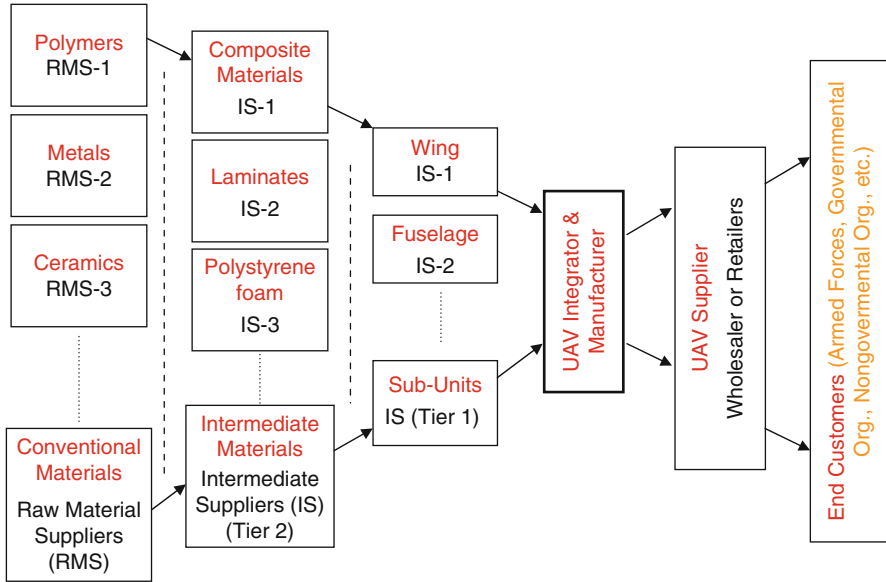

Fig. 108.3 A supply chain example for UAV system

that for every hour of flight, 12 man-hours of maintenance occur. Maintenance was defined as any activity performed on the ground before or after flight to ensure the successful and safe operation of an aerial vehicle. Maintenance generally includes the following:

- Assembly
- Fuelling
- Preflight inspections
- Repairs
- Regular maintenances
- Software updates

Maintenance activities may involve the vehicle as well as equipment such as the UAV ground control station. According to the maintenance point of view, activities can be classified as either corrective or preventative. Corrective maintenance involves the repair or replacement of systems that have experienced wear or damage. In many cases, corrective maintenance is nonroutine and is performed in response to an operational event such as a hard landing or a system failure. Nonroutine tasks are more likely to require fault diagnosis, problem-solving, and special skills. Preventative maintenance tasks are performed before a problem occurs and may involve tasks such as inspections, lubrication, or the replacement of components at predetermined intervals. Preventative maintenance tasks are typically routine and tend to require a more limited range of skills and knowledge than corrective maintenance tasks [20].

108.8.2.1 Maintenance Plan for UAVs

In general perception a maintenance plan describes the requirements and tasks to be accomplished for achieving, restoring, or maintaining the operational capability of the UAVs. A maintenance plan is a concise summary of maintenance requirements that is performed on the system. It is prepared at the beginning of the project with the other project plans. A maintenance plan should preserve the inherent design levels of the UAV subsystems reliability with minimum expenditure of maintenance and support resources.

A maintenance plan establishes and defines the line-replaceable units (LRUs) categories in groups of repairable LRUs and consumable LRUs that required maintaining UAVs. For each LRU, the maintenance plan identifies the maintenance level authorized to perform the required maintenance tasks. The maintenance plan also provides Source, Maintenance, and Recoverability (SMR) codes, which summaries the maintenance concept of each LRU.

For preparing a maintenance plan, some preliminary estimated information is used. This information reflects the general requirements of UAVs. These requirements include, but are not limited to, the following:

- Flying hours: The expected flying hours of UAV in a year, also this includes consecutive flying hours.
- Reliability: The probability of realization of the required function in identified case and in between a certain time.
- MTBF (mean time between failures): Average time duration of a system or equipment not working or malfunctioning in a certain interval.
- MTBM (mean time between maintenance): Average time between all maintenance actions (protective and corrective).
- MCMT (mean corrective maintenance time): Mean corrective maintenance time is composed of some elements. It is mathematically modeled as follows:

$$MCMT = T_p + T_{fi} + T_d + T_i + T_r + T_a + T_{co} + T_{st}$$

T_p = Mean readiness time

T_{fi} = Trouble shooting time

T_d = Mean disassembling time

T_i = Mean replacing time

T_r = Mean assembling time

T_a = Mean corrective time

T_{co} = Mean checkout time

T_{st} = Mean starting time

- Mean preventive maintenance time – MPT: The preventive maintenance contains the procedures to keep the system in a certain performance level and the functions such as periodic inspections, services, and calibration. MPT is the average of time duration passed during preventive maintenance.
- Logistic delay time – LDT: Total duration of required time to receive the repair equipment, spare parts, or maintenance test equipment.
- Maintenance labor hours per month – MLH/month: The total cost of monthly maintenance labor man-hour.
- Probable expired and obsolete parts on a time table.

After determining the life-cycle requirements of UAVs, a maintenance plan is established by using the information of requirements and the experiences of contractor and customer. Maintenance plan shapes the maintenance structure during sustainment.

108.8.2.2 Maintenance Levels

Maintenance level structure is a strategic decision which depends on the budget of project, verdict of the contractor, and the facilities of customer. Also defining boundaries and abilities of these levels is another decision area. Decision process for maintenance levels starts in the planning phase. Maintenance levels and borders of them, the responsibilities of the project stakeholders, are determined according to the requirements and defined in the maintenance plan.

The organizational structure of maintenance will be designed to produce appropriate sortie rates in order to meet requirements. Both customer and contractor personnel will operate the system and provide technical expertise and maintenance capability down to the subcomponent level. Because of the requirement to maintain UAVs at the same level of safety and availability as manned aircraft, a similar maintenance concept and execution like manned aircraft is required, especially for the UAVs larger than small UAVs.

In order to establish a reliable and robust maintenance system for UAVs, probable generic operational employment scenarios can be used during the planning phase. These scenarios are composed of, but not limited to, the following:

- First, create a required UAV employment scenario
- Define periodic maintenance requirements such as operational-level maintenance, depot-level maintenance
- Define possible disorders such as mishaps and emergencies which create logistic requirements
- Show all operational steps and logistic footprints on a sketch

As mentioned above and in the maintenance plan subsection, planning is the dominant part of shaping the maintenance level. At this point it is proper to explain the maintenance levels. In general maintenance concept has three maintenance levels. These levels are operational-level (O-Level), intermediate-level (I-Level), and depot-level (D-Level) maintenances. The relation of levels is shown in Fig. 108.4.

In the below figure the relationship and the capabilities of the maintenance levels are outlined. Three-level maintenance activities can be summarized as follows [21];

- Operational-level maintenance: This level consists of the on-equipment tasks necessary for day-to-day operation, including inspection and servicing and remove-and-replace operations for failed components
- Intermediate-level maintenance: This level consists of off-equipment repair capabilities possessed by operating units and in-theater sustainment organizations. These capabilities can be quite extensive and include remove-and-replace operations for subcomponents of line-replaceable units (LRU), local manufacture, and other repair capabilities

- **Depot-level maintenance:** This level consists of all repairs beyond the capabilities of the operating units, including rebuild, overhaul, and extensive modification of equipment platforms, systems, and subsystems

Generally the responsibility borders between maintenance levels are drawn by using maintenance allocation chart (MAC). MAC reflects the responsibility allocation for the performance support tasks for each LRU and assigns the tasks to the proper maintenance activity in accordance with the maintenance concept. MAC structure generally includes Logistic Control Number (LCN), Description (item nomenclature), and Source Maintenance Recovery (SMR) codes.

The details and aims of the maintenance levels and their capabilities are detailed in the following subsections.

Operational-Level (O-Level) Maintenance

This is the first step of the maintenance levels, so it has the least maintenance capability. The maintenance activities at the O-Level are performed on the UAV systems and subsystems in the flight line and in the hangar. O-Level maintenance for UAV system consists of those maintenance tasks intended to keep the system operational and prevent deterioration.

O-Level maintenance is performed by operating units on a day-to-day basis in support of their operations. The O-Level maintenance mission is to maintain assigned UAV equipment in a full mission-capable status while continuing to improve the local maintenance process. While O-Level maintenance may be done by I-Level or D-Level activities, O-Level maintenance is usually accomplished by maintenance personnel assigned to operation area. Generally, O-Level maintenance can be grouped under “inspections, servicing, and handling” categories.

The main problem in O-Level is fuselage defects of UAVs. Most small UAVs and some parts of big UAVs are produced by composite materials. During their employment, the air vehicles can be smashed, cracked, chipped, or dented. Generally O-Level technicians are not trained to repair composites.

Fig. 108.4 Relationship of maintenance levels

O-Level maintenance includes, but is not limited to, the following activities:

- UAV system servicing
- Failure detection and isolation using the UAV System built-in test (BIT)
- Replacement of faulty LRUs
- Limited cabling and structural repair on UAV System and subsystems
- Preventive maintenance checks and services (UAV System serviceability checks, cleaning, etc.)
- Periodic inspection or replacement to comply with scheduled maintenance requirements, corrosion prevention, detection, and removal
- Inspection after abnormal events
- Functional tests
- Loading software to UAV System LRU
- Simple adjustments/calibrations
- Packing for transportation
- Discarding defective LRUs
- Shipping defective LRUs to intermediate level

Intermediate-Level (I-Level) Maintenance

I-Level maintenance has more capabilities than O-Level maintenance. I-Level personnel focus on only repair and testing elements and sub-elements of UAVs, rather than operational activities. This level is an intermediate level but not in the middle; its abilities are closed to D-Level abilities. I-Level personnel are not only composed of technicians but also engineers and administrative. Generally I-Level maintenance organization is made up of maintenance managers, staff divisions, and production divisions.

I-Level maintenance mission is to enhance and sustain the combat readiness and mission capability of supported activities by providing quality and timely material support at the nearest location with the lowest practical resource expenditure.

The maintenance activities that are performed at I-Level involve maintenance procedures, which require specialized skills and resources for inspection, testing, refurbishment, or repair. I-Level maintenance includes, but is not limited to, the following activities:

- Detection and isolation, by using test equipment for selected items, the faulty SRU (shop replaceable unit) in the faulty LRU (line-replaceable unit) which was sent from the O-Level
- Test of LRU, by using test equipment, whose SRU has been replaced
- Calibration of designated equipment
- Processing aircraft components from stricken aircraft
- Providing technical assistance to supported units
- Performance of on-aircraft maintenance when required
- Age exploration of aircraft and equipment under reliability-centered maintenance (RCM)
- Loading software to LRU
- Intermediate-Level LRU periodic maintenance
- Off-system limited cabling and structural repair

Fig. 108.5 Organizational chart for I-Level maintenance

I-Level maintenance has more capabilities than O-Level maintenance. This capability increase is caused by both personnel and equipment. In I-Level maintenance the technicians are well trained about the systems; there are few engineers taken system course. Also this maintenance level covers advanced test equipments, Automatic Test Equipments (ATEs), I-Level technical orders (TOs), and shops. The shops are electrical, electronics, mechanical, and composite shops. In addition to these capabilities, a forward distribution depot consists in I-Level maintenance structure. I-Level has considerable capability, but this capability is limited when compared with the D-Level maintenance capabilities. Notwithstanding I-Level has a chance for obtaining new abilities, but not as much as D-Level.

In order to establish I-Level maintenance, a segmentation structure is required. This structure is not required in O-Level maintenance, because it is fulfilled with only a group. Every sub-function of O-Level can be realized with one or few people. But the sub-functions of I-Level require more personnel. Basic organization structure for I-Level maintenance is shown in Fig. 108.5.

Depot-Level (D-Level) Maintenance

Maintenance actions that cannot be accomplished at O or I-Level are conducted in D-Level maintenance. D-level maintenance has the capability to do anything necessary to repair failed equipment or to make periodic D-Level maintenances. D-level maintenance facilities have the wider range of tools, test equipment, and knowledgeable maintenance personnel. Fabrication of structural parts, major overhauls, refurbishment, and rebuilding of equipment can be done at D-Level.

D-level maintenance is performed at aviation industrial establishments to ensure continued flying integrity of airframes and flight systems during subsequent operational service periods. D-level maintenance is also performed on material requiring major overhaul or rebuilding of parts, assemblies, subassemblies, and end items. D-level maintenance supports O-level and I-level maintenance by providing engineering assistance and performing maintenance beyond their capabilities.

The maintenance activities that are performed at D-Level maintenance of UAVs involve maintenance procedures, which require specialized skills and resources for inspection, testing, refurbishment, or repair. D-Level maintenance of UAVs generally includes the following activities:

- Standard D-level maintenance of UAVs and ground assets
- Rework and repair of engines, fuselage, and components
- Faulty SRU repair

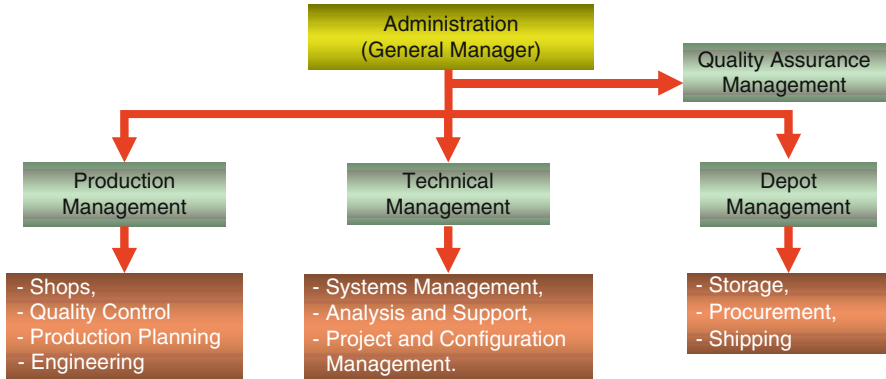

Fig. 108.6 Organizational chart for D-Level maintenance

- Extensive structural control, repair, and modifications
- Calibration exceeding O- and I-Levels
- Harness repair exceeding O- and I-Levels
- Configuration control, authorization, and classification
- Update maintenance plans and documents when required
- Technical management
- Depot-level periodic maintenance and inspection
- Participate in design change process to improve maintenance

Organization structure of D-Level maintenance is relatively larger than that of I-Level. As mentioned above D-Level includes manufacturing parts, modifying, testing, inspecting, sampling, and reclamation. In order to achieve these functions, D-Level has a comprehensive organizational structure. Every sub-function of D-Level requires an additional segmentation structure. A general organization structure for D-Level maintenance of UAVs is shown in Fig. 108.6.

Also it is beneficial to deal with the kinds of shops in D-Level maintenance of UAV systems. The shops cover whole facilities of UAV system. This means that they cover not only UAVs but also ground assets. For this purpose the shops and their capabilities are listed as follows:

- Structural (composite) shop: Standard structural repair processes and required kits, composite material processes (repair, replace, modify, etc.), wet layups technology, hinge replacement, panel replacement, integral fuel tank sealing, finish and touch-up repairs, and structural checks
- Mechanical shop: Standard mechanical repair processes and required kits, maintenance and repair processes of UAV motors and propellers, maintain processes of motor-and motor and related parts, replacement of faulty mechanical LRU
- Electronic shop: Standard electronic repair processes and required kits, fault detection and isolation, removal and replacement capability for faulty LRUs,

repair and maintenance processes for avionics, motor electronics (Full Authority Digital Engine (or Electronics) Control – FADEC), payloads and ground assets, and fault detection and isolation for data link

- Electrical shop: Standard electrical repair processes and required kits, processes for defining condition of electrical assemblies, fault detection and isolation for UAVs electricity, and system generator and power supplies

108.8.3 Configuration Management

In this part configuration management (CM) process for UAV systems is identified and described. CM is a field of management that focuses on establishing and maintaining consistency of a system or product's performance and its functional and physical attributes with its requirements, design, and operational information throughout its life [22]. Before entering into more details about CM, it will be beneficial to give some related definitions. The definitions are given in terms of UAV.

- Configuration: Physical and functional characteristics of a UAV system that is defined in the technical documents and reached form after using.
- Configuration verification: Conformance control of a UAV system according to configuration documents.
- Configuration item (CI): CI refers to the fundamental structural unit of a configuration management system.
- Configuration identification: Selection of configuration item (CI), defining required configuration document for every CI, giving ID numbers for technical documents and CIs.
- Configuration baseline: A baseline is a group of configuration items (products, deliverables) developed during a specific phase of the development process that has been formally accepted. Once the baseline is established, changes to the items can only be done through a formal change process. There are five baselines typically used in system development: functional, allocated, design, product, and operational. The functional baseline may contain an initial investigation baseline, a feasibility study baseline, and a requirements definition baseline.
- Configuration control (CC): Endorsing proposed engineering changes to UAV systems systematically and executing them fully coordinated and documented.
- Configuration control board (CCB): The technical and administrative board that makes decisions regarding whether or not engineering change proposals (ECPs) to an endorsed configuration document should be implemented.
- Configuration management plan: A managerial discipline applied to a UAV system for controlling and tracing functional and physical specifications during whole life cycle.

After giving the above definitions, it will be beneficial to depict the basic elements of configuration management. Elements of configuration management are shown in Fig. 108.7.

UAV systems have both air and ground assets. Also they have many electronic hardware parts, complicated and different kinds of software. As many other

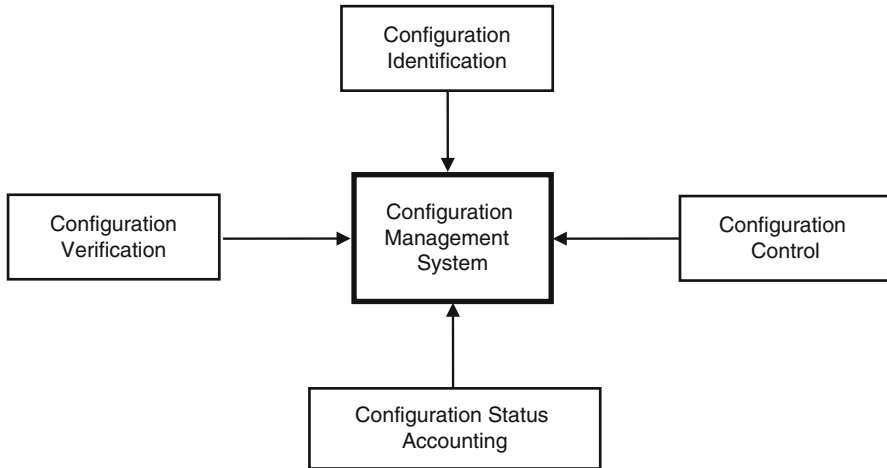

Fig. 108.7 Elements of configuration management system

complicated systems, configuration management is an essential assignment for an organization. Otherwise managing and maintaining a system during its life cycle is almost impossible. In fact configuration management system for UAVs is not different than any other complicated system. For this purpose the elements of configuration management system are given in general. In the following part the elements of configuration management system are given separately. By the way the elements will be elaborated in the following headings:

108.8.3.1 Configuration Identification

Configuration identification is the process of identifying the attributes that define every aspect of a configuration item. In order to fulfill configuration identification process, the following operation should be performed successively:

- Selection of configuration item must be realized
- A system must be established for disseminating configuration documents
- Selection of the documents used for developing configuration baseline must be done
- The interfaces must be identified and documented
- Functional, allocated, and product baselines must be composed
- Configuration item, configuration definition, series, and band numbers must be identified
- A correlation among branding, labeling, configuration documents, and the other data must be established

108.8.3.2 Configuration Control

Configuration control ensures that proposed engineering changes to configuration items are fully coordinated and documented. Configuration control is tailored during each life-cycle phase of a configuration item as follows:

- **Acquisition Phase:** During this phase configuration control will be applied to a new item's operational and functional requirement; during this phase configuration control will be applied to all documents which establish the functional baseline documentation. This phase represents the acquisition of a new device and as such establishes the product baseline documentation.
- **Operational Support Phase:** During this phase configuration control will be applied to any revisions to the established functional and product baseline documentation of an existing item. This phase represents the modification/update of existing devices.

An engineering change proposal is the standard method for proposing changes to a configuration item. Engineering change proposal is used to initiate engineering change proposals. There are two categories of engineering change proposals:

- **Solicited.** Solicited ECPs are submitted by the contractor in response to a written request made by the government. At NAWCTSD, it occurs as a result of a solicited ECP on a weapon system platform (WS/ECP) from the major claimant which, in turn, could affect the training device/system.
- **Unsolicited.** Unsolicited ECPs are those submitted without a formal written request. Such proposals are not encouraged and will be rejected unless they satisfy one or more of the following criteria:
 - Correct deficiencies.
 - Make significant reduction in manufacturing, operational, or logistics support costs.
 - Prevent slippage in production schedules.
 - Are a value engineering proposal.

Also ECPs are classified in two groups as Class I and Class II. These ECP classes can be explained as follows:

- **Class I engineering change proposals:** There are two types of Class I engineering change proposals.
 - **Preliminary engineering change proposal.** A preliminary engineering change proposal is used to determine if a formal engineering change proposal is justified. It is not reviewed by a change control board and cannot be used to authorize a change to a configuration item.
 - **Formal engineering change proposal.** A formally submitted engineering change proposal which has been engineered, documented, and priced in sufficient detail to support approval.
- **Class II engineering change proposals:** The ECPs that falling outside Class I ECPs are Class II ECPs. Generally unless otherwise specified by contract, Class II ECPs are not reviewed and approved. Only the contractor has the authority to approve the classification and implementation of the change as Class II.

108.8.3.3 Configuration Status Accounting (CSA)

Objective of CSA report is to provide visibility into the current status of configuration items whether part of a baseline or not. CSA reports also depict the changes made to base-lined configuration items. CSA is the process of creating and organizing the knowledge base necessary for the performance of configuration management. In addition to facilitating configuration management, the purpose of CSA is to provide a highly reliable source of configuration information to support all program/project activities including program management, systems engineering, manufacturing, software development and maintenance, logistic support, modification, and maintenance. CSA includes the following:

- A record of the approved configuration documentation and identification numbers
- The status of proposed changes, deviations, and waivers to the configuration
- The implementation status of approved changes
- The configuration of all units of the configuration item in the operational inventory
- Discrepancies from functional and physical configuration audits

108.8.3.4 Configuration Verification

The objective of verification is to detect and manage all exceptions to configuration policies, processes, and procedures. The configuration verification process includes the following:

- Configuration verification of the initial configuration of a CI and the incorporation of approved engineering changes, to assure that the CI meets its required performance and documented configuration requirements
- Configuration audit of configuration verification records and physical product to validate that a development program has achieved its performance requirements and configuration documentation or the system/CI being audited is consistent with the product meeting the requirements

108.9 Logistics at Disposal Operations Phase

The purpose to dispose a system from inventory is to redistribute, transfer, donate, sell, abandon, or destroy the system. In other words the disposal phase is the process for eliminating the system. At the end of the system's life cycle, the program manager must perform the actions defined in the disposal plan to properly remove the system from the inventory. At the end of its useful life, a system shall be disposed in accordance with all legal and regulatory requirements and policy relating to safety (including explosives safety), security, and the environment.

Before going further on this subject, let's look at the problem from another direction. If the problem is to define the end of life cycle of a system, the definition will predominantly depend on economical, political, and maybe forensic issues. The technical issues may not be as dominant as the other factors. Actually there

is no definitive end to a system. Systems normally evolve or transition to the next generation because of changing requirements or improvements in technology.

The disposal activities ensure the orderly termination of the system and preserve the vital information about the system so that some or all of the information may be reactivated in the future, if necessary. Particular emphasis is given to proper preservation of the data processed by the system so that the data is effectively migrated to another system or archived in accordance with applicable records management regulations and policies for potential future access. This point of view is interesting and may be taken into account in some cases. But in this study it is not the case. In the following explanations disposal subject proceeds without regarding information transfer between generations, and it is accepted that with some assumptions end-time definition of a system exists.

In this part disposition options of UAV system and the secondary market alternatives are examined. At the end of the sustainment period, a decision process is taken into account. This process interrogates the discarding method of a system from inventory. This method may be either return the UAV to vendor, to the landfill, or to the secondary market [23].

Actually disposal of a system is an inventory management problem and depends on economic concerns and cost-effective aims. The reasons of disposal or transfer to a secondary market may be listed as follows:

- UAV system does not meet the customers requirements anymore
- To repair the malfunction or defect of a UAV system isn't cost-effective
- The obsolete percentage of material requirement list on the system is relatively high and equivalent components are not available
- Maintaining a UAV system in operation is not cost-effective because the end of systems life cycle is reached

Especially for UAV systems malfunctions and defects are more encountered than piloted aircraft systems. This feature affects not only the maintenance procedures but also the disposal procedures. For that reason the flying part of UAV systems are generally disposed before their life cycle. On the other hand life cycle of ground assets of UAV systems is limited with obsolescence of subsystems. Disposing before life-cycle trend for flying part of UAV systems is more valid for small UAVs than larger ones. In fact disposing large UAVs before their life cycle is not so cost-effective. Nonetheless, repairing and replacing most parts of large UAVs and increasing the periodic maintenance frequency of them are applied methods for lasting the life cycle of UAVs longer.

108.9.1 Disposition Methodologies

Disposition of a system means remove the system from inventory of an organization. The organization may be military, governmental, or nongovernmental. Whole kinds of organizations have an inventory, and inventory removal methods are similar by some means or other. Disposition methods and rules of UAV systems are similar to any other airborne system; the only difference is additional ground assets. Disposition of a UAV system is an economical, political, and managerial decision,

and for some cases it can be a strategic decision. For removing a UAV system from inventory, there are basically three methods. These methods are listed as follows:

- *Method 1:* Remove the UAV system and whole its subsystems from inventory for good, and do not operate any reverse logistics processes:
- *Method 2:* Remove the UAV system from the inventory, but don't dispose the whole subsystems. Some subsystems are recycled to the system, in order to reuse in somewhere else in the organization.
- *Method 3:* Remove the UAV system from inventory by selling a secondary market.

All the methods have some advantages and some disadvantages in some ways. Methodology selection process is conducted by assessing many merits into account. Some of these merits are listed as follows:

- The condition of UAV system, in operation or failure
- Technology level of UAV system and its relative condition with the state-of-the-art technology
- Cost efficiency of maintenance
- Reusing case of UAV subsystems
- Operational requirement for the system
- Predetermined life cycle of the UAV system

108.9.2 Life-Cycle Cost Analysis

Disposal decision for a system is given at the beginning of the project with life-cycle cost (LCC) analysis. For this purpose LCC analysis is mentioned under disposal phase. Generally it is carried out in the planning part of a project, but it can be performed in all phases of life cycle. Also LCC analysis can be performed in during sustainment phase. By the way corrective calculations due to usage can be added into LCC analysis. If the LCC analysis is made at the beginning phase of a project, then the inputs of sustainment phase experiences may not be covered. As mentioned before the accident rate of UAV systems is higher than that of piloted aircraft. The source of accidents can be categorized as human, material, or environmental factors. Human causal factors relate to human errors. Material causes being the result of equipment failure and damage as a result of design flaws, component, or system failure such that the system becomes inoperable. Environmental factors include noise, illumination, and weather conditions [24]. If the LCC analysis is carried out in the beginning of the project, the undesirable conditions of UAV system during operations and usage may lead the organization to make the LCC analysis during sustainment phase again.

Before explaining LCC analysis, giving the definition for LCC will be beneficial. Fundamentally LCC is cumulative cost of a product over its life cycle. There are a lot of different definitions for LCC. One short and to the point of them is defined as, "LCC is the total cost of ownership of machinery and equipment, including its cost of acquisition, operation, maintenance, conversion, and/or decommission" [25].

LCC are summations of cost estimates from inception to disposal for both equipment and projects as determined by an analytical study and estimate of

total costs experienced in annual time increments during the project life with consideration for the time value of money. The objective of LCC analysis is to choose the most cost-effective approach from all possible alternatives to achieve the lowest long-term cost of ownership. LCC is an economic model over the project life span. Usually operation, maintenance, and disposal costs exceed all other first costs related with procurement. The best balance among cost elements is achieved when the total LCC is minimized [26].

LCC helps change provincial perspectives for business issues with emphasis on enhancing economic competitiveness by working for the lowest long-term cost of ownership which is not an easy answer to obtain. Consider these typical problems and conflicts observed in most organizations:

- Project engineering wants to minimize capital costs as the only criteria
- Maintenance engineering wants to minimize repair hours as the only criteria
- Production wants to maximize uptime hours as the only criteria
- Reliability engineering wants to avoid failures as the only criteria
- Accounting wants to maximize project net present value as the only criteria
- Shareholders want to increase stockholder wealth as the only criteria [27]

LCC analysis is a collective term comprising many kinds of analysis. These analyses cover reliability-availability-maintainability analysis, economic analysis, and risk analysis. A main objective of the LCC analysis is to quantify the total cost of ownership of a product throughout its full life cycle, which includes research and development, construction, operation and maintenance, and disposal. The predicted LCC is useful information for decision-making in purchasing a product, in optimizing design, in scheduling maintenance, or in planning revamping. LCC analysis may be applied for:

- Evaluation and comparison of alternative design
- Assessment of economic viability of projects/products
- Identification of cost drivers and cost-effective improvements
- Evaluation and comparison of alternative strategies for product use, operation, test, inspection, maintenance, etc.
- Evaluation and comparison of different approaches for replacement, rehabilitation/life extension, or disposal of aging facilities
- Optimal allocation of available funds to activities in a process for product development/improvement
- Assessment of product assurance criteria through verification tests and their trade-offs – long-term financial planning [28]

An LCC analysis procedure has some essential subprocesses. To be mentioned these subprocesses will be helpful for understanding LCC analysis. These subprocesses may be summarized as six basic processes as follows:

- Problems definition
- Cost elements definition
- System modeling
- Data collection
- Cost profile development
- Evaluation [29]

108.10 Future UAV Logistics Trends

108.10.1 Airborne Logistics Support

UAVs will fill in the physical gap between satellites and the manned aircraft in the near future. Some sort of UAVs will access to the stratosphere and stay aloft for weeks, months, or even years without landing. They would accomplish the missions of the satellites such as TV broadcast, and radio communication with more reasonable costs. These UAVs should be designed to tolerate the special environmental conditions in the stratosphere and have the ability to serve for a long period of time without any important intervals requiring any logistics support on the ground. Thus, such UAVs required staying aloft for a long period of time; airborne logistics support will be needed.

Airborne logistics support will be done manned or unmanned aircraft which will have necessary equipment to diagnose the malfunctions and to do periodic tests. They also have the capability to carry enough supply materials such as fuel, oil, and lubricants. How the maintenance will be done will depend on the type of the maintenance requirement. If periodic maintenance such as supplying fuel or doing periodic tests is required, it would be done automatically by the technicians on the ground. But for the malfunctions requiring the replacement of parts, the technicians should be on the airborne logistics support vehicle with required spares.

108.10.2 Power Refueling by Laser

Apart from some solar-powered high-altitude UAVs currently under development, UAVs have to land to have their batteries recharged or fuel cells filled. There are currently some experiments to develop economically viable technology to use lasers to remotely power motors and recharge batteries while UAVs are flying. The concept under development works by turning electricity into laser light which is beamed to a remote receiver on the UAV. This converts the light back into electricity where it can be used to drive a motor or power a battery or payload. If this laser technology matures enough, some type of UAVs can fly and do mission much longer than today.

UAV Applications

Aníbal Ollero

Kimon P. Valavanis and George J. Vachtsevanos

UAV Applications offers a “taste” of possible civil and public domain applications in which single or multiple UAVs may be used. As the roadmap of the UAS integration into the global airspace is formulated amidst current obstacles and skepticism, it is only logical to consider that the spectrum of possible applications will be much wider in the years to come. At the present stage, UAVs have either been considered for or have seen (very) limited utilization in a wide range of applications that include but are not limited to power line inspection; pipeline inspection; ship inspection; mine inspection; dam inspection; anomaly detection/prevention; early fire detection and forest protection; hazard monitoring; traffic monitoring; environmental monitoring; search and rescue operations; emergency response; border patrol; harbor patrol; police surveillance; aerial photography; SWAT support; imaging and mapping; intelligence, surveillance, and reconnaissance (ISR); chemical spraying; crop dusting; night vision; and entertainment industry and filming.

However, in addition to enabling and mature technologies, UAV utilization will also be affected by cost considerations, certification restrictions (which may or may not be application specific), and supply and demand.

► **Survey of Unmanned Aerial Vehicles (UAVs) for Traffic Monitoring** by Kanis-tras, Martins, Rutherford, and Valavanis focuses on surveying UAV-based systems for traffic monitoring and management. Although there is voluminous research on the subject, UAVs are proven to be a viable and less time-consuming alternative to

real-time traffic monitoring and management as they provide the dynamic “eye-in-the-sky” solution to the problem.

► **Measurement and Exploration in Volcanic Environments** by Melita, Longo, Muscato, and Giudice presents a challenging application for UAVs in volcanic environments, as they may be used to collect typical aerial measurements and data. The main forms of measurements concern the collection of visual/thermal images and gas analysis and sampling. An overview of the major worldwide projects carried out in the last few years by several research organizations is summarized and discussed.

► **Cooperative Unmanned Aerial Systems for Fire Detection, Monitoring, and Extinguishing** by Merino, Martınez-de Dios, and Ollero deals with the application of cooperative UAVs to forest fires. It presents a decision and control architecture for multi-UAS teams that are equipped with diverse sensors (e.g., infrared and visual cameras) and details the perception techniques (fire segmentation, geo-localization, and data fusion) that are used toward fire extinguishing.

► **Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States** by Ambrosia and Zajkowski describes some of the UAS lessons learned by both the U.S. Forest Service (USFS) and the National Aeronautics and Space Administration (NASA) during their more than 10-year efforts on identifying appropriate UAS wildfire observation capabilities. The agencies, along with the UAS community, have demonstrated the use of both low-altitude, short-endurance (LASE) and medium-altitude, long-endurance (MALE) platforms for wildfire sensor intelligence gathering. Those experiences are identified along with an examination of the future direction of UAS for supporting the wildfire management community.

► **Unmanned Aerial Systems Physically Interacting with the Environment: Load Transportation, Deployment, and Aerial Manipulation** by Kondak, Ollero, Maza, Krieger, Albu-Schaeffer, Schwarzbach, and Laiacker discusses the novel and very challenging applications of using UAVs for aerial manipulation and load transportation. A specific application of using autonomous helicopters equipped with robotic arms for aerial manipulation is detailed, along with field experiments demonstrating joint load transportation with multiple autonomous helicopters.

► **Unmanned Aircraft Systems for Maritime Operations** by Borges de Sousa, McGuillivary, Bento, Morgado, Matos, Gomes Bencatel, and de Oliveira discusses current practices and major UAS trends for maritime operations, along with projections of future UAS maritime applications. Various aspects of UAS program management, including organization, operator responsibilities, program operation, and overall program costs are reviewed, followed by maritime aircraft missions and required capabilities. Technological trends are highlighted focusing on developments relevant to maritime UAS operations. Trends including miniaturization of sensors and computer systems, high energy density of power sources, and increased subsystem standardization and modularity will have important effects in the future, including increased system autonomy via new command and control frameworks.

► **Autonomous Remote Sensing of Invasive Species from Robotic Aircraft** by Goktogan and Sukkarieh presents an ensemble system consisting of a helicopter,

a fixed-wing UAV, and their supporting infrastructure that is used in a number of environmental research experiments focused on autonomous remote sensing, detection, classification, and management of invasive species, weeds, in Australia. In these experiments, three distinct families of weeds on three different terrains are investigated. In the first group of experiments, a helicopter UAV equipped with a high-resolution imaging payload is flown over difficult to reach water channels and wetlands for detection of aquatic weeds. The second set of experiments is performed in relatively flat rangelands to map woody infestations. The third set of experiments is focused on the airborne detection of wheel cacti on remote mountainous terrain using fixed-wing aircrafts. Successful results of these experiments suggest that robotic aircrafts in a properly designed UAS can play an important role in environmental robotic science.

► **Cyber-Physical Systems Enabled by Small Unmanned Aerial Vehicles** by Coopmans, Stark, Jensen, Chen, and McKee provides several examples of unmanned aircraft sensing-enabled cyber-physical system (CPS) scenarios, enabling adaptive management and effective control of complex physical systems such as water distribution based on measurement of soil moisture and crop evapotranspiration, radio tag-based tracking of fish, alternative energy harvesting, mapping of invasive plant species, and airborne plume (pollution) tracking. This chapter serves as a motivator for potential wide-spreading UAS applications where UAS are used as mobile sensors and/or mobile actuators in large-scale, closed-loop CPS.

Abstract

The focus of this chapter is on surveying UAV-based systems for traffic monitoring and management. Although there has been voluminous research on the subject, unmanned aerial vehicles (UAVs) are proven to be a viable and less time-consuming alternative to real-time traffic monitoring and management, providing the solution to the problem.

110.1 Introduction

The continuous increase of vehicles on roadways forces transportation managers to look for more effective ways to reduce the traffic congestion problem. Because of the increasing traffic volume, there is a demand for state-of-the-art intelligent traffic information for real-time traffic monitoring and management. This requires collection of accurate information, for not only the state of the traffic and roadway conditions but also real-time information in case of emergencies like car accidents that lead to traffic congestion and/or rerouting (Puri 2005; Puri et al. 2007).

Research is being conducted on this topic and several methods proposed to investigate what is the most effective way of transmitting and analyzing traffic data acquired from (UAVs) (Bethke et al. 2007; Kim 2005; Chen et al. 2007). Research is also focused on the type of data that should be collected and the information that should be extracted to design traffic simulation models and evaluate traffic networks (Puri et al. 2007; Coifman et al. 2006; McCormack 2008; Heintz et al. 2007). UAVs are preferred over the traditional technologies (inductive loop detectors, video, radar, ultrasound technologies, etc.) because of their mobility and because the cost of the operation is considerably lower than manned systems. The ability to hover, and fly above highways, allows the UAV to provide information such as vehicle trajectories and routing information which is not possible to be provided from detectors that are positioned in certain areas along the highway. Visual data are collected in real time by the unmanned systems, and they are used to generate traffic-related statistical profiles, serving as inputs to traffic simulation models (Puri 2008) as Fig. 110.1 shows.

This survey presents current research in the area of UAVs for traffic monitoring and management. A search on related research using UAVs for traffic monitoring and algorithms that could be implemented on UAVs for that purpose since 2005 was performed. Journal and conference papers related to the subject have been considered. The databases and keywords used to complete the survey are given in Table 110.1.

The rest of the chapter is organized as follows: Sect. 110.2 discusses comprehensive surveys in traffic surveillance and monitoring, while Sect. 110.3 summarizes current research that is being done in the area since 2007 when the last survey related to traffic monitoring was conducted. They are classified in three subsections mentioning universities and research centers with projects on UAVs that could be used for traffic monitoring implementing some tests up to 2007 (Puri 2005; Ro et al. 2007), universities that implemented tests with UAVs for traffic monitoring from

2007 up to today, and others claiming that those systems or algorithms could be implemented on UAVs for the same purpose. Section 110.4 concludes the chapter.

110.2 Existing Surveys in Traffic Monitoring

After surveying the literature, two comprehensive surveys in traffic monitoring were found. In Puri (2005) the author provides a technical report of research related to the application of UAVs for traffic management. The advantages of using UAV platforms over the traditional technologies of traffic sensing are pointed out. A wide list of UAV platforms used for traffic monitoring is also proposed.

Table 110.2, copied from Puri (2005), summarizes all research done up to 2005 at several universities around the world in the area of traffic surveillance with UAV platforms. It presents, per university, the performed research, the platforms that were used for the experiments, and the objectives of each research project.

In Ro et al. (2007), applications of small UAVs for urban highway traffic monitoring related to a specific project were conducted at Western Michigan University. In this report, FAA regulations and standards for UAVs are described in detail. Also, the classification of airspace and entry requirements are summarized and illustrated. Finally, a list of suitable network protocols, which are standards of networking, is also provided.

110.3 Current Research Work

Real time is a difficult task for a UAV to accomplish not only due to the high level of complexity of the aerial images due to the need for full 3D control. Following a road implies that the UAV should be able to *see* it first; therefore there is no doubt that rich information could be provided by vision and radar sensors. However, processing that information is difficult especially in real time (Kim 2005). Ongoing research is focused on the type of sensors used onboard and on the way that data are processed (onboard or off board) for traffic monitoring.

110.3.1 Airborne Road Traffic Monitoring with Radar

This paper Bethke et al. (2007) introduces a possible solution to traffic monitoring with radars and sensors on unmanned systems. According to the authors, travel time is an important measure for characterizing traffic flow. Only high-flying platforms offer the possibility of wide area coverage of infrastructure as well as of the road traffic situation without the need of additional equipment. SAR (Synthetic Aperture Radar) processors provide two-dimensional radar images from the earth surface and are usually suitable for monitoring stationary scenes. GMTI (Ground Moving Target Indication), which is the detection of moving targets against a stationary background, gives the ability to calculate major parameters for estimating the traffic

flow with radars. At the German Aerospace Center (DLR), an operational, compact SAR system for high-flying airborne platforms is planned to be developed over the medium term, and it will be used for traffic management.

Advantages – Using radars on high-flying platforms allows not only the capture of data in wide areas regardless of the weather conditions but also the detection of vehicles independently of their instrumentation onboard (Bethke et al. 2007). The resolution of SAR images is on the order of 1–2 m (Bethke et al. 2007).

Disadvantages – Techniques to reduce the amount of data that must be processed and transmitted are not yet developed. Also techniques to detect vehicles with precision are under investigation but not yet implemented.

110.3.2 Real Time Road Detection by Learning from One Example

At the University of California at Berkeley, an algorithm for real-time road detection is presented. Additionally, an algorithm capable of detecting any type of road (or corridor/quasi-linear structure) is proposed (Kim 2005). According to the author, this is a new approach to detect roads in real time by processing a single image of a target road. On that image the road structure is represented as a one-dimensional intensity profile, and the detection is done by matching each horizontal scan line of

a target image. Once the road positions for each line are found, a fitting algorithm can be used to find the final road position.

The Random Sample Consensus algorithm is applied for robust fitting which has been used for computer vision problems (Fischler and Bolles 1981). The purpose is to calculate vanishing points from pairs of line segments and rectify the image in order to detect the road boundaries and then define the road structure. The results show that the algorithm successfully learns the road structure from their first frames and applies that to the rest of the video. No visible error is detected in any single frame except when the road structures are drastically changed due to an entrance ramp.

Advantages – Real-time computation for road detection in urban environments is an important application. The real-time constraint related with the search algorithm can be overcome by reducing the vertical sampling rate. The same algorithm could be applied to a non-straight road with the assumption that it is partially straight. Also, the algorithm could be applied to other applications and not necessarily to road detection.

Disadvantages – It is not adequate to apply algorithms to detect lane markings unless the UAV flies at a low altitude to make the lane markings visible. The position errors of the hypotheses do not follow a Gaussian distribution; thus least-square line fitting gives inaccurate fitting results (Kim 2005). Real-time adaptation for a changing road structure and curved road detection is hard to accomplish.

110.3.3 Statistical Profile Generation for Traffic Monitoring Using Real-Time UAV Based Video Data

The eye-in-the-sky project is proposed from the University of South Florida, where small unmanned helicopters were used to monitor traffic, evaluate and assess traffic patterns, and provide accurate vehicle counts. The purpose of this research is to develop a system, which will optimize the traffic network, to improve the performance and flow of traffic at both normal and peak hours. Each helicopter is equipped with custom-made vision systems for onboard and on-the-ground data processing and pan-tilt cameras for dynamic tracking and car-following. Data are collected and traffic parameters such as occupancy, capacity flow, and density are calculated and modified based on those data. Traffic parameters are generated and fed to a simulation model which will be used in the future for modeling traffic conditions. Also the ratio of the vehicles that turn left or right or continue through the intersection is necessary for traffic management, and this could be calculated by tracking every individual vehicle.

Density is calculated using a Virtual Detection Frame (VDF) as shown in Fig. 110.2. This method uses a single still image at one time and calculates the vehicles present inside the VDF (Puri 2008). A method to calculate the delay, which is an important component of traffic behavior, due to the fact that minimum delay in a network implies a free flow network, is also mentioned in the paper. The simulation model gave promising results.

Fig. 110.2 Virtual Detection Frame (Puri 2008)

The proposed and utilized conceptual framework is shown in Fig. 110.3. The real-world traffic network block depicts the physical traffic network. The bold outline blocks depict the utilization of unmanned helicopters and the onboard/on-the-ground image processing system. Data is collected in real time by cameras mounted on the UAV.

Virtual detectors are implemented as colored boxes in the image processing algorithm as Fig. 110.4 depicts. Each lane has its own corresponding box, which is responsible for detecting every vehicle passing through it. The boxes can be either automatically placed after the system recognizes the road environment or the experimenter can manually place the box to the desired detection region (Puri 2008).

Advantages – A simulating model based on real-time, dynamic, and traffic network data improves the prediction of the traffic behavior in real time. The vision system, which has onboard and on-the-ground processing capabilities, contains algorithms which give the ability to adapt to different environmental setups automatically.

Disadvantages – The helicopter's instability leads to a vehicle count error. All data are collected from a fixed point. Also data were not collected while the helicopter was moving (Puri et al. 2007).

110.3.4 Vehicle Detection from Aerial Imagery

This paper (Gleason et al. 2011) is focused on feature extraction methods and classification techniques for automatic vehicle detection by UAVs on traffic control and other applications. The proposed method has two stages wherein in the first stage the algorithm is *looking* for man-made objects, which in this case are vehicles, and rejects most of the background. This stage has four steps:

- (i) Feature detection: Image features based on edges detection. Harris corner detection is used.

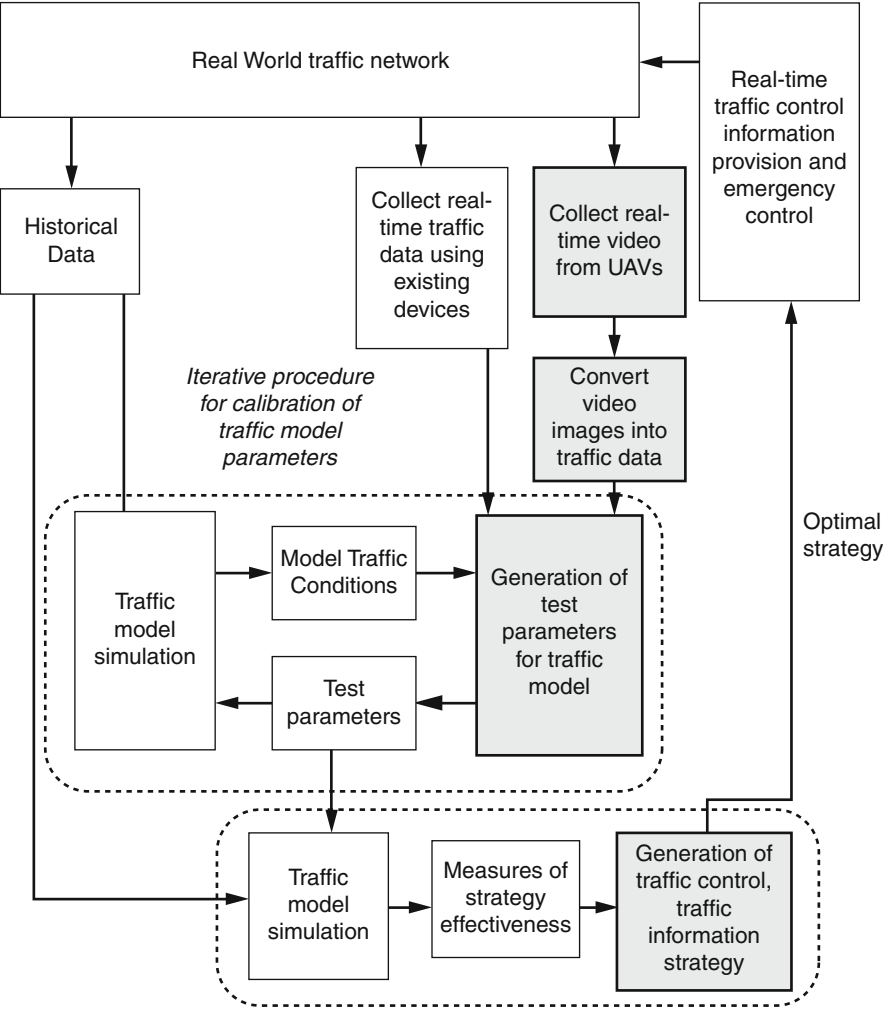

Fig. 110.3 Conceptual framework of real-time data collection and traffic simulation control (Puri 2008)

- (ii) Feature density estimation: The algorithm determines areas with feature density higher than a fixed threshold.
- (iii) Target clustering: The overlapping responses are grouped together and the overlapping detection is rejected.
- (iv) Color-based detection refinement: Color information is used to reduce the false alarms.

The target classification is implemented during the second stage, where further reduction of the false alarm rate is done. Two feature extraction methods (Histogram of Oriented Gradients, Histogram of Gabor Coefficients) and three

Fig. 110.4 *Colored boxes* show implementation of virtual detectors in the image processing technique (Puri 2008)

different classification techniques (k-nearest neighbors (k-NN) (Cover and Hart 1967), random forests (RF) (Breiman 2001), and support vector machines (SVM) (Hearst et al. 1998)) are used and explained in detail in this paper.

Advantages – A reasonably accurate estimate of the overall accuracy of the program was achieved by using the threshold of the fast detection algorithm. The performance of Gabor features under different lighting conditions was good, due to its ability to retain nearly all of the vehicles in the set while successfully reducing the false positives by half.

Disadvantages – The rotation invariant HoG did not perform well due to the reflective water that was in the background.

110.3.5 An Improved Object Tracking Method in UAV Videos

In Fang et al. (2011) Mean Shift tracking algorithms are studied because, according to the authors, those algorithms have problems tracking objects either whose size is changing or which are moving fast. The authors claim that the proposed filtering-based Mean Shift algorithm solves both problems. To overcome the tracking problem, the building of object models according to known target appearance and possible areas that may appear in it is proposed. During the matching process which is important for tracking purposes, it is suggested that the object's bounding box should be fixed so the probabilistic density function value can be calculated afterwards. When the algorithm may converge into a region of background if it is applied on UAVs because the objects are small and move rapidly. To reduce the mistakes in the Mean Shift algorithm, particle filtering is suggested. According to the authors, the along with particle filtering can solve the problems caused by fast-moving objects in UAV videos.

Advantages – Optimizing the suggested algorithm and combining Mean Shift and particle filtering to adapt to changing object size. Also, small objects are rarely lost which makes this algorithm valuable in UAV videos to track small fast-moving objects like vehicles in highways.

Disadvantages – Only when the regions are known, the Mean Shift can track the objects on time (Fang et al. 2011).

110.3.6 Visual MTI for UAV Systems

In Evans and Turkbeyler (2007) focus is given on the problem of detecting moving objects on the ground with video cameras that are mounted on unmanned air vehicles. The main approach is to compare pairs of image frames that are captured a short time apart. This paper provides an approach which is not based on image registration but on the analysis of the motion of the features with respect to a static scene model. The feature analysis is divided in three stages. First, a pair of image frames is used to locate the fixed objects. A method based on random consensus RANSAC is used to calculate a matrix with the largest number of matched features. Then, during the second stage, the objective is to obtain an improved stationary and moving classification. A temporal analysis is done on results from many frame pairs in order to identify the set of features that are judged to be moving or stationary with high confidence. In the last stage, a process for further improvement of the performance is used for the remaining that are caused by the missing targets. The algorithm is evaluated on frames of a motorway roundabout and a car park of a supermarket.

Advantages – The algorithm performs well on the datasets from the supermarket even with complex 3D structures. That scene is challenging because pedestrians are walking between the parked cars and the algorithm is still able to detect the cars.

Disadvantage – False alarms and missing targets remain even after stage 2; thus some clearly moving objects are not detected. That is because the algorithm is blind to motion in some directions. The geometrical interpretation of the scene is not well constrained, and that causes problems even with a smooth traffic flow on the motorway. Finally, additionally problem will be caused if the camera is not fixed onboard.

110.3.7 Real-Time Video Relay for UAV Traffic Surveillance Systems Through Available Communication Networks

At Western Michigan University, a project for real-time video relay for UAV traffic surveillance is conducted (Chen et al. 2007). According to the authors, the challenging part of the project is that the ground control station is located near a highway and the surveillance videos collected need to be relayed to the office at the Michigan Department of Transportation in a timely manner.

The task of relaying is focused on how to deliver the data from the ground station to the control office, and for that purpose the public Internet was used. The ground

control laptop informed the end user computer of a dynamic IP address which is generated each time that a connection occurred, and the end user computers could open a media player to retrieve the video stream. Those videos in their original state are too big to deliver within available network bandwidth; thus compression is needed. The Windows Media Encoder is used to convert and compress media content into a traversal network media format. During the field experiments, data were collected and a comparison between two transmission schemes in different image resolutions in real-time distributions was conducted.

Advantages – More than one user computer can receive the video stream simultaneously with acceptable data rate. Experimental results showed that the proposed method can deliver quality videos to the control office in real time.

Disadvantage – The bandwidth of the cellular network influences the image of the video stream. During the field experiments, the video stream was frozen or buffered while the end users were watching the video. The results showed that the transmission with no server system scheme could only provide a video stream in continuous and smooth image in a bit rate of 45 Kbps and also showed that any rate below that may not meet the requirement of the UAV project.

110.3.8 Roadway Traffic Monitoring from an Unmanned Aerial Vehicle

Another project to investigate and calculate traffic parameters was conducted at the University of Ohio State University using the BAT III UAV technology (Coifman et al. 2006). The unmanned system is carrying a payload of two cameras at a speed of 50 km/h while transmitting video images to the ground station in real time. The purpose of the experiment is to measure the level of service, estimate the average annual daily travel, examine the operation of the intersection and the flow, and measure parking lot utilization.

Two methods of estimating roadway density and flow are developed for this project. The first method uses still frames, and the second method obtains information from a series of frames. The first method is straightforward to apply, but using individual frames is problematic because each frame represents a very small sample size (Coifman et al. 2006). GIS is used to measure the length of the roadway accurately in order to calculate the hourly volume. However, to calculate the speed from a single still frame, it is not possible, but it can be estimated either from the posted speed limit or from the video stream. In addition to the length and the speed, the number of passenger cars and trucks is needed to calculate the density according to the authors. By using the second method, the UAV flies over the traffic and the sensor observes conditions over a longer time and distance.

Advantages – The platoon matching method is proposed, where network OD flow is been calculated in unobserved regions. Since time and distance are known, it is only important to differentiate between entering and leaving the region, without tracking the vehicles the whole time. All the applications were demonstrated from data that were collected from less than 2 h of flight time.

Disadvantages – The field of view of the UAV is not wide and the fluctuations in the traffic cause large variations in density measured from a single still frame. Also the field of view continuously changes, and the sample size is small in order to calculate density and flow from individual frames. The data analysis and reduction were made manually and not automated.

110.3.9 Detecting and Counting Vehicles from Small Low-Cost UAV Images

From the School of Geosciences and Geomatics, East China Institute of Technology, comes another paper for detecting and tracking vehicles with UAV systems (Cheng et al. 2009). The main goal of this project is to develop techniques for generating high-resolution video flow from UAV videos. The UAV is carrying a video camera, GPS receiver, and INS sensor.

After the data are collected, an algorithm is implemented for detecting and counting from video data. The idea is to track the pixel from consecutive video frames. The algorithm was divided into four steps:

- (i) Interesting point feature extraction
- (ii) Conjugate point prediction
- (iii) Implementing cross correlation
- (iv) Verification of matched results

All four steps are explained in detail. The results show that this algorithm is effective and efficient because the vehicle can be detected tracked and accounted from a UAV system.

Advantages – With that method the results showed that the vehicle can be tracked, and from that the accounting vehicle from the video can be obtained. According to the author, the algorithm used the inherent characteristics of UAV video system of parallax to predict the corresponding points while it deletes the mismatching points.

Disadvantage – The average parallax vector is calculated from the tie points of the video stereo frames, and in some cases it cannot be calculated because there are no tie points. However, the algorithm works well and the vehicles can be tracked to reduce the statistical errors is not mentioned.

110.3.10 A Vision Algorithm for Dynamic Detection of Moving Vehicles with a UAV

Work has been conducted at the University of Picardie, to develop a UAV able to autonomously perform surveillance of an area in order to be able to detect vehicles for traffic monitoring (Kaaniche et al. 2005). A UAV was built for that project which was able to fly over a predefined area and collect. The collected data are communicated through two wireless modems where one was in charge of collecting the data and the other one of sending video information to the ground station. The algorithm was based on Dempster-Shafer theory (Shafer 1976). The *common fate*

law was used in two sets, one for representing the background and the other one for the moving objects.

All the steps of the detection algorithm are explained in detail, and focus is given to the matching operation between two images. The operation of matching between corners was followed because according to the author Kaaniche et al. (2005), it is not only less complicated than edge matching but also experimental tests have shown that corner rate reputability is more relevant than edges. To perform the matching process, for each detected corner a set of invariants is computed and then the information is stored in a vector; thus the process is then based on a vector comparison. Also, by following that operation, false matching effects are reduced. Finally the verification algorithm is discussed and the proposed algorithm is based on Dempster-Shafer theory (Shafer 1976) for vehicle recognition.

Advantages – The system is able to treat sequences with different resolutions and sequences that were taken from different altitudes. False matching effects are reduced by using the corner matching operation. Finally, the algorithm is fast and can be used for real-time applications.

Disadvantage – Matching errors are observed due to strong similarities between corners in two images. Although the system is able to detect several vehicles in the same frame, errors are observed because tree shadow edges were close to the vehicle shadow edges.

110.3.11 Supporting Traffic Flow Management with High-Definition Imagery

A feasibility study on the quality of the traffic data that could be achieved by operating an unmanned helicopter was conducted from the research group of the University of Arizona in cooperation with the Ohio State University (Toth et al. 2003).

A 2-min flight is performed in order to extract traffic flow data, and 21 images are taken. The vehicle classification is divided into three main categories: passenger cars, trucks, and multipurpose vehicles. Two subcategories are also presented, along and against, regarding the direction of the vehicles relative to the UAV direction. A small group of vehicles is tracked and velocity and tracked distance are estimated. Simulations are conducted to estimate the standard deviations of error sources as image coordinates, focal length, principal point, perspective center position, and attitude angles. The matching scheme is based on using existing road geometry information and a location from the estimated velocity of the vehicles being tracked.

Advantages – That method proves that high-definition airborne imagery should be used for obtaining traffic flow data. Also, vehicles could be tracked and traffic parameters could be calculated.

Disadvantages – Due to camera limitations on the 6-s image acquisition, an adequate sampling of vehicles position was not accomplished. Thus, only a small group of vehicles was able to be tracked for a long distance.

110.3.12 Robust Data Alignment Based on Information Theory and Its Applications in Road-Following Situation

A new approach to data fusion has been proposed from a research group at Ohio State University, focused on target recognition, surveillance, and tracking research areas in transportation (Jwa et al. 2006). The objective of that project is the implementation of a robust data alignment method without knowing the explicit pairwise correspondence between the two feature sets. An algorithm that will be able to use a shrinking error-bound or reducing the degree of uncertainty will be able to recover the best pairwise match of according to the author (Jwa et al. 2006).

The data alignment problem and two methods to solve that problem are explained in this paper. The proposed method targets a low computational cost; thus, the cost criteria and the search strategy are explained in detail. The proposed method is considered as a correspondence-less method according to the author, and it is compared with a correspondence-based method which is the least-square (LS) method. The results showed that both images are almost the same, but the performance evaluation showed that the proposed method is more robust than LS method because the average pixel error was ten times less (Jwa et al. 2006).

Advantages – The RDA method can successfully recover the transformation even under difficult conditions where noisy data are collected. By using a combined search strategy, the cost can be minimized successfully, and since the random search can avoid the local minima, that gives the ability to improve its numerical stability for a global minimum.

Disadvantages – The performance of the method depends on the characteristics of the UAV's dynamics and sensors.

110.3.13 From Images to Traffic Behavior: A UAV Tracking and Monitoring Application

Another project from the department of Computer and Information Science of the Linköping University in Sweden has to do with the implementation of a system to achieve high-level situational awareness about traffic situations in an urban area (Heintz et al. 2007). The system was tested both in simulation and on data collected during test flight, where a Yamaha RMAX helicopter powered by a 21-horsepower 2-stroke engine and endurance up to 1 h is used.

Image processing is used to calculate world coordinates of vehicles tracked in video sequences with the help of GIS and thermal cameras. Due to the fact that two cameras are onboard and the distance to an object appears different in color and infrared images, the distance to a specific object needs to be determined. The distance could be calculated given the camera specifications, the helicopter pose, and the ground elevation. DyKnow, which is a software framework that provides a set of functionality for contextually accessing, storing, creating, and processing traffic recognition algorithms, was used in order to provide the software support needed to the project (Bethke et al. 2006).

The project consists of two parts: the traffic monitoring application to monitor activities in an intersection and observing with a UAV a road segment and collecting information about the behavior of the vehicles passing by. In the first case, the UAV stays close to an intersection and monitors the cars going through. Each car is tracked for the whole path in order to create a stream of observations. In the second part, the focus was on recognizing overtakes. To do that, a stream of qualitative spatial relations between pairs of cars, such as behind and beside, are computed and used as input by the chronicle recognition system DyKnow.

Advantages – A beneficial approach for solving the problem of object recognition is proposed. The object linkage structures allows one to track a new moving object if the link to the previous is lost. Also, it could replace a lost object with a simulated object and predict the development of the object based on its history. Combined input sequences of color and thermal images are used to construct and maintain objective structures and recognize the traffic behavior of the tracked vehicles in real time.

Disadvantages – The accuracy of the computation of the true location of the car is influenced by the error of the UAV position and the springs in the camera platform suspension. The maximum error is estimated below 4–5 m for distances to the object of 80 m.

110.3.14 The Use of Small Unmanned Aircraft by Washington State Department of Transportation

A study was conducted at the University of Washington in cooperation with the U.S. Department of Transportation on June 2008 (McCormack 2008). Two types of UAVs were used for a study focused on evaluating the use of a UAV as an avalanche control tool on mountain slopes above state highways. In the first test, a fixed wing MLB BAT UAV was used, and the flight was designed to test the capability of the video camera onboard. The camera was needed to be able to view the roadway, to operate off a highway, and to survey the surrounding terrain. All three tasks were successful despite the bad weather conditions. The aircraft had operational limitations related to difficult terrain and weather. On top of that, the aircraft required a 100-foot-long flat stretch of roadway for a miniature airstrip which will limit the use of these aircraft in urban areas.

The second test was deployed by a rotary wing UAV, the RMAX, made by Yamaha. An autopilot application was demonstrated in which the aircraft followed a road with predetermined waypoints. This test was designed to simulate a survey before the start of snow clearing operations on the road, but it was also a successful test of the UAV's ability to fly along a road centerline to record traffic or weather conditions. The ability of the aircraft to hover provided a stable platform on which camera use was effective. The results show that both aircraft systems present considerable potential for aerial roadway surveillance and avalanche control. This paper describes the implementation of the experiment without focusing on the algorithms that are used on the platforms; thus, it is not included in Table 110.4.

Table 110.3 Summary of current research work covered regarding traffic surveillance with UAV platforms

| Team | System(UAV) | Objective |
|--|---|--|
| German Aerospace Center, DLR | Dornier DO-228 (Manned) | |
| Bethke et al. (2007) | Alternatively HALE (high-altitude long-endurance)-UAV is proposed | The development of an operational compact SAR system for high-flying airborne platforms |
| Department of Computer and Information Science | The WITAS Yamaha RMAX autonomous helicopter | The implementation of a system to achieve high-level situational awareness about traffic conditions in an urban area |
| Linköping University, Sweden (Heintz et al. 2007) | | |
| University of California at Berkeley (Kim 2005) | MLB BAT (fixed wing) | The implementation of an algorithm capable of detecting any types of corridors |
| Department of Electrical and Computer Engineering Western Michigan University (Chen et al. 2007) | (Not mentioned) | The implementation of a data link that connects the camera onboard an UAV to the monitoring terminals in the office of the Michigan Department of Transportation |
| Department of Civil and Environmental Engineering and Geodetic Science, Columbus (Toth et al. 2003) | (Not mentioned) | Study on the quality of the traffic data that could be achieved by operating an unmanned helicopter |
| Air Force Research Laboratory and Ohio State University (Jwa et al. 2006) | (Not mentioned) | A new approach to data fusion focused on target recognition, surveillance, and tracking research areas in transportation |
| Department of CSE, Unmanned Systems Lab University of South Florida (Puri et al. 2007) | Custom-made unmanned helicopter | Collect real-time data to monitor traffic, evaluate and assess traffic patterns, and provide accurate vehicle counts |
| Washington State Transportation Center (TRAC), University of Washington, Georgia Technical University (McCormack 2008) | MLB BAT (fixed wing) and RMAX helicopter | Two types of UAVs were used on a study focused on evaluating the use of a UAV as an avalanche control tool on mountain slopes above state highways |
| University of Nevada and NASA Ames Research Center (Gleason et al. 2011) | (Not mentioned) | Features extraction methods and classification techniques for automatic vehicle detection by UAVs on traffic control and other applications |
| Institute of Command Automation, PLA University of Science and Technology, China (Fang et al. 2011) | (Not mentioned) | Mean Shift tracking algorithms |

(continued)

Table 110.3 (Continued)

| Team | System(UAV) | Objective |
|---|---|--|
| | | The proposed algorithms build the object model according to known target appearance and possible areas that those may appear in |
| Roke Manor Research Romsey, Hampshire (Evans and Turkbeyler 2007) | (Not mentioned) | Detection of moving objects on the ground with video cameras that are mounted on UAVs |
| School of Geosciences and Geomatics, East China Institute of Technology (Cheng et al. 2009) | Custom-made small UAV | Development of techniques for generating high-resolution video flow from UAV videos |
| University of Picardie (Kaaniche et al. 2005) | UAV based on a model plane using thermal engine with a 1.5- m wingspan | Development of a UAV able to realize autonomously the surveillance of an area in order to be able to detect vehicles for traffic monitoring |
| Washington State Transportation Center (TRAC) University of Washington (McCormack 2008) | MLB BAT and Yamaha RMAX | The exploration of the general capabilities of UAVs and the evaluation of those platforms as an avalanche control tool on mountain slopes above state highways and capturing aerial images suitable for traffic and data collection surveillance |

Table 110.3 summarizes all the current research described in this paper. The information is presented similarly to Table 110.2. Table 110.4 summarizes the work done in this area by highlighting the advantages and disadvantages of each method used to solve the problem of traffic monitoring.

110.3.15 Not Yet Implemented on UAVs

In Bethke et al. (2006) the authors claim that the TRAMRAD (Traffic Monitoring with Radar) project aims to solve traffic surveillance problems by radar remote sensing techniques for wide-scale monitoring. Road traffic MTI (Moving Target Indication)/SAR techniques and methods were used on that project. According to the authors, standard SAR processing in general is not enough to detect and focus moving targets on the ground; thus other techniques that are described in the paper were considered. Ideas for along-track velocity were proposed, but it was shown that clutter suppression and vehicle acceleration are major challenges for a current estimation of the motion status of road vehicles.

In another study, by performing direct georeferencing and the use of GPS/IMU data, according to the authors Rosenbaum et al. (2008), near-real-time traffic data extraction can be implemented. Road extraction and two types of vehicle detection

Table 110.4 Advantages and disadvantages of the methods used on traffic monitoring

| Title | Advantages | Disadvantages |
|---|--|--|
| Airborne Road Traffic Monitoring with Radar (Bethke et al. 2007) | Capture of data in wide areas regardless of the weather conditions | Amount of data to process and transmit is large |
| | Resolution of SAR images is of order of 1–2 m | Does not detect vehicles with precision |
| Realtime Road Detection by Learning from One Example (Kim 2005) | Algorithm can be applied to a non-straight road with the assumption that it is partially straight | The UAV needs to fly at low altitude in order to make the lane markings visible |
| | Algorithm can be applied to other applications and not necessarily to road detection | The position errors of the hypothesis do not follow a Gaussian distribution; thus least-square line fitting gives inaccurate fitting results Real-time adaptation for a changing road structure and curved road detection is hard to accomplish |
| Statistical Profile Generation for Traffic Monitoring Using Real-Time UAV-Based Video Data (Puri et al. 2007) | The proposed algorithms can adapt on different environmental setups automatically | The helicopter's instability leads to a vehicle count error |
| | | All data is collected from a fixed point Data was not collected while the helicopter was in a moving state |
| Vehicle Detection from Aerial Imagery (Gleason et al. 2011) | The threshold of the fast detection algorithm gave a reasonably accurate estimate of the overall accuracy of the program | The rotation-invariant HOG did not perform well due to the reflective water that was in the background |
| | The performance of Gabor features under different lighting conditions was good, reducing the false positives by half | |
| An improved object tracking method in UAV videos (Fang et al. 2011) | The combination of Mean Shift and particle filtering allows the change of object size | Mean Shift can only track objects on time when their regions are known |
| | Small objects are rarely lost Valuable to track fast small moving objects like vehicles in highways | |

(continued)

Table 110.4 (Continued)

| Title | Advantages | Disadvantages |
|--|--|--|
| Visual MTI for UAV Systems (Evans and Turkbeyler 2007) | The algorithm performs well on the datasets from the supermarket even with d complex 3D structures | False alarms and missing targets remain even after stage 2; thus some clearly moving objects are not detected |
| | The algorithm is still able to detect the cars even with pedestrians walking in the scene | The geometrical interpretation of the scene is not well constrained and that causes problems even with a smooth traffic flow on the motorway |
| Real-Time Video Relay for UAV Traffic Surveillance Systems Through Available Communication Networks (Chen et al. 2007) | More than one user computer can receive the video stream simultaneously with acceptable data rate | The bandwidth of the cellular network influences the image of the video stream |
| | Experimental results showed that the proposed method can deliver quality videos to the control office in real time | During field experiments the video stream was frozen or buffered while the end users were watching the video |
| | | The results showed that the transmission with no server system scheme could only provide a video stream in continuous and smooth image in a bit rate of 45 kbps and also showed that any rate below that may not meet the requirement of the UAV project |
| Roadway traffic monitoring from an unmanned aerial vehicle (Coifman et al. 2006) | Application of platoon matching method where the network OD flow is been calculated in unobserved regions | The field of view of the UAV is not wide and the fluctuations in the traffic cause large variations in density measured from a single still frame |
| | It is not necessary to track the vehicles the whole time | The field of view continuously changes, and the sample size is small in order to calculate density and flow from individual frames The data analysis and reduction was made manually and not automated |
| Detecting and counting vehicles from small low-cost UAV images (Cheng et al. 2009) | Vehicle can be tracked | The average parallax vector is calculated from the tie points of the video stereo frames, and in some cases it cannot be calculated because there are no tie points |

(edge extraction, normalized cross correlation) are the steps that were followed on the traffic processor. Due to the powerful cameras (3-head camera system) that were used in order to cover wide areas, the amount of data collected was large. The proposed system is capable of accomplishing traffic data extraction on 1 km² area within seconds. It also gives the ability to add a radar sensor and provide data in case of bad weather, where remote sensing techniques based on optical sensors fail. The data collection and experiments were not implemented on UAVs although the authors state that the system could be mounted on UAVs also. Those papers are not included in Tables 110.3 and 110.4 because those techniques are not yet implemented on UAV platforms.

110.4 Conclusion

This chapter presents a survey of current research activities going on in universities and research centers around the globe in the area of UAVs used for traffic monitoring. As a conclusion, it may be stated that UAVs can be very useful for traffic monitoring. However, issues with UAV deployment for civil applications must be addressed. Due to the fact that the approval of the Federal Aviation Administration (FAA), Federal Communications Commission (FCC), and other regulatory agencies for flying the UAVs in civil airspace keeps on delaying, universities have not yet implemented a lot of real-life scenarios.

Maneuverability and wireless network communication are two of the key points that make unmanned air vehicles more useful than the other methods currently used. The first one makes them capable of tracking vehicles on the ground, while the

second one allows the transmission and reception of instructions and image and video information to a ground base. Research is focused not only on the types of the sensors that could be used onboard (radar, vision, hybrid) but also on the type of processing (onboard, off board) of the data in vision sensors.

This research is partially supported by U.S. National Science Foundation (NSF) Grant CNS-1229236. A short version of this paper has appeared at the proceedings of the 2013 International Conference on Unmanned Aircraft Systems (ICUAS' 13), May 2013, Atlanta, GA.

Abstract

Volcanic environments are a challenging application for UAVs. About 10 % of the world's population lives in areas directly threatened by volcanoes, and scientists are continuously asked to perform measurements and also to better forecast volcanic activity. This chapter describes the importance of the study of volcanoes and the typical aerial measures that could be usefully executed. The main forms of measurement concern the collection of visual/thermal images and gas analysis and sampling. The specific advantages offered by the use of UAVs in comparison with manned solutions are discussed in terms of cost, simplicity, and readiness to operate. Then an overview of the major worldwide projects carried out in the last few years by several research organizations is summarized and discussed.

111.1 Introduction

The study of volcanoes is of primary importance due to the huge impact that eruptions could have on several human activities. Volcanic events can influence air-traffic safety, can lead to climate change, can seriously damage infrastructure, and may sometimes result in casualties (Alwyn 2002).

The adoption of robots as a tool for the study of Earth processes, and in particular those of volcanoes, is an open challenge to robotics: the collection and analysis of data executed by a robot in the proximity of a volcano is a difficult task faced by a limited number of research groups (Muscato et al. 2012).

In this context, in the last few years Unmanned Aerial Vehicles (UAVs) have been adopted as a powerful instrument for environmental monitoring (Ramanathan et al. 2007; Holland et al. 2001). However, even if several aerial platforms have been developed for adoption in volcanic scenarios, these studies are mainly at a preliminary stage, and there are still many open problems.

Currently, 1,500 volcanoes on Earth are potentially active, approximately 500 of which have been active during the twentieth century and about 70 are presently erupting. At the beginning of the third millennium, 10 % of the world's population lives in areas directly threatened by volcanoes. About 30,000 people have died from volcanic eruptions in the past 50 years, and damages of billions of euros have been suffered.

In these scenarios, effective prevention, or first response strategy, requires the accurate knowledge of volcanic activities. Significant advances have been made in recent years in the understanding of the behavior of volcanoes and in volcanic eruption forecasting. One of the main reasons is the improvement in the collection of field data with innovative methodologies and sensors. Such data are typically used as input for computer simulations of volcanic activity, to improve forecasts for long-lived volcanic phenomena, such as lava flow eruptions and ash-rain (Aiuppa et al. 2010; Symonds et al. 1994; Stix and Gaonac'h 2000).

Fig. 111.1 Volcanologists measuring volcanic activity at a safe distance

The most valuable data relates to volcanic activity during paroxysmal phases of eruptions, which unfortunately are the periods of greatest risk to human operators, as shown in Fig. 111.1. Thus, the collection of field data with innovative methodologies and sensors plays a key role in current research for improving volcanic models. Up to now, data has been mainly collected by means of field measurements, aerial pictures, and satellite images. This kind of measurement is usually prone to errors and is expensive, especially if quantitative and/or qualitative data is required.

As a consequence, the adoption of autonomous robots seems to be the right choice: all the required instrumentation can be carried directly close to the volcanic scenario to obtain different kinds of measurements (Muscato et al. 2012).

Remotely operated or fully autonomous flying vehicles can support, or replace, the actual methodologies used to perform environmental measurements. Several research projects are investigating the adoption of UAVs with the aim of developing an innovative, easy to manage, low-cost, and readily available survey system to be applied for the frequent monitoring of eruptive phenomena and lava flows.

As demonstrated in the following sections, the adoption of unmanned systems allows several improvements in volcanic monitoring:

- Faster and more accurate response than human-based monitoring, providing the means for the improved collection of data, both from a qualitative and quantitative standpoint

- Safer for human operators as volcanic activity can be monitored at a safe distance
- Cheaper than human-based monitoring, because UAVs do not require the use of expensive manned helicopters and highly trained operators

This is mainly possible thanks to the availability of lightweight and compact sensors that allows the adoption of small and versatile flying platforms; moreover, the present state of the art in the field of onboard stabilization, control, and navigation systems makes these aircrafts capable to be managed also by not-skilled operators.

In this chapter, the measurements of interest needed to understand, model, and predict the behavior of a volcano will be analyzed; then the principal problems related to data collection in a volcanic scenario and how the adoption of UAVs could help overcome these issues will be investigated. Finally, an overview of the main research projects related to the adoption of unmanned flying platforms for the study of volcanoes will be described and reviewed.

111.2 Typical Aerial Measurements in a Volcanic Scenario

In the last few years, the surveillance of active volcanoes has greatly improved according to the general progress of technology. The integration among several kinds of measures, obtained from different sensors, allows the quality of data to be increased. Ground-based sensor networks (Brenguier et al. 2012), aerial photogrammetry (Marsella et al. 2008), gas measures (Aiuppa et al. 2011), and information from satellites (Ganci et al. 2012), as reported in Fig. 111.2, can be used to obtain a system that is more robust to sensor noise and hardware failure, thanks to the redundancy obtained.

Many different types of aerial measurement can be useful for researches of volcanic activity. As will be explained below, UAVs can improve the collection procedure, mainly in visual and thermal data acquisition and in gas analysis and sampling.

111.2.1 Visual/Thermal Data

Pictures and videos within immediate proximity to craters allow the better understanding of the evolution of an eruption. Indeed, on active volcanoes, each new effusive eruption alters the local topography and builds new morphological features. Lava flows can threaten towns, roads, and infrastructure with complete destruction, as occurred, for example, several times for Mt. Etna volcano in the last century and which may probably occur again. Data extracted from eruption monitoring can help forecast, through simulations of the lava flow emplacement, the course and rate of advance of an ongoing flow. These pieces of information are of great potential for enabling mitigation measures, such as plans for people evacuation and the building of barriers for preventing a lava flow from destroying existing infrastructure.

In this scenario, aerial vehicles can be provided with high-resolution video and thermal cameras to take pictures of the volcanic area and of lava flows.

Fig. 111.2 An image of the 2011 eruption of Nabro volcano, Eritrea, taken from an Advanced Land Imager (ALI) on the Earth Observing-1 (EO-1) satellite, showing the volcano in visible and infrared light (Credit: NASA Earth Observatory image by Robert Simmon, using EO-1 ALI data. Caption by Holli Riebeek (<http://visibleearth.nasa.gov/>))

The collected data can be processed by adopting strategies derived from traditional aerial photogrammetry, representing an evolution with respect to the qualitative analysis generally carried out on close-range images, that are compared with the pre-eruption orthophotos and topographic maps. Visible images can be orthorectified for defining the planimetric (2D) expansion of a lava flow, while thermal images can be analyzed to identify the active portions of the lava flow. Images acquired with a suitable overlap can also be processed for measuring 3D coordinates of sparse or lined up points (to evaluate the average lava thickness) or for extracting the orthomosaic or Digital Elevation Model (DEM) of the area being monitored (Coltelli et al. 2007).

111.2.2 Gas Analysis and Sampling

The analysis of the gas ejected from volcanic vents is one of the main indicators of volcanic activity (Shinohara et al. 2008).

Recently, gas analyzers were independently developed by different scientists of the *Istituto Nazionale di Geofisica e Vulcanologia* (INGV, Italian Institute of Geophysics and Volcanology) and the *Geological Survey of Japan* (GSJ) allowing real-time in situ measurements of gas composition in volcanic plumes, a so-called Multi-Gas unit. Further improvements were found by strictly cooperating with other gas researchers (in Japan, USA, UK, France).

A very good correlation between variations in concentration ratios in volcanic main gases (CO_2 , SO_2 , H_2O , etc.) and volcanic activity was found in many cases. More precisely, it is important to measure the fluxes of these gases and especially the CO_2 flux (Aiuppa et al. 2011). This gas in fact is less soluble than the other main components of volcanic plumes, so it begins to exsolve from the magma at higher pressures, which is equivalent to a greater depth. In practice, a change in CO_2 flux is probably one of the earliest signals of a probable change in the volcanic activity. Of course, even the relative flux changes between these plume gases are important to understand the volcanic dynamics. Sometimes, these data were used for forecasting volcanic eruptions or explosions in Italian volcanoes (Aiuppa et al. 2010). The importance of this kind of measurement is becoming relevant for civil protection, to decide the level of risk in areas frequented by tourists that may be very attracted by active volcanoes, from all over the world.

While determining SO_2 flux is relatively easy with remote sensing techniques, CO_2 is difficult to measure remotely; only LIDAR systems are potentially useful, but cost, power requirements, weight, and dimensions are constraining parameters. In every case, all these remote measurements cannot be carried out during cloudy weather.

In fact, the most advanced techniques to obtain plume gas fluxes are based on SO_2 remote sensing flux measurements and on direct in situ monitoring with Multi-Gas units. Combining the ratios of CO_2 and other species with SO_2 , and SO_2 flux, it is possible to derive all the other fluxes.

Airborne measurements are one typical method performed to obtain gas fluxes, moving across the volcanic cloud and measuring gas concentrations and wind velocity, but again costs and safety are less guaranteed in this harsh environment, and usually only diluted parts of the plume are reached, which are not the most useful.

Bad weather conditions and issues of maintenance limit the abundance and continuity of these measurements.

111.3 Importance of Unmanned Aerial Systems for Measurements in Volcanoes

The main goal of using robotic systems for volcanoes is to reduce the level of risk for the volcanologists involved who are working too closely to volcanic vents during eruptive phenomena (Muscato et al. 2012). The need for a robotics solution for operation in hazardous environments has been already focused on and tackled by several research projects (Trevelyan et al. 2008).

However, the adoption of autonomous UAVs in volcanic environments increases the safety of the operators but also improves and simplifies many measurement operations usually performed for the study of volcanoes.

For example, leaving aside the issue of safety, at the beginning of an eruption if aerial shots are urgently needed, a helicopter or a microlight aircraft should

be available. Consequently all the facilities and operators needed should be ready at the same time: a trained pilot and an instrumentation technician (usually a volcanologist). Moreover, the takeoff/landing field is usually not in the proximity of the volcano. This would entail a considerable delay in the intervention. In addition the cost of the purchase or lease and maintenance of an aircraft and of the related facilities should not be underestimated.

On the other hand, the use of small UAVs can represent a considerable improvement in all of the phases of the operations mentioned. First, it is not necessary to have an expensive manned aircraft and the relative facilities available: UAVs can also be easily stored inside some of the numerous observatories of volcanology available in the proximity of volcanoes. Moreover the presence of highly trained personnel is not necessary: the level of autonomy provided by modern UAVs also allows non-skilled operators to use such systems and to easily control the payload (cameras and other sensors and measuring instruments). In addition UAVs can be quickly launched and consequently be able to collect information before any impending crisis, when it is easier to mitigate its effect.

All these advantages mentioned are obtained with a considerable cost reduction. The overall cost of acquiring, operating, and maintaining UAVs is much lower with respect to manned solutions. This last aspect allows the possibility to frequently repeat the surveys, thus enabling scientists to monitor the evolution of the lava flow and to collect, with sufficient temporal resolution, data to be used as input of simulation codes and for studies on flow emplacement. All these operations can be performed with no risk to the operators, since they will always stay at a safe distance from the site.

For example, the adoption of UAVs, with respect to traditional aerial photogrammetry, allows for frequently performing aerial surveys in volcanic areas, which are usually limited by the availability and costs of the traditional platforms (airplane/helicopter).

Moreover, for the same reasons, several researchers in volcanic gas monitoring in the last few years have tried UAVs to obtain plume gas fluxes. The idea is to reach the same results as airborne measurements, integrating UAV systems and Multi-Gas units, offering the possibility to get closer to the vent and to potentially even fly in cloudy or dangerous environments.

The specific environmental and working conditions of volcanoes in which UAVs have to carry out the missions suggest the adoption of an autonomous navigation system for the plane. There are two main problems that do not allow using a classic remote-controlled plane. The first is the usually long distance between a safe place and the volcanic craters. The volcanic scenario is very rugged, and it is not often possible to find a runway in proximity to the crater; so takeoff is usually executed in safe areas from where tele-operations are very difficult due to the distance between the takeoff area and the target. The second problem is related to the loss of the line of sight when the plane flies into the fumes: the gas within the volcanic plume, as can be observed from Fig. 111.3, is usually very dense and does not allow the visual recognition of the vehicle flying inside it.

Fig. 111.3 A picture taken by International Space Station crew members during the eruption of Mt. Etna in 2002 showing the density of the volcanic plume (Credit: astronaut photographs taken on October 30, 2002, provided by the Earth Sciences and Image Analysis Laboratory at Johnson Space Center (<http://visibleearth.nasa.gov/>))

Moreover, an intelligent and autonomous system requires less interaction with the first responders, requiring a minimal amount of operators, fast setup procedures, and no particular expertise.

Regarding the kind of aerial vehicle to be adopted, several considerations must be taken into account with respect to:

- The desired complexity of the system
- The payload to be carried (in terms of cost and weight)
- The logistics available
- The goal of the mission

Kites, balloons, and airships are very simple systems already adopted in meteorology and by volcanologists for studying the composition of volcanic plumes, measuring and modeling ash dispersion. However, their limited maneuverability makes these kinds of system ill-suited for adoption in complex missions or in the presence of bad weather conditions (strong winds, turbulence).

On the other hand, several groups of volcanologists have adopted helicopters for their research studies. Helicopters have a high degree of maneuverability that makes them ideal to be used in different kinds of missions in hostile environments. Moreover, these vehicles do not need a runway for takeoff and landing, can carry heavy payloads, and are suited for data acquisition, thanks to their capacity to hover and their stable flight (Saggiani and Teodorani 2004). However, helicopters are characterized by a mechanical complexity and need continuous maintenance; moreover, highly trained operators are required to fly these vehicles.

These limits have been partially overcome in the last few years thanks to the advent of multicopters, able to carry suitable payloads, equipped with low-cost autopilots, that make these aircrafts easy to be piloted.

Finally, fixed-wing UAVs are used in all those situations where the autonomy of the mission plays an important role. They are usually adopted for medium-/high- altitude flights or for long-endurance missions, which is a typical situation in a volcanic environment where the operators must stay at a safe distance from the activity.

Fig. 111.4 A graphical representation of the interaction between three cooperating UAVs flying in the proximity of a crater

Fixed-wing UAVs can carry heavy payloads and consequently be equipped with several different sensors during the same mission. Moreover, the control of these vehicles is usually simpler with respect to helicopters, thanks to the intrinsic stability of the fixed-wing vehicles adopted for data collection and monitoring. On the other hand, they are not able to hover above a target or to approach close to the terrain to perform detailed measurements on the ground.

A further possibility is to use a fleet of UAVs rather than a single aircraft. A team of UAVs could bring several advantages with respect to a single UAV system (Ollero et al. 2005; Ramanathan et al. 2007):

- It is more efficient, by allowing for a faster time to collect data or the possibility of a greater geographical coverage within a single mission.
- It is more robust to sensor noise and hardware failure, due to the redundancy in data acquisition and hardware.
- It is more powerful because it allows joint actions to be performed, such as coordinated data acquisition and dynamic allocation of surveying tasks.

For example, in the specific case of lava flow monitoring, a fleet of cooperating small UAVs can be used as shown in Fig. 111.4. An “Explorer UAV” could be used to provide a global view of the area to monitor. This airplane will be launched from a safe area and, after a climbing phase, will reach a loiter altitude over the area of interest. A video camera and thermal camera, mounted onboard the UAV, will be used to gather information about the scenario affected by the eruption and to estimate the significant geographical locations of the lava flow; this data will be used to build a global coarse map to be used by two other “Surveyor UAVs,” flying at a lower altitude, in order to decide on the appropriate configuration for collecting several high-resolution pictures of the established area. These aerial images, together with sensor poses and Ground Control Points (GCPs), will be used to reconstruct the geometry of the lava flow. Natural features, to be measured on pre-eruption high-resolution DEMs and orthophotos, and artificial features, to be placed before the survey, can be adopted as GCPs.

111.4 Overview of Existing Research Activities and Projects

In this section a summary of the main activities performed by several research groups will be briefly discussed. The main features of each system and the type of measurements and results are described.

111.4.1 Observation Flight at Erupting Volcano, Mt. Usu, Japan

One of the first reported activities concerning the adoption of UAVs in volcanoes was performed by YAMAHA Motor Co. Ltd. in Japan (Sato 2001). In April 2000 a Yamaha RMAX helicopter was used for the surveillance of the Mt. Usu volcano in the Hokkaido region of Japan. A complete autonomous control system was developed: the onboard payload was based on the Yamaha attitude control system (YACS), a differential GPS, and three digital cameras. The remote control of the RMAX was performed from a ground control station by means of a radio/video link. Another onboard video camera and a still digital camera were used to collect images and videos, performing several surveillance missions. The hazards caused by volcanic sediments and ashes were observed; moreover, thanks to the possibility of flying close to the ground, the images acquired had a better quality with respect to those taken from manned helicopters.

The helicopter was also used in February 2001 after the eruption of Mt. Oyama on Miyake-jima Island, Japan. During the missions, the sensor payload was based on a video camera and a gas detection meter, used to measure the densities of volcanic gas. Moreover, lance-shaped poles were launched from the helicopter to measure the thickness of the volcanic mudslide.

111.4.2 Volcano Surveillance by ACR Silver Fox

In 2004, thanks to a collaboration between the U.S. Geological Survey (USGS) and Advanced Ceramics Research (ACR), acquired by BAE Systems in 2009, a Silver Fox UAV by ACR (Fig. 111.5), equipped with sensor payload, was deployed to monitor the activity of Mt. St. Helens in Vancouver, Washington (Patterson et al. 2005).

The Silver Fox has a weight of 11 kg, a wingspan of 2.4 m, an endurance of up to 8 h, a speed between 35 and 60 knots (65–83 km/h), a nominal mission altitude of 150–365 m AGL, and a service ceiling of 3,657 m AMSL. It could carry a payload of up to 3.5 kg and is equipped with a navigation system that makes the vehicle fully autonomous.

In November 2004, just after the first eruption of October 2004, several flights were executed over Mt. St. Helens, as shown in Fig. 111.6. During the preliminary missions, a Silver Fox was equipped with visible electro-optical and infrared video cameras; a radio/video link was adopted to transmit data collected from the UAV

Fig. 111.5 The Silver Fox UAV by Advanced Ceramics Research – BAE Systems (Copyright © 2012 BAE Systems)

Fig. 111.6 The Silver Fox UAV ready to be launched: Mt. St. Helens is in the background (Copyright © 2012 BAE Systems)

to the ground station, flying at an altitude of 2,600m at a speed of 50 knots (92.5 km/h). Two important events were observed: a rock fall and an explosion, shown in Fig. 111.7, with a subsequent small eruption.

A similar payload was used 1 month later in a mission executed with the aim of collecting thermal data: the data acquired, used to investigate the formation of a new lava dome, were consistent with the information acquired by the USGS using the traditional methodology based on the use of a helicopter.

An attempt to obtain information on the composition of gases was executed by mounting electrochemical gas sensors onboard the UAV. The technology available in 2004 did not allow relevant information to be obtained, because the lightweight sensors available were too slow with respect to sampling time and not sensitive enough.

Fig. 111.7 Image of an explosion taken by the onboard camera of the Silver Fox UAV in November 2004 (Copyright © 2012 BAE Systems)

However, the trials, executed during the activity of Mt. St. Helens in 2004, represented a good demonstration that a flying autonomous vehicle, equipped with the appropriate sensor payload, is a winning methodology in the study of volcanic behavior.

111.4.3 Unmanned Aerial Vehicle Measurements of Volcanic Carbon Dioxide Fluxes

In this project a small remotely piloted helicopter was adopted to carry a system for the sampling and analysis of gas inside volcanic plumes (McGonigle et al. 2008). The UAV, shown in Fig. 111.8, was a Thunder Tiger Raptor 90 helicopter with a 15 cc internal combustion engine and 710 mm standard carbon fiber blades. Without a payload the aircraft weighted 5.2 kg and was able to carry payloads of up to 3 kg: with the onboard instrumentation it reached speeds of 45 knots (83.4 km/h) and had an endurance of up to 16 km.

The methodology developed needed the adoption of two sensor suites to measure SO_2 concentration and the CO_2/SO_2 ratio: this allowed the CO_2 concentration to be indirectly obtained. These measures, as explained in the previous sections, are among the main precursory signals of changes in volcanic activity.

For this reason two payloads were needed: in the first sensor suite, an ultraviolet spectrometer was mounted onboard the helicopter to measure SO_2 flux, while in the second configuration of the payload, an infrared spectrometer, together with an electrochemical sensor, was used to measure the CO_2/SO_2 ratio. An onboard GPS was used to precisely geo-localize the acquired samples.

The helicopter was remotely piloted by a human operator, and the complete mission was executed in two phases. In the first phase the helicopter was equipped with the sensor suite able to measure SO_2 flux. The vehicle was flown below the

Fig. 111.8 The Thunder Tiger Raptor 90 helicopter and the sensor payload used to measure volcanic carbon dioxide fluxes (Photo: ©Rolex Awards/Marc Latzel)

Fig. 111.9 A representation of the mission executed for the measurement of volcanic carbon dioxide fluxes. The two phases allowed the measurement of the SO_2 flux and CO_2/SO_2 ratio (Photo: ©Thames & Hudson/Rolex Awards Reference)

plume (not inside it) and, taking into account the plume transport speed, the SO_2 flux was determined (McGonigle 2007). In the second phase, the second payload was mounted, and the helicopter was flown inside the plume to measure the CO_2/SO_2 ratio, as represented in Fig. 111.9.

Several tests were performed in 2007 in the proximity of the La Fossa crater, Vulcano, Italy, in collaboration with the INGV. The measures collected allowed the scientists to calculate the flow of gases from the volcano, giving proof to the validity of the methodology adopted. However, this strategy presented all the limits related to a human-operated vehicle: the operational range was limited by the line of sight (≈ 400 m) and could not be adopted in the presence of dangerous events in the proximity of the area of interest.

111.4.4 Utilization of In Situ Airborne MS-Based Instrumentation for the Study of Gaseous Emissions at Active Volcanoes

The goal of this research activity is the realization of unmanned airborne-based instrumentation architecture for the acquisition of data to be used for the calibration and validation of satellite remote sensing data (Diaz et al. 2011).

Four NASA centers (Ames Research Center, Goddard Space Flight Center, Jet Propulsion Laboratory, Kennedy Space Center's Hazardous Gas Detection Laboratory), together with the Organization for Tropical Studies (Costa Rica) and the University of Costa Rica, are investigating the potential for small UAVs to be used for the in situ transportation of several kinds of sensors: mass spectrometers, electrochemical sensors, and ultraviolet and infrared cameras will be used to analyze the composition of gases inside volcanic plumes. The involvement of two public institution of Costa Rica represents a key to the success of the project, thanks to the presence in this country of several active volcanoes that can be used to develop and test the entire system.

With respect to the airborne system, a tethered balloon system is used to carry a payload of up to 1 kg to a maximum altitude of 5 km. Moreover, the University of Costa Rica has a WING 100 by Maryland Aerospace Inc., a small UAV with electrical propulsion, shown in Fig. 111.10, that could carry a payload of up to 1 kg and has a maximum flight time of 30 min.

For the transportation of heavier payloads, it is planned that the Sensor Integrated Environmental Remote Research Aircraft (SIERRA) will be adopted, a medium-class unmanned aircraft system actually used by NASA's Ames Research Center for remote sensing and Earth science research. This platform is able to carry up to 45 kg of payload and has been developed for long-endurance missions (up to 11 h) in harsh environments.

Several instruments are under development. The actual sensor package is represented by two systems: the first is a small and light sensor suite to be carried by balloons and has been adapted for the WING 100. It contains GPS, SO₂, and temperature sensors. The second sensor suite, named "ULISSE" (utilization of lightweight in situ sensors and remote sensing to study active volcanic emissions sites), is a portable mass spectrometer system (Diaz et al. 2010) developed in order to measure the concentration of different chemical species inside volcanic plumes.

The system was tested during the eruption of the Turrialba volcano in Costa Rica in January 2010: the data acquired before and after the eruption allowed the

Fig. 111.10 The WING 100 by Maryland Aerospace Inc. used by the University of Costa Rica for the activities related to the study of volcanoes (Courtesy of Dr. Jorge Andres Diaz, University of Costa Rica)

demonstration of the validity of the architecture under development, as well as the importance of the correlation between in situ measurements with remote sensing data obtained from satellites.

During these trials, the actual version of the ULISSE package was tested onboard a manned light aircraft, but a new prototype, to be carried by the SIERRA UAV, is under development.

111.4.5 The Volcan UAS Project

The Service Robots Group of the “Dipartimento di Ingegneria Elettrica, Elettronica e Informatica” (DIEEI) at the University of Catania is involved in several research projects focused on robotics applied to the study of volcanoes (Service Robots Group 2012). The proximity of Mt. Etna, Europe’s largest active volcano, allows the prolific cooperation with the researchers of the INGV: in the last few years several robotic platforms have been developed, taking into account the necessities and the suggestions of the volcanologists (Muscato et al. 2012).

Some of these activities are related to the development of autonomous aerial systems for applications in volcanic environments such as the *Volcan UAS Project*. The target is the realization of a flying system able to autonomously perform aerial surveillance and analyze the composition of gases inside volcanic plumes (Astuti et al. 2008a). The Volcan is a fixed-wing UAV, shown in Fig. 111.11, developed by taking into account the problems related to flight at high altitude in a volcanic scenario: harsh environment, strong winds and turbulence, rapid changes in weather, and presence of corrosive gases.

The mission will be performed at the top of Mt. Etna (3,300 m AMSL), flying over the two main, most active, degassing vents on volcano craters “Voragine” and “North-East.” Takeoff and landing procedures will be executed from “Piano delle Concazze” (37° 45′ 55.59″ N, 15° 00′ 50.35″ E, 2,800 m AMSL), an almost flat area

Fig. 111.11 The Volcan UAV ready to be launched by means of an elastic rope

near the main craters. The UAV will carry the gas-sensing instrumentation inside the plume by following a preplanned trajectory: CO_2 and SO_2 plume concentrations will be measured using onboard infrared and electrochemical cells. Data gathered will be correlated with the positions, given by the onboard GPS, for obtaining an exact map of the gas concentrations. Figure 111.12 shows a typical mission scenario.

In the laboratories of the DIEEI, a complete mission management and navigation system has been developed: it is based on the onboard modules, the communication radio link, and the ground control station.

The onboard avionics is supervised by the developed autopilot module that takes care of both the navigation and the stability of the vehicle. Taking into account the information coming from the onboard instrumentation, the control algorithms, running on an embedded microcontroller, compute the control signals to be sent to the developed actuators interface board.

An Air Data Attitude and Heading Reference System (ADAHRS) has also been developed: it computes, by means of quaternion-based Kalman filtering techniques, the attitude and the position of the plane by integrating measurements from gyros, accelerometers, magnetometers, pressure and temperature sensors, Pitot tube, and GPS.

The communication between the onboard modules is based on CAN bus and CANAerospace protocol; this protocol allows both the increase in robustness and reliability of the system and of obtaining a plug and play architecture. Thanks to

Fig. 111.12 A typical mission of Volcan UAV on the *top* of Mt. Etna. After takeoff from the base station in Piano delle Concazze, the UAV will reach the target plume and will start to collect samples. Then it will return to the base station to be recovered

the developed hardware and software interface modules, based on the adoption of the CANAerospace protocol, the onboard sensor and actuator payload can be easily changed as required (mono and stereo cameras, chemical sensors, infrared and thermal vision systems, data loggers).

A high-rate wireless Ethernet gateway ensures long-range communication between the onboard modules and the ground control station: the latter allows, with easy “click and fly” operations, mission planning, monitoring, and in-flight adjustment on a rugged notebook PC from a safe, remote location.

A Hardware-In-the-Loop architecture, based on the adoption of an X-Plane flight simulator by Laminar Research, has been used in the development phase of the modules involved in the navigation and stability control of the Volcan UAV (Astuti et al. 2008b, 2007). The developed modules have been “closed in the loop” with the flight simulator in order to test and tune the different algorithms of both autopilot and ADAHRS, allowing for a reduction in development time, cost, and risk.

Many on-field tests have been performed at the top of Mt. Etna, confirming the validity and reliability of the Volcan UAS. The completed phases of the Volcan project are:

- Test of avionics
- Test of autonomous navigation system

- Test of launching system
- Test of instrumentation
- High-altitude test of airplane

Extensive measurement campaigns in the Mt. Etna volcanic area are ongoing.

111.4.6 Mt. Erebus Volcano Observatory Project

The Mt. Erebus Volcano Observatory (MEVO [2012](#)) is developing an autonomous quadcopter for unmanned mapping and gas concentration measurements. An initial target will be the volcano's fumarolic ice caves (Curtis and Kyle [2011](#)), to be explored using a simultaneous localization and mapping (SLAM) system based on a 2D laser scanner (Hokuyo URG-04LX) mounted on the quadcopter. A UAV is required for this application because sensitive microbiology and elevated CO₂ levels complicate human entry into these environments.

The UAV will also be adapted for gas studies of Erebus' persistently degassing lava lake. Initial flight tests conducted in January 2012 demonstrated good flight performance, despite an atmospheric pressure of 650 mbar and a temperature of -15°C (Fig. [111.13](#)).

The vehicle was a quadcopter powered by a 2,200 mAh 3 cell lithium polymer battery and 950 kV brushless motors, stabilized by an ArduPilotMega controller with onboard 3-axis gyroscope, 3-axis accelerometer, and magnetometer and barometric pressure sensor for attitude, heading, and altitude control. The quadcopter was able to carry payloads of up to 1 kg with a maximum wind velocity of 15.5 knots (28.8 km/h); in the flight tests on Mt. Erebus, the payload was a GoPro HD video camera. In Fig. [111.14](#) a frame from the video, showing the Lower Erebus Hut and surrounding camp, is provided.

111.4.7 UAV System Development for the Monitoring and Study of Volcanic and Natural Hazard Events

A pioneering flight experiment to investigate the feasibility of using UAVs over volcanoes was carried out by the "Centro Nazionale Terremoti, INGV," Italy (INGV-CNT, National Earthquake Center of the Italian Institute of Geophysics and Volcanology), and the University of Bologna, DIEM Engineering Department, Forlì, Italy, on October 2004 (Saggiani et al. [2004](#)). The target was the Stromboli volcano. Stromboli is an active volcano, the island of which has a low population during the autumn and winter, and it is a good site for UAV experiments on a volcano. The University of Bologna was responsible for the aircraft, a radio-controlled plane named "Butterfly," while INGV was responsible for the payloads, campaign logistics, and civil protection relations. Butterfly, shown in Fig. [111.15](#), was a proof of concept demonstrator able to carry small scientific payloads and cameras; it is a fixed-wing UAS made of composite materials like glass, carbon, and Kevlar fibers in order to obtain a lightweight structure. It has been designed to perform different civil

Fig. 111.15 The INGV Butterfly aircraft ready to take off (Courtesy of Amici S. CNT-INGV e Saggiani G.M., DIEM, University of Bologna)

missions by means of an interchangeable fuselage. It is characterized by a wing span of 3.5 m, a 50 cc boxer 4-stroke engine, and a cruise speed of 70 km/h. It can carry a payload of 3 kg, with autonomy of 4–5 h. A ground control station allows flight management, also displaying pilot cameras views, payload data, flight instruments panel, and terrain maps. Two flights were successfully realized on October 2004 and recorded by a pilot view camera (Fig. 111.16) demonstrating how promising this technique could be for volcanoes and in risk assessment and management applications.

Based on the experience of the Butterfly UAV, another UAV is under development for natural hazard surveillance missions (Saggiani et al. 2007). It represents an evolution of the previous airplane, not only with respect to the increased dimensions and payload capabilities (it is a fixed-wing plane with a wingspan of 4.6 m and a payload of 8 kg), but also for the introduction of a flight control system: the developed onboard avionics allows the UAV to autonomously perform its mission, carrying a sensor payload (EO/IR camera, gas sensors). Several on-field campaigns have been executed and are still ongoing.

111.4.8 Low-Altitude Remote Sensing of Volcanoes Using an Unmanned Autonomous Helicopter: An Example of Aeromagnetic Observation at Izu-Oshima Volcano, Japan

In 2008, the magnetization intensity mapping of Izu-Oshima volcano, Japan, was obtained by means of an unmanned helicopter carrying a magnetometer (Kaneko et al. 2011a, b). The vehicle was an RMAX-G1 helicopter by YAMAHA Motor Co. Ltd. with a 250 cc two-stroke engine, a main rotor of 3.1 m, a weight of 84 kg (including fuel), a video camera, and a payload of approximately 10 kg.

Fig. 111.16 Two Butterfly flights over volcano Stromboli have been realized in October 2004. Weather conditions were extremely good, and the wind was not very strong. A video was recorded by the pilot sight view camera during the flights. A snapshot clearly shows the volcano plume while approaching the crater in flight (Courtesy of INGV. Copyright © 2012 Google (Google Earth) © 2012 European Space Imaging @ 2012 Cnes/Spot Image)

It could reach a maximum speed of 72 km/h and a maximum altitude of 1,500 m, with an operational range within 5 km.

The helicopter was equipped with an autonomous navigation system, based on the Yamaha attitude control system (Sato 2001) and on a real-time kinematic GPS. Onboard video, acquired by a high-resolution camera and transmitted through a radio link, was broadcast to the ground control station, together with the main data transmitted from the onboard electronics.

Regarding the measurement of magnetic intensity, this was obtained by mounting a lightweight cesium magnetometer onboard the UAV. Particular attention was needed in the installation phase of this sensor, the device being influenced by the magnetic disturbances coming from the body of the helicopter; for this reason the sensor was attached beneath the helicopter by means of a three meter-long rope, as shown in Fig. 111.17.

The flights executed allowed significant magnetic observations to be obtained and for a detailed magnetization intensity map of the area around the craters to be reconstructed: from the information obtained it was possible to detect the shallow level structure beneath the caldera area. These kinds of measurements can be useful during eruptions to detect magma movement, and it is not easy to obtain the same information with a manned helicopter since it is necessary to fly at low altitude close to the terrain.

111.4.9 An Unmanned Aerial Vehicle Synthetic Aperture Radar System (UAVSAR)

Several NASA projects and research centers are involved in the study of aerial platforms for earth science (NASA ARC 2012; NASA DFRC 2012). One of the most interesting research activities related to the adoption of UAV for the study of volcanoes is the “Unmanned Aerial Vehicle Synthetic Aperture Radar System” (UAVSAR) project, supported by the Jet Propulsion Laboratory and NASA Dryden (NASA JPL 2012; Rosen et al. 2006).

The developed architecture includes a sensor suite that uses a polarimetric L-band synthetic aperture radar (SAR) for acquiring differential interferometric measurements: this type of information is useful for the study of terrain deformations. The sensor suite has been designed to be mounted on a Northrop Grumman autonomously operated Global Hawk aircraft. However, the first tests and demonstrations have been executed on a Gulfstream III, assisted by a Platform Precision Autopilot designed at NASA’s Dryden Flight Research Center.

The system has already been used for the study of the activities of several volcanoes in the last few years: Mt. St. Helens (2008), Aleutian Islands, Alaska (2009), Kilauea, Hawaii (2011).

Fig. 111.18 Interferogram images of Kilauea volcano obtained by processing the data collected by the UAVSAR in 2010 and 2011: the different colors indicate the amount of deformation caused by the eruption of March 2011 (Image credit: NASA/JPL-Caltech)

Figure 111.18 shows two interferogram images of the Kilauea volcano obtained by processing the data sets collected in January 2010 and May 2011: these color-enhanced pictures represent the deformations of the volcano caused by the eruption of March 2011.

111.4.10 U.S. Geological Survey: “Unmanned Aircraft Systems Project Office”

The USGS has also planned to adopt UAVs for the study of volcanoes: the “Unmanned Aircraft Systems Project Office” (USGS 2012a) is supporting USGS in the adoption of unmanned flying platforms for Earth-science-related research activities. This project office is actually using three kinds of platform:

- AeroVironment Raven RQ-11A, a small and light hand-launched UAV equipped with an electro-optical (EO) color camera and two infrared (IR) thermal cameras, used for rapid deployment and the acquisition of data
- Honeywell RQ-16A T-Hawk Gasoline Micro Air Vehicle, a Vertical Takeoff and Landing (VTOL) UAS, adopted for real-time EO/IR video acquisition
- General Atomics MQ-9 Predator B, a high-altitude, long-endurance (HALE) UAS equipped with electro-optical, thermal infrared, and synthetic aperture radar (SAR)

The USGS is one of the most important research organizations in the world, and its contribution to the field of UAVs applied to the study of volcanoes is of fundamental importance. In its “Unmanned Aircraft Systems Roadmap 2010–2025”

(USGS 2011), the USGS details the planned action to be executed for the adoption of UASs and their integration in the Volcano Hazards Program (USGS 2012b).

111.5 Conclusions

In this chapter an overview of the importance of UAVs for volcanic measurements has been provided. UAVs can be integrated with the actual measurement methods adopted by volcanologists, allowing relevant cost reductions and more rapid deployment in the field with respect to traditional techniques. Several existing projects have been described. Most of the results are still preliminary because of the harshness of the volcanic environment, which makes it hard to operate, and because of the difficulty of synchronizing a research project plan with the unpredictable event of an eruption.

However, the actual results demonstrate the validity of this choice, and, since most of these projects are still ongoing, significant new results will certainly be obtained in the near future.

Abstract

This chapter deals with the application of cooperative unmanned aerial systems to forest fires. Fire detection and fire monitoring and measurement to assist in fire extinguishing are discussed. The chapter presents a decision and control architecture for multi-UAS teams in forest firefighting. Then, the applications to fire detection and fire monitoring/measurement are studied by including in both cases the sensors, mainly infrared and visual cameras, the perception techniques (fire segmentation, geolocalization, and data fusion), and some experimental results. Finally the fire extinguishing is also considered, and some results are presented.

112.1 Introduction

Most studies on civilian applications of UAS have pointed out the interest in forest firefighting applications. Several validations in experimental fires and even in operational conditions have been presented ([►Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States](#)).

Hundreds of thousands of hectares are devastated by wildfires each year. Forest fires lead to the destruction of forest and the wildlife that inhabits them and have a disastrous social, economic, and environmental impact. Forest firefighting involves extensive human resources and is a very dangerous activity, which originates many casualties every year. In many cases, the lack of information about the dynamic evolution of fire plays an important role in these accidents. As very suitable platforms for information gathering in inaccessible places, UAS are a potentially powerful tool in the fight against forest fires (see Fig. 112.1).

Forest firefighting involves several different tasks, usually classified as pre-fire activities, during-fire activities, and post-fire activities.

- Pre-fire activities include all the tasks related to prevention of fire, like:
 - Estimation of vegetation maps, risk maps, and a general assessment of the situation.
 - Fire detection: the detection and localization of potential fire spots. An early fire detection is very important to avoid large damage.
- Once a fire has been declared, two main activities are considered:
 - Forest fire monitoring can be defined as the estimation in real time of the evolution the fire spread.
 - Forest fire extinguishing. Different means are employed to extinguish the fire and/or avoid its further propagation. For instance, manned helicopters are usually employed to carry and deploy water and retardants over the fire.
- After a fire has been extinguished, several additional tasks have to be performed:
 - Embers mapping and monitoring: the reminders of the fire have to be carefully monitored in order to avoid a reignition of the fire.
 - Burnt area assessment: an analysis of the affected zone is important for future actuations, insurance, etc.

Fig. 112.1 A view of a controlled fire from a helicopter. Aerial systems can be very valuable to obtain information about the fire evolution

- Reforestation activities: this task is devoted to the recovery of the affected burned area.

UAS can be employed in a greater or smaller degree in nearly all of these activities; in fact, there has been already systems demonstrated in several of them, like vegetation mapping (Bryson et al. 2010) and fire monitoring ([►Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States](#)). This chapter summarizes the works of the authors in the last 10 years on the topic. In particular, on the use of teams of UAS for the tasks of forest fire detection, monitoring and extinguishing. No major road blocker is seen to prevent the use of UAS even in more complex tasks like reforestation (for instance, by deploying seeds) or extinguishing by carrying water or other products over by the teams of UAS ([►Unmanned Aerial Systems Physically Interacting with the Environment: Load Transportation, Deployment, and Aerial Manipulation](#)).

In order to accomplish the missions related to forest firefighting, this chapter considers the use of fleets of UAS, instead of single, very powerful, UAS, discussing some of the advantages and drawbacks. Sometimes it can be helpful to have a team because one single UAS may not have the payload to carry the sensors and actuators required for the tasks. Also, in many missions, like fire detection, a large area has to be covered, and it may be more convenient to devote several UAS to the task. Moreover, in some applications, such as fire monitoring, measurements should be taken in different places at the same time.

112.2 An Architecture for Multi-UAS Teams for Forest Firefighting

As commented above, this chapter describes the application of UAS teams in different forest firefighting missions/tasks. From a high-level point of view, an

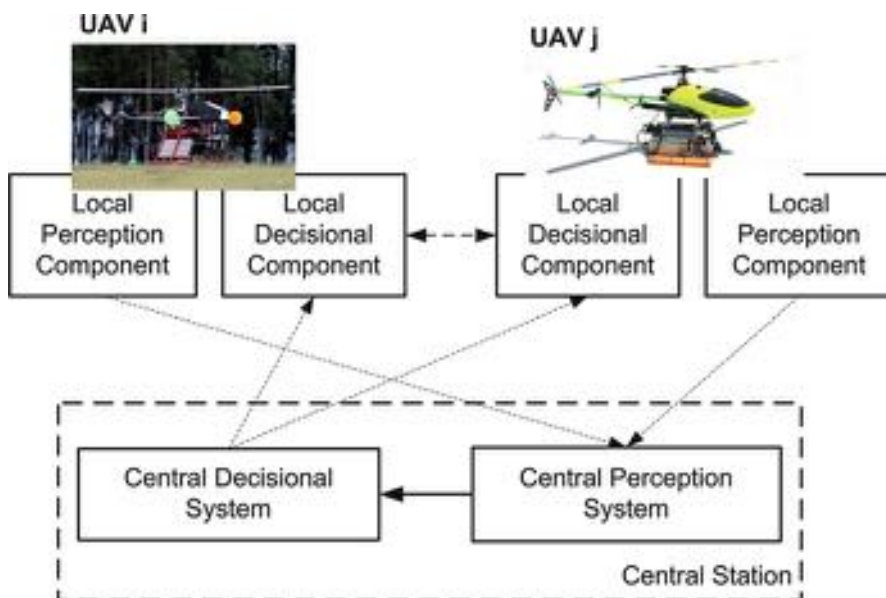

Fig. 112.2 The system consists of several vehicles and two main components: the decisional system and the perception system

architecture to integrate and control all the UAS in these missions consists of two main components (Ollero and Maza 2007): a decisional system, in charge of coordinating the UAS fleet, and a perception system to process the sensor payload.

The system considered in this chapter is composed of a team of aerial vehicles and a central station (see Fig. 112.2). Both, the decisional system and the perception system, consist of local components onboard the UAVs and components in a central station. Depending on the tasks performed by the local and central components, the system can be adapted from a more centralized system in which the UAS have less autonomy, to a more decentralized system in which more decisions are delegated to the UAS.

112.2.1 Vehicles and Sensors

The system was designed to integrate heterogeneous unmanned aerial vehicles such as helicopters, fixed-wing aircrafts, and airships. Of course, some minimal requirements on the platforms and their capabilities are needed:

Operational Autonomy: The UAS should be able to perform a set of basic (atomic) tasks, mainly to fly waypoints and to hover (or to perform flights in orbits around the desired points in the case of planes) at given places autonomously (Ollero and Merino 2004).

Localization: They should be able to localize themselves on the same reference frame. In general, the vehicles are equipped with differential GPS receivers and Inertial Measurement Units (IMUs), which allow them to localize themselves in a common world reference frame.

Perception Payload: For perception purposes, the vehicles carry a sensor payload that will depend on the particular application. For forest firefighting, infrared and visual cameras are the usual payload, together with additional sensors. In some firefighting missions, even additional actuators may be required. More information will be considered in the following sections.

Communications: The UAS carry onboard communication devices to be able to receive commands from the ground station, and to send information back to it, or to communicate directly with other UAS.

112.2.2 Decision-Making System

Conventional UAS systems can perform autonomously flights between waypoints. However, the integration of a fleet of UAS in a forest fire mission requires a decisional system for the coordination and control of the fleet.

This decisional system implements four main different mechanisms:

Task Allocation Arises in a multi-Unmanned Aerial System, where each of the UAS is able to perform tasks in response to the tasks requests. The issue is to decide which system should be endowed with each given task to be performed (for instance, which UAS should go to the different viewpoints to observe the fire). This requires the capability to assess the interest of assigning a certain system to a given task. This operation is especially difficult when the decision has to be done taking into account the current individual plans of the UAS as well as the tasks left to be assigned.

Task Planning Aims at building a sequence of basic tasks to perform, in order to achieve a given high-level mission, for instance, a fire monitoring mission.

Coordination Is a process that arises within a system if given resources (either internal or external) are simultaneously required by several components of this system. In the case of a multi-UAS system, a classic coordination issue to deal with is the sharing of space between the different vehicles, to ensure that each vehicle will be able to perform its plan safely and coherently regarding the plans of the other systems. For instance, as a fire detection mission involves complete coverage of a given area, the region should be divided among the available systems according to their relative capabilities (such as maximum speed, autonomy, field of view of the cameras).

Another example can be found in the context of fire monitoring: several synchronized perceptions of the event are required with convenient locations and orientations of the involved cameras.

Supervision Deals with the management (control) of the tasks execution, in several ways:

- A first concern is simply to keep the system aware of the tasks processing evolution during their executions.
- A second concern is to detect the possible task failures and (if possible) to react to such events in a way that will prevent the system to fail.

The decisional system employed in the UAS presented in this chapter has been evolving with the years, from more centralized implementations to decentralized implementations. The instantiations of the system are described in detail in Lacroix et al. (2007) and Maza et al. (2011) and deal with all the topics considered above.

112.2.3 The Perception System

The Perception System should obtain the high-level information required by the decisional system to achieve the firefighting mission.

It involves mainly the following tasks:

Sensor Low-Level Processing Each of the sensors carried out by the different UAS should be processed to remove noise, stabilize images, etc.

Information Extraction The relevant information for the tasks at hand should be extracted from the sensorial data. Different algorithms will be employed depending on the particular task.

Data Fusion One of the main advantages of having a fleet of UAS is that it is possible to combine the information gathered by all of the vehicles in order to reduce the inherent uncertainty due to noise, incomplete information, etc. Therefore, the main task of the perception system is to determine how the information from the different UAS should be combined to achieve a better assessment of the situation.

The instantiations of the system are described in detail in Ollero et al. (2005) and Merino et al. (2007). The next sections will describe in further detail the different subelements of the architecture for the particular applications of forest fire detection, monitoring, and extinguishing.

112.3 Fire Detection

The Forest Fire Detection Mission can be defined as the task of finding potential fire spots on a given area and determining their location in geographical coordinates, so the fighting means can be deployed as soon as possible.

Important issues for this mission are the typical requirement of coverage of large areas and the potential generation of false alarms, which should be minimized.

In general, fire detection is performed by persons that observe a fire and then call the local firefighting agencies. Systems have been developed for the automatic

detection of fires. Most automatic systems are based on cameras placed on ground as, for example, the BOSQUE system, which relies on infrared cameras and automatic image processing techniques for fire detection, including false alarm rejection (Arrue et al. 2000). Color ground cameras are also used for autonomous detection of forest fires (de Vries and Kemp 1994; Dierre et al. 1999). Some systems are based on smoke plume detection algorithms (Den Breejen et al. 1998; Gómez Rodríguez et al. 2002). Other sensors have been also employed for automatic forest fire detection, like LIDAR (Utkin et al. 2003), due to its interesting characteristics for smoke plume detection in situations where visual cameras cannot operate (as, for instance, during night). These systems have some drawbacks, such as the coverage and the lack of reliability of the automatic detection in changing environmental conditions.

The use of satellites for fire detection has been also considered (San Miguel Ayanz et al. 2005; Kelhä et al. 2003). Besides, manned airborne-based systems have been also used, like in the Airborne Wildfire Intelligence System (AWIS), in Canada (Campbell et al. 2002).

Here, it is described how a team of UAS can be used for automatic forest fire detection, confirmation, and localization. In this mission, a given area has to be patrolled looking for potential fire alarms. If an alarm is detected, its geographical position should be communicated to the authorities, discarding false alarms. The use of a multi-UAS team in this case has several benefits: the area can be divided into different zones, assigned to different UAS, and the UAS can collaborate, as it will be seen, to confirm the detected alarms by means of sensor fusion techniques (Merino et al. 2006).

112.3.1 Sensors

Automatic fire perception is a complex problem. Besides the general difficulties of autonomous perception in natural scenarios, due, for example, to uncontrollable and sudden changes in environmental conditions, there are others related to the particular characteristics of fire including the harsh environment (e.g., smoke) and the difficulties in predicting the spread of fire and smoke. The proposed system addresses the sources of error present in forest fire perception by exploiting complementarities between different types of sensors that are mounted on UAS.

The multi-UAS fire detection system relies on two main types of imaging sensors with different wavelength bands: infrared cameras and visual cameras, which have interesting synergies for fire perception. Visual cameras provide images in the visible range [0.4–0.7] m. Flames are visible in visual images if images are not occluded by smoke.

Infrared cameras generate images of the scene that contain the radiation intensity field within the infrared band. They can transform radiation measurements in temperature estimations and can also generate thermograms containing temperature of the objects in the scene (Hudson 1969). Infrared cameras can “see” in pitch black

Fig. 112.3 (Left) Visual image taken in one multi-UAS fire perception experiment. (Right) Infrared images of the same scene taken with one Raytheon 2000AS OEM infrared micro-camera

conditions and are not affected by smoke, being highly transparent compared to the high radiation levels originated in a forest fire. Infrared cameras in the mid-infrared spectral window [3–5] μm are usually preferred for fire detection mainly due to its lower atmospheric absorption ([► Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States](#)).

In the last decade infrared camera technology has evolved significantly. While in the decade of the 1990s, most infrared cameras weighted several kilograms, consumed hundreds of watts, and their cryogenic cooling systems required frequent maintenance; now it is possible to find radiometric infrared cameras that weigh less than 150 gram, consume less than 1.5 W, and require no maintenance since they have no cooling system. These advances together with a remarkable cost decrease have motivated their use in a growing number of applications.

Figure 112.3 shows two images, one infrared and one visual, of the same scene taken during a multi-UAS fire detection experiment. While the fire base is easier to be detected with the infrared images, the fire flames are better detected if the smoke does not hide them.

UAS can be equipped with one camera (visual or infrared) or two cameras (visual and infrared). UAS also have GPS or Differential GPS (DGPS) receivers and Inertial Measurement Units (IMUs) so that their location and orientation are known. The accuracy depends on the characteristics of the sensors and also of the satellite visibility, which deteriorate significantly in low-altitude flights in mountainous terrains, and communication conditions (corrections of the DGPS). The photograph of a helicopter UAS, Heliv, used in the experiments is shown in Fig. 112.4. It carries a pan and tilt device with one low-weight infrared micro-camera and one visual camera.

An additional sensor considered for fire detection is a fire detector, whose main component is a photodiode setup to limit its sensibility to the band of [185, 260] nm, normally associated to fires (see Fig. 112.5). The data of this sensor can be processed to obtain a binary value indicating if a fire is present or not within the field of view of the sensor. However, the fire positioning information obtained from these

Fig. 112.4 (a) Main sensors and components of Heliv helicopter used in forest fire perception experiments. (b) Detailed picture of the pan and tilt device with one Raytheon 2000AS OEM infrared micro-camera and one visual camera

sensors is poorer than that given by the cameras, as they do not provide any bearing information. Also, it is not possible to determine if a measure is due to a big fire far away or a nearby small fire, or if the fire is generated by one or several sources (the data cannot be segmented into contacts).

112.3.2 Perception Techniques

The detection and precise localization of fire spots require to address several issues within the perception system:

112.3.2.1 Fire Segmentation

When using cameras, the first step in the processing stack is to estimate potential fire spots on the image plane. For that, segmentation algorithms are employed.

Fig. 112.5 One of the helicopters, Marvin, has attached at its nose a fire detector sensor

Fig. 112.6 The images from the cameras of Fig. 112.3 can be combined, obtaining a multimodal sensor. Resultant combined image: the image is obtained filling the *red field* with the infrared pixel intensities and the *green field* with the visual image. This is more effective in discarding false alarms. To relate both images, calibration patterns also seen in the infrared band are required

The nature of these algorithms depends on the type of the images, but in general they look for signatures related to the fire, like color signatures of infrared features. A summary of the main algorithms employed can be found in Martínez de Dios et al. (2008).

If a pair of infrared and visual cameras is available, it is even possible to combine them to create a multi-modal sensor, which allows for a more reliable fire detection (Martínez-de Dios et al. 2005), as shown in Fig. 112.6. In general the algorithms will have a certain probability of producing false alarms.

112.3.2.2 Geolocation

The fire spots detected on the image plane should be related to their geographical coordinates, to indicate to the fighting means where they should send their resources. In order to do that, the information from GPS and IMUs is combined with calibration information and a Digital Terrain Map to determine the coordinates corresponding to a given pixel on the image plane.

Fig. 112.7 During the demonstration, small controlled fires were performed

112.3.2.3 Data Fusion

As a result of the fire segmentation algorithms, not only fire spots, but also false alarms can occur. Moreover, the limited precision of the localization devices can produce large geolocalization errors.

Having a set of UAS, it is possible to use complementary sensors and points of view, so that the different sensorial information can be fused and, therefore, the number of false alarms can be decreased and the precision on the localization of the alarms greatly enhanced. Bayesian approaches have been employed for that, including grids and Kalman filters (Merino et al. 2006).

112.3.3 Experimental Results

The algorithms and architecture were tested in a set of experiments involving a fleet of three UAVs, namely, two helicopters (Heliv and Marvin) and one blimp (Karma). In the experiments, small controlled fires were set by firemen. Figure 112.7 shows a photograph of one of these fires. In every experiment, the position of the fire was recorded by using GPS receivers for validation purposes.

The mission usually consisted of a detection and a confirmation phase. In the detection phase, each UAS of the fleet is commanded to a certain area to patrol and

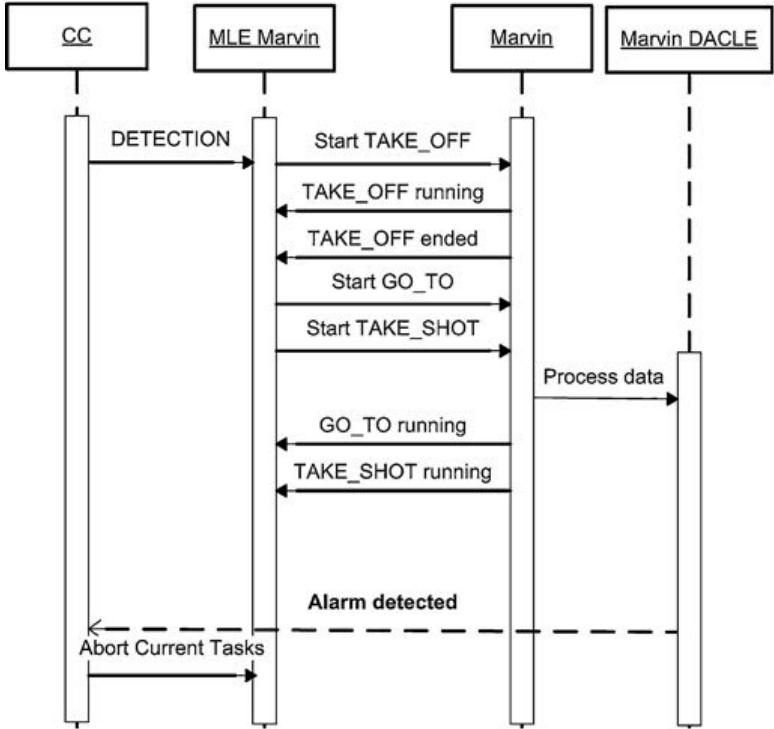

Fig. 112.8 Exchange of tasks for the detection phase. A detection mission is sent to Marvin from the Control Centre (CC). The local decisional component (called MLE) generates a set of waypoint tasks to cover the area. It also initiates the processing of data from the local perception component (called DACLE)

process their sensors, individually looking for potential fire alarms. If an alarm is detected, a confirmation phase is launched, in which a different UAS, if possible with complementary sensors, is sent to the same place. Data fusion is used to confirm (or discard) the alarm and to refine its estimated position.

In one of the performed experiments, during the first phase, the helicopter Marvin is commanded to perform a detection mission (see Fig. 112.8). The decisional layers decompose the mission into a set of atomic tasks: the helicopter takes off (TAKE_OFF) and determines a set of waypoints to cover the area (GO_TO). At the same time, it gathers information from its fire detector and commands its perception component to process the data, estimating the position of the potential fire alarms (TAKE_SHOT).

A grid representation is used to integrate measurements on time. Figure 112.9 shows the status of the grid in two instants of one particular experiment. After a while, several regions of high probability are detected. Each region is converted into a Gaussian representation for the position and then sent to the central station.

Fig. 112.9 Marvin employs a grid representation to integrate the data gathered by its fire sensor. Each cell of the grid represents an small portion of the scenario. The *red square* indicates the actual position of the fire. *Black* indicates a very low fire probability, while *white* indicates a high probability. High probability regions are extracted and approximated by Gaussian distributions. Due to false alarms, other high probability regions are also detected

Also, the mean probability of the cells of each region is used to estimate the probability that the region contains a fire.

Once an alarm (or several) has been detected, the central station aborts the current mission, and a fire confirmation phase starts (see Fig. 112.10). The first helicopter, Marvin, is moved to a safe place (GO_TO), and a second helicopter, Heliv, is sent to the place to confirm the alarm (GO_TO). Heliv carries an infrared camera, which is used to take images of the same zone where the alarms were detected (TAKE_SHOT). The images are segmented into potential fire objects, and these objects are geolocated. The information from Heliv is then fused with that from Marvin. If one of these objects is associated to an alarm already detected by Marvin, its position is used to reduce the uncertainty on the estimated position of the alarm. Moreover, the probability of being a real fire is increased for this alarm.

Moreover, the scheme allows using negative information. If one alarm is within the field of view of the Heliv's camera, but it is not associated to a segmented object, then its probability is decreased, although nothing can be said about its position. Figure 112.11 shows the potential alarms estimated by Marvin projected on the images of Heliv. It can be seen how the actual fire alarm is associated to the segmented fire object, while the false alarms do not correspond to fire regions. Eventually, the alarm is confirmed, when the current mission is finished.

Figure 112.12 shows the final trajectories of both UAVs and the final estimated position of the alarms. The estimated position of the actual fire alarms is within 1 m of the correct position. The evolution of the estimation on the position error is shown in Fig. 112.13. Also, the probability of the alarms is shown. It can be seen how the false alarms are discarded.

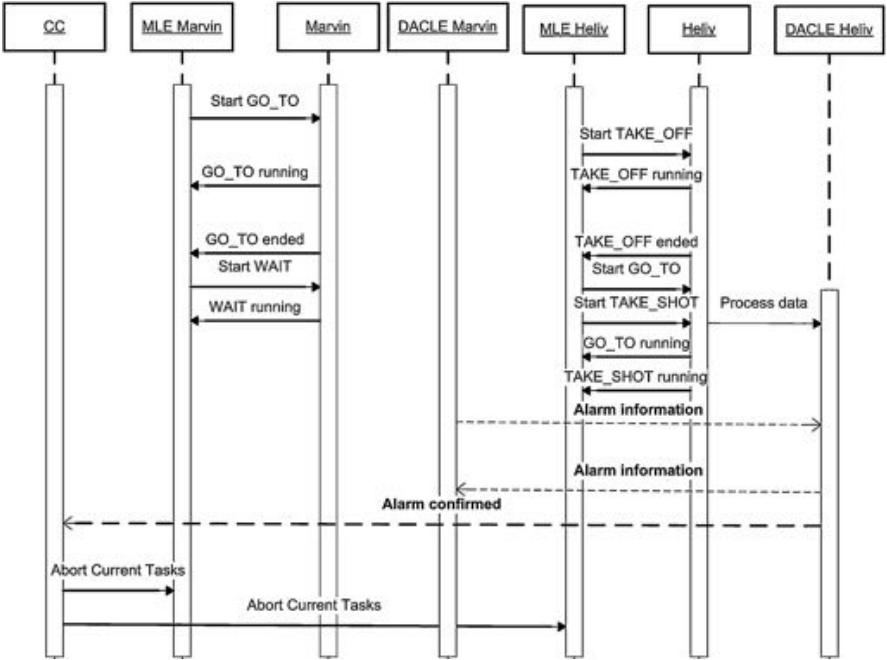

Fig. 112.10 Scheme of the exchange of tasks for the confirmation phase. Heliv is commanded to go to a close position of the detected alarm and to take and process images to confirm or discard the alarm. It uses the information provided by Marvin. Meanwhile, Marvin is commanded to wait at a safe place

Fig. 112.11 Heliv receives the information of the alarms detected by Marvin and fuses this information with the information obtained using its infrared camera. This figure shows the estimated position and uncertainty of the alarms detected by Marvin projected on the Heliv's infrared camera

112.4 Fire Monitoring and Measurement

Once a fire has been detected and confirmed, the firefighting activities begin. These fighting activities require to know, in real time, information about the evolution of the fire. In many cases, the lack of this information about the dynamic evolution

Fig. 112.12 Final complete trajectories of Marvin (*solid*) and Heliv (*dashed*). The ellipses represent the final estimated position of the different alarms. The *square* indicates the actual fire position. In the experiment, besides the correct alarm, two false alarms are generated. The scheme also shows the landing platform from where the UAVs take off

Fig. 112.13 *Left*: estimated standard deviation on the error. First, when Marvin detects the alarm the uncertainties are high due to the poor localization capabilities of the fire sensor. When Heliv fuses the information with its camera, the uncertainty decreases. Moreover, the probability of being an actual fire alarm is updated accordingly

of fire plays an important role in accidents that happen in firefighting activities. The objective of the fire monitoring missions is, then, to gather this information by using a team of UAS.

Figure 112.14 shows the state of an experimental controlled fire at several time instants. Among the most important parameters for firefighting management are the shape and position of the fire front, its rate of spread (how this front evolves with time), and the maximum height of the flames (Viegas 1998). If available, this information, integrated within a Geographical Information System (GIS), can be used by the fire brigades for firefighting planning, for instance, by predicting the potential evolution of the fire and determining the optimal location of fighting means.

Fig. 112.14 Different stages in the evolution of a fire

Fire monitoring is usually performed by experts that estimate, visually or from images gathered by cameras, the rate of spread and height of the flames. More recently, airborne systems are used in order to have a broad overview of the fire evolution, but still the monitoring activities are carried out by people. Satellite-based systems have been also proposed for forest fire monitoring (Chuvieco and Martin 1994; San Miguel Ayanz et al. 2005). The temporal and spatial resolutions of these systems are still very low for the requirements of forest firefighting in many cases. There are some fire analysis techniques based on computer vision for fires carried out in laboratories, as (Martínez de Dios et al. 2006; Pastora et al. 2006). However, the application of the same techniques to noncontrolled outdoor environments is not considered in those papers.

Here it is shown how a team of UAS can be also used for this mission. The objective of the fire monitoring mission is, therefore, to estimate spread of the fire front and other parameters in real time and to transmit this information to the firefighting brigades. The use of multiple UAS can provide several advantages: it is possible to devote a different UAS to different parts of a large fire, and/or the UAS can again cooperate to estimate the different parameters with more precision.

Fig. 112.15 Images from UAS onboard visual (*left*) and infrared (*right*) cameras taken during a fire monitoring experiment

112.4.1 Sensors

As in forest fire detection, monitoring and measurement require visual and infrared cameras as main perception sensors. Visual images can be used to obtain measurements of the base of the fire (location and shape). They can be also used to obtain flame measurements, but the accuracy in this case is often low due to the parallax problem. However, the fire can be occluded by the smoke in the visual images.

Infrared cameras are also useful for fire monitoring and measuring. The radiation intensity emitted by the base of the fire is considerably higher than that of the flames (Hudson 1969). Thus, infrared images can be used to obtain measurements of the fire base (location, shape) but are not useful for measuring the flames.

The fire measuring system can use thermal infrared cameras and also nonthermal cameras, which do not provide temperature measurements but do allow qualitative estimations of the radiation intensity. Although cameras in the mid-infrared spectral window [3–5] μm are preferred, the proposed system can indistinguishably use cameras in the mid-infrared or far-infrared windows. In fact, both types of cameras were used in most of the field experiments that have been carried out. For more details see Martínez-de Dios et al. (2011).

Figure 112.15 shows images of the same scene taken with a visual image and one infrared image during a forest fire measuring experiment.

112.4.2 Perception Techniques

112.4.2.1 Data Fusion

The system should consider all the information gathered by the different UAS to estimate the evolution of the fire applying data fusion techniques. The general picture is given by Fig. 112.16. In the system, each vehicle will locally process its images and provide features related to the fire front evolution. All this information

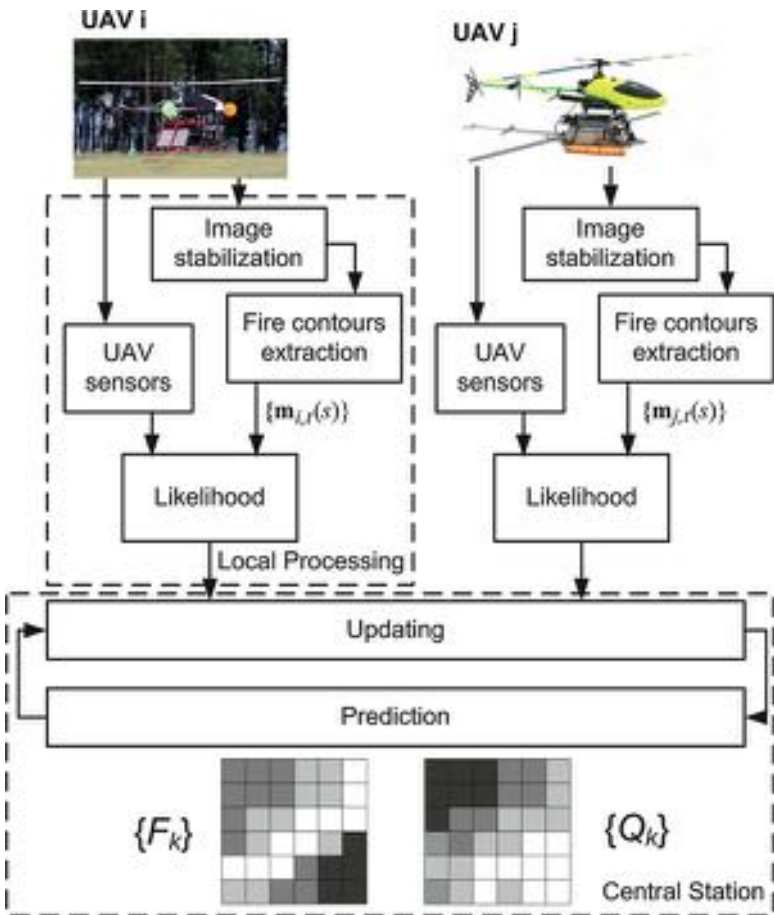

Fig. 112.16 The system estimates two probability grids (fire presence and fuel at each cell). The state of the grids is estimated incorporating data obtained from the fleet of UAVs. The prediction step incorporates the increase in uncertainty due to the motion of the fire

is received at the central station, in which the estimation takes place, taking into account all the data from the fleet.

Fire is dynamic and propagates, changing in size and shape. An evidence grid is chosen to represent the state of the fire at a given time instant. The area is divided into a rectangular grid, in which the state of each cell k is defined by two binary values: $F_{k,t} \in \{0,1\}$, indicating if there is fire in the cell, and $Q_{k,t} \in \{0,1\}$, indicating if the fuel in the cell is completely exhausted. The system cannot be certain about these values, and, therefore, two probability values $\{f_k, q_k\}$ are stored for each cell. These two values correspond to the probabilities $f_k = p(F_{k,t} = 1)$ (there is fire at a given cell) and $q_k = p(Q_{k,t} = 1)$ (the fuel in that cell is completely exhausted). Each cell also has an associated 3-D position, given by a

digital elevation map that is previously loaded in the system (and that can be the result of a previous mapping mission performed by a UAV Hygounenc et al. 2004).

The state of the cells is then recursively estimated from the information provided by the cameras onboard the UAS (see below) using a Bayesian filter. Prediction models can be used within the filter (Merino et al. 2012).

112.4.2.2 Information Extraction from the Images

The information about the fire front position is encoded in the images as the contour of fire regions on the image plane. The techniques described in Sect. 112.3.2 can be used to segment the fire objects on the images and to extract their contours. This contour is further characterized in order to distinguish the pixels of the contour related to the fire front and the pixels related to the top of the flames, therefore obtaining the height of the flames in pixel coordinates. The dynamic properties of the fire base and the flames are used for this characterization. The position of the fire-base pixels on the image plane generally changes more slowly than the position of the flame pixels (as the flames flicker). The application of a temporal low-pass filter over a sequence of consecutive segmented images is therefore used to filter out the flame pixels. Finally, these fire fronts are geolocalized to incorporate the information into the grid maps. Further information on these techniques can be found in Martínez de Dios et al. (2008).

112.4.2.3 Image Stabilization

Considering a UAS with hovering capabilities, unavoidable control errors, turbulence, and vibrations produce changes in the camera position which leads to image motion. This motion can affect to the previously described algorithms, and, therefore, it is necessary to cancel it. Electromechanic systems can be used to cancel vibrations, but these systems are usually heavy, expensive, and have a residual vibration.

Image processing procedures can be also used for software-based image motion estimation and cancellation. This can be achieved if the apparent motion between consecutive images is computed. In this system, a sparse image motion field is computed by a feature matching algorithm (see Fig. 112.17). Then, this sparse motion field is used to estimate a model of the motion of the complete image. Finally, the model is applied to all pixels to warp the current image to a common frame, therefore eliminating the background motion between the current image and the previous one. The details can be found at Merino et al. (2012).

112.4.3 Experimental Results

The fire monitoring system was also tested in the experiments mentioned in Sect. 112.3.3. The multi-UAS monitoring mission begins after the alarm has been confirmed and precisely localized as shown in this Sect. 112.3.3.

This fire monitoring mission is generated for Marvin, Heliv, and the airship Karma, involving synchronization tasks to take and process pictures of the event

Fig. 112.17 Interest points extracted and tracked in two consecutive images to obtain a sparse image motion field

from the correct viewpoints at the same time (Fig. 112.18). The decisional layers of the vehicles (Lacroix et al. 2007) manage the task planning, allocation, and the synchronization signals between UAVs in a decentralized manner, and also the generation of the adequate viewpoints for monitoring the fire, covering the detected alarm from several directions (the vehicles are situated surrounding the fire with a relative orientation of 120°). When the synchronization is correctly achieved, Marvin and Heliv begin to obtain pictures of the fire simultaneously and for a given time. Also, Karma is commanded to take images of all the area from a high vantage point.

Each UAS, locally, stabilizes the images captured by its cameras and processes the results obtaining an estimation of the position of the fire front in pixel coordinates. The data from all the systems are sent to the central station, where all the information is fused for the estimation of the evolution of the fire. Figure 112.19 shows the images of the same fire from the three vehicles and how the fire contours are correctly extracted.

After the time for taking pictures has expired, Marvin and Heliv are commanded to return to home and to land. At the same time, a mapping mission is generated for Karma. Afterwards, the mission is terminated.

In the previous experiments the controlled fires performed are of small scale, and it is difficult to appreciate an evolution on the fire front, although Fig. 112.19 shows how the shape of the fire is correctly estimated. The techniques described have been also validated in many controlled medium-scale forest fire experiments carried out in Serra da Gestosa (Portugal). In these field experiments, square plots of up to 150 by 100 m were burned under controlled safety conditions. The rectangular plots burned in the experiments can be observed in the images. The experiments mobilized significant resources including 80 firemen and 5 firefighter trucks. A more detailed description of this kind of experiments can be found in Viegas et al. (2002).

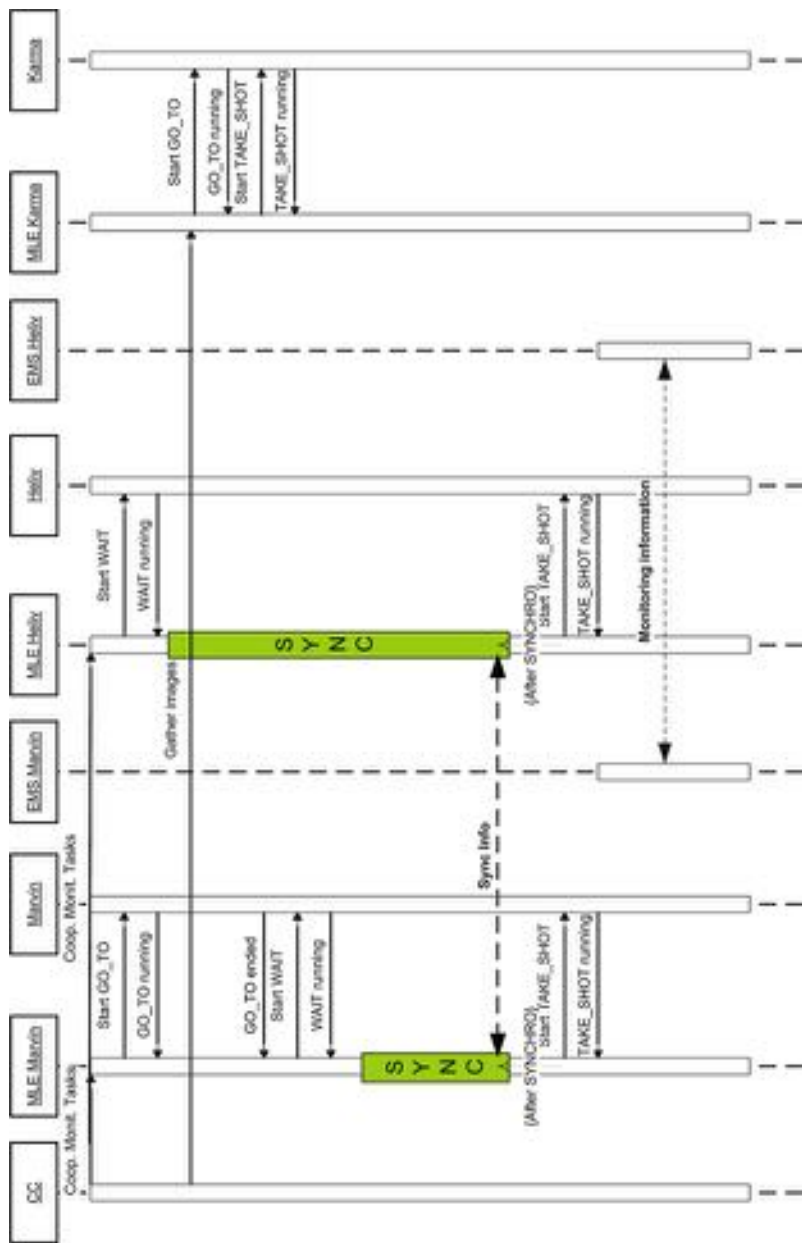

Fig. 112.18 Exchange of tasks for the monitoring phase. The UAVs can synchronize their tasks, and therefore they can begin the monitoring of the fire from different points of view at the same time. The synchronization signals are employed as preconditions for the tasks to be synchronized

Fig. 112.19 *Top: left, image from Heliv, after stabilization and feature extraction; middle, image from Marvin after stabilization and feature extraction; right, image from Karma. Bottom: details of the extracted contours. Green: fire front. Red: top of the flames*

Figures 112.20 and 112.21 show results of one of these experiments. In it, a plot of approximately 10,000 m² was burnt. In this case, a helicopter is commanded to gather aerial images.

Figure 112.20 shows several frames gathered from the helicopter, after the application of the image stabilization and feature extraction algorithms. It can be seen how the stabilization algorithm effectively removes the motion induced by the helicopter. It can be also seen how the fire front shape is adequately extracted from the images.

112.5 Cooperation of UAS with Ground Infrastructure for Fire Extinguishing Tasks

Fire extinguishing is a very dangerous task that has been traditionally carried out with low level of automation involving significant human resources. Although the idea of firefighting has been early proposed (Bradshaw 1991), few implementations have been carried out. The works developed have been focused more on the robotization of specific firefighting tasks rather in demonstrating a full robotized system for automatic firefighting.

The work (Su 2006) proposes an automatic multi-sensor fire detection system. The robot after detecting and localizing the fire extinguishes the fire autonomously. The Genbu robot (Kimura et al. 2001) is an articulated multi-wheeled firefighting mobile robot. This robot uses the fire hose's hydraulic energy as source of energy for its actuation. Fire trucks supply water at a high pressure through the fires hoses, so that the robot could powerfully thrust its way through the debris inside a fire scene.

Fig. 112.20 Frames 3, 77, 144, and 219 of the aerial sequence gathered during the fire experiment 520, after automatic stabilization. The extracted fire front contour is also shown

The operation range of this robot is not sufficient for forest fire scenarios. Besides, this robot should involve human actuation since it is not equipped with a perception system that allows its fully autonomous operation.

Fire extinguishing takes place at the same time as fire monitoring. The information provided can be used to decide how to attack the fire. Fire extinguishing involves the use of water, chemicals, and other means. The UAS considered in the multi-UAS system do not have enough payload to carry the required actuators for this objective: cooperation with automatic ground means is necessary for this purpose. This section focuses on the cooperation of multi-UAS fleet with ground infrastructure. The integration of UAS with an automated fire extinguisher on a fire truck is presented. The cooperation of the multi-UAS system with Wireless Sensor and Actuator Networks (WSN) for fire extinguishing is also summarized. UAS integration with the fire extinguisher and with the WSN were tested in experiments with controlled real fires in close-to-operational firefighting conditions.

112.5.1 Sensors and Actuators

The multi-UAS team was integrated with devices that can be actuated to fight the fire. And thus, the network allows to communicate with a fire truck equipped with

Fig. 112.21 Evolution of the fire front (in georeferenced coordinates) for plot 520 estimated from the images gathered by the helicopter (*solid*) and compared with the front obtained with a static camera (*dashed*)

an automated water cannon. The water cannon was an adaptation of a commercial system with manual operation. It could be pointed in pitch and jaw angles. Although the driving of the fire truck has to be done manually, the pointing, activation, and deactivation of the water cannon can be carried out automatically.

Accurate temperature and humidity measurements are very important in fire extinguishing. These readings cannot be obtained from the multi-UAS system, and in many cases local sensors are the only way to gather the measurements. For instance, making accurate temperature estimations from onboard infrared images requires knowing physical parameters such as emissivity of the material, ambient temperature, humidity, among others. In the approach presented here, UAS are used to deploy at interest locations Wireless Sensor Networks (WSN) nodes equipped with temperature and humidity sensors.

WSN are comprised of a large number of nodes with sensing, computing, and wireless communication capabilities. Low size, cost, and energy consumption are between their main features. A good number of cooperative methods have been developed in the recent years to endow WSN with high flexibility, robustness, and tolerance to failures. These features together with battery-based power, efficient and flexible deployment has extended WSN technology to a growing number of applications.

Cooperation between UAS and WSN provides interesting complementarities. Below are some examples. Autonomous deployment of WSN nodes using UAS for WSN repairing has been proposed in Corke et al. (2006). WSN data collection with a fixed-wing UAS has been proposed in Teh et al. (2008). A system in which a helicopter UAS is used for wireless powering and collecting a low number of nodes is described in Todd et al. (2007).

In this chapter, UAS-WSN integration for fire extinguishing is explored. UAS equipped with ad hoc mechanisms are used to deploy WSN nodes at interest locations in order to gather high-accuracy fire measurements necessary for firefighting.

112.5.2 Techniques

Fire extinguishing requires the fire detection and monitoring techniques described in previous sections. Besides, it requires extending the decisional system with modules to deal with the new components, like the fire extinguishing truck.

The water cannon pointing angles were computed by means of parabolic throw equations using the location of the fire computed by the multi-UAS fire perception system and the pose (location and orientation) of the fire truck. The truck was equipped with DGPS receiver and IMU. A simple protocol was implemented to integrate the fire truck operation within the fire detection and monitoring system. The protocol has commands for controlling the pitch and yaw angles and for activating and deactivating the water cannon. It should be noticed that the water cannon itself is not equipped with any sensor that allows it to know if the fire has been actually extinguished or not. It is the multi-UAS perception system which confirms extinction or corrects water cannon angles if necessary.

The integration of multi-UAS system and the WSN allows complementarities in firefighting tasks. In particular, UAS can be used to transport and accurately deploy WSN nodes at desired locations. UAS and WSN complement each other: WSN nodes provide accurate local information on the fire, while UAS obtains more global information. Also, the WSN nodes deployment locations can be determined dynamically depending on the fire evolution. This can also be interesting in case of risks of fire spreading to a dangerous area, e.g., a house in the wildland-urban interface, or to prioritize fire extinguishing efforts in presence of threats, e.g., barrels full of petrol in a factory environment.

Figure 112.22 shows an autonomous helicopter deploying WSN nodes. Although the UAV is just at 2 m while deploying the nodes, WSN housings are used for impact protection and ensure that the antenna is vertical after the deployment.

112.5.3 Experimental Results

The following shows an experiment of multi-UAS fire detection, monitoring, and extinguishing mission that was performed in 2009. The initial situation was as follows:

Fig. 112.22 Automatic deployment of WSN nodes using Marvin helicopter UAS

- A fire alarm was declared inside the building.
- Two UAS were ready to fly on the landing pads. UAS1 was equipped with one infrared camera and UAS2 equipped with the WSN node deployment device and three sensor nodes.

The multi-UAS fire confirmation task was triggered by the fire alarm. UAS1 took off. It detected the fire with the infrared images confirming the alarm and estimating its location. UAS1 also detected a number of fuel barrels near the building. As there was risk of fire propagation from the building to the fuel barrels, a WSN node deployment mission was specified in order to place several sensors in between at the locations of the waypoints wp1, wp2, and wp3 (see Fig. 112.23). According to this mission, UAS2 was launched, and it autonomously moved to the waypoints and deployed sensor nodes. Once deployed, the WSN node was properly integrated into the ground WSN and provided accurate readings to monitor the fire spread. After accomplishing the WSN node deployment mission, UAS2 landed.

Meanwhile UAS2, equipped with an onboard infrared camera, kept monitoring the fire. The fire monitoring system integrated infrared images gathered by UAS2 with the data from the WSN in order to obtain accurate fire location estimations. Once the fire was accurately located, the automatic extinguishing system was ready to operate. Then, the position of this fire was transmitted to proceed with the extinction, while the UAS1 hovered at a safe location. The fire extinguisher installed in a fire truck was commanded to point to the fire taking into account the fire

Fig. 112.23 Paths followed by UAS1 and UAS2 (red and blue, respectively) during the experiment

position, the positioning measurement of the truck GPS, and IMU data. The water cannon was activated, and the fire was extinguished, see Fig. 112.24. UAS2, which was waiting in hovering during the extinguishing, confirmed the extinction of the fire by means of the onboard infrared camera. The WSN nodes deployed near the fire also confirmed extinction and the mission finished.

112.6 Conclusions

The chapter describes the application of teams of UAS to several tasks related to forest firefighting, like fire detection, monitoring, and extinguishing. The main issues and techniques are described, and experimental results are shown, in which an actual fleet of UAS is tested in controlled setups involving fires.

The main conclusion of the chapter is that the use of UAS in firefighting is feasible, not facing any major unbearable problems. Of course, there are still many issues to be solved for a commercial application. One of them is the integration of UAS with manned aircraft usually present in firefighting operations. This is both a legal and a technical problem (► [Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States](#)). Here it should be noted that manned aircraft cannot operate by night, and then there are no conflicts with the

Fig. 112.24 Picture of the fire truck with the implemented fire extinguishing system during the experiment

UAS operation. Moreover, the weather conditions usually involve high wind gusts, and harsh conditions, which require the development of more robust UAVs and controllers. The application of firefighting also need of UAS with higher endurance and larger payloads. Nowadays there are UAS, mainly developed in the military field, that have the required endurance, and therefore the extension of the techniques for their use by environment management agencies seems affordable ([►Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States](#)).

Another issue is the particular UAS platform to be used in different applications. For the tasks of fire detection or large-scale fire monitoring, airplanes are more suitable than hovering-capable UAS. Also airships can be considered, although they should be big enough in order to withstand winds. On the other hand, small UAS with hovering capabilities could be employed by fire brigades for, at least, obtaining views of areas difficult to be accessed.

An additional question is if the use of several cooperating UAS offers advantages when comparing with the use of one complex UAS. For the task of fire detection (or in general, for exploration activities), a fleet of vehicles adds two different advantages. Firstly, the time needed to cover wide areas can be reduced. Also, the complementarities between UAS and their payload can help to reduce the false alarm ratio, which is one of the main problems with currently employed detection systems. For the case of fire monitoring, employing several UAS allows obtaining different and complementary views. Moreover, the application of teams of UAVs can be useful to perform simultaneously not only fire detection and monitoring but

also to have communication relays and to acquire high-resolution meteorological information. Future applications can include the transportation and deployment of a big payload by means of several vehicles as shown in ► [Unmanned Aerial Systems Physically Interacting with the Environment: Load Transportation, Deployment, and Aerial Manipulation](#).

The use of fleets of UAS requires a higher degree of autonomy on the UAS. Controlling the fleet would require more complex control centers or an amount of people if the UAS are not endowed with autonomous decisional capabilities. In this case, also decentralized autonomous perception functions are required in order to reduce the computational power needed to process the huge amount of data from the different vehicles of the team.

(UAS) are being examined more closely for their potential roles in safely gathering data over those events. Wildfires are consistently one of the most common worldwide “disaster” events, and therefore the wildfire management community is experiencing a surge in UAS interest to support intelligence gathering and pertinent data delivery over those fire incidents. There are numerous, often confusing differences amongst UAS platforms and their sensors. Coupled with the various mission roles required by observation platforms in the wildfire domain, the UAS landscape can be a daunting place for a wildfire manager (or any disaster manager) to select the appropriate UAS solution capability that matches his/her requirements. This chapter describes some of the UAS lessons learned by both the U.S.. Forest Service (USFS) and the National Aeronautics and Space Administration (NASA) during their +10-year efforts on identifying appropriate UAS wildfire observation capabilities. The agencies, along with the UAS community, have demonstrated the use of both Low-Altitude, Short-Endurance (LASE) and Medium-Altitude, Long-Endurance (MALE) platforms for wildfire sensor intelligence gathering. Those experiences are identified in this chapter as well as an examination of the future direction of UAS systems for supporting the wildfire management community.

113.1 Introduction

The use of UAS systems to support disaster monitoring is the perfect civilian niche for the platform capabilities. Airborne assets have been used to provide remote sensing-derived information in support of wildfire events since the advent of the airplane. The USFS started using manned aircraft to provide information on fire activity in the vast western U.S. forests during the 1920s and 1930s, first through sketch-mapping fire locations on paper maps; later, camera systems were employed to image and then transfer to paper maps for delivery when the aircraft landed. As imaging systems improved and with the advent of thermal scanning systems more readily available in the late 1960s, a leap forward in technology provided the wildfire management community with more reliable fire imaging capabilities. With the introduction of Unmanned Aerial Systems (UAS), more disaster management agencies are starting to examine the use of UAS in lieu of manned assets to perform these hazardous tasks. As UAS platforms have improved and operations have been simplified, there is keen interest in the disaster community, and specifically the wildfire management community, in employing these resources in the wildfire battlefield.

This chapter will provide a perspective on the use of UAS systems to support wildfire observations, including the physics behind fire that dictate the appropriate sensor design characteristics, UAS platform characteristics, the airspace issues regarding UAS operations over fire, and the history of wildfire imaging UAS use in the United States. This information will improve the understanding of UAS platforms and appropriate sensor systems, to ease the transition into operational utility.

113.2 Fire Physics: Dictating Spectral Optimization for Sensing Systems

In order to employ the proper remote sensing sensor system for observing, it is important to understand the emittance characteristics of fire. Fires and combustion materials emit radiation. The Stefan-Boltzmann Law states that hot “radiators” emit more energy per unit area than cooler ones (this applies to thermal wavelengths shorter than microwaves) (Wolfe and Zissis 1989). The magnitude of emitted energy rises rapidly with increasing temperature of an object. Then, Wien’s Displacement Law states that the spectral distribution (wavelength) of that emitted energy varies with temperature. The energy from fires is emitted as electromagnetic energy within specific wavelength bands. Most of the energy emitted by heat from wildland fires is in the mid-wavelength infrared (MWIR, 3.0–5.0 μm) and long-wavelength infrared (LWIR, 8.0–14.0 μm) portion of the spectrum (Ambrosia and Brass 1988; Zajkowski et al. 2011). While the human eye detects energy in the short wavelength range of 0.3–0.7 microns (μm), energy from fires is emitted at wavelengths an order of magnitude longer (nominally, 2–14 μm) (Table 113.1). Most heat, or fire-mapping applications utilize LWIR sensors. The higher the temperature of the heat source, the more energy is emitted and the shorter the wavelengths that can be used to detect and map that source. In essence, fire detection lies in measuring radiance emitted in the mid-infrared region for typical encountered fire temperatures (Fig. 113.1). Although the spectral “range” for useful fire detection at MWIR is \sim 3.0–5.0 μm , an optimum center-wave measurement at 4.0 μm avoids the variable water vapor absorption frequencies at lower portions of that region and reduces reflected solar radiation influences to the 4.0 μm region by 40 % (Kaufman et al. 1998) (Fig. 113.2).

The two most common wavelength bands for fire remote sensing are 3–5 and 8–14 μm . These wavelength regions are consistent with both the wavelengths of typical fire sources and good atmospheric windows. Detectors or sensors that operate at shorter wavelengths “see” reflected energy and not emitted energy; this, coupled with atmospheric attenuation, limits the utility of shorter wavelength or optical systems to map fire emissivity.

Infrared energy and the sensors used to detect and map heat sources have limitations. These limitations may generally be broken down into a few categories: solar radiation effects, source temperature, water vapor attenuation, and saturation. Solar radiation (reflected sunlight) may mix with the emitted infrared energy;

Table 113.1 Wavelengths and temperature relationships for nominal fire condition classes

| Source | Temperature ($^{\circ}\text{C}$) | Nominal wavelength (μm) |
|---------------|------------------------------------|--------------------------------------|
| Background | 25 | 10.0 |
| Fuel ignition | 275 | 5.0 |
| Glowing | 550 | 4.0 |
| Cool fire | 725 | 3.0 |
| Hot fire | 1,200 | 2.0 |

Fig. 113.1 Blackbody curves for wavelength regions for given temperature peaks. Typical background land surfaces are at ~300 K, while a smoldering fire can be at ~600 K and a flaming fire can be at 1,000 K. Therefore, fire measurements are best optimized at a wavelength region ~4 μm (Courtesy of/derived from Wolfe and Zissis 1989)

Fig. 113.2 Thermal infrared energy emitted by earth features ranges from 3 to 14 μm. Fires are detectable in this range, but various absorption frequencies and atmospheric effects restrict the useable “clear” windows to 3–5 and 8–14 μm (Courtesy of/derived from Kaufman et al. 1998)

thus, highly reflective surfaces (rock outcrops, water, snow, bare ground, metal roofs) may appear “hot” in thermal IR image. This can create false-positives (i.e., the sensor detects fire where there isn’t one). This problem can be mitigated by utilizing more than one thermal band to reduce false-positives. Often LWIR data is collected to portray background areas around the heat source. Because smoke does not prevent this long wavelength energy from passing through, one can discern the background (surface features) at these wavelengths. Visible wavelength sensors (aerial photography and visible bands of sensors) cannot see through the

smoke because it scatters and absorbs short-wavelength energy in those wavelength regions, much like the human eye cannot see through smoke. Fires are not perfect emitters of infrared energy. Emitted energy can be absorbed by a heavy canopy or overstory above the fire/thermal emitter. The ability to detect heat beneath a canopy may be reduced by heavy (moist) smoke, vegetation, or water vapor.

113.2.1 Plume Characteristics Affecting UAS Fire Sensing

Fire imaging in discreet thermal channels allows avoidance of spectral obscuration from smoke plume events. Smoke plumes (if minimal/no moisture is present in plume) are transparent in the MWIR and LWIR regions, though visible in shorter wavelengths (near infrared (NIR, 0.7–0.9 μm)) and visible wavelengths. This information is critical to selection of appropriate sensor systems for fire observations; the use of visible or NIR systems is generally inadequate for fire imaging purposes, since the particle sizes that constitute the plume attenuate the signal in those general wavelength regions. Results from a study by Uthe and colleagues (1982) indicate significantly greater plume attenuation at 0.53- μm wavelength than at 1.06 μm , indicating ~ 0.1 - μm mean particle diameters or the presence of gaseous constituents that absorb the visible radiation. The inclusion of black carbon particles in plumes also reduces the opacity index of visible and NIR imaging systems (Mazurek et al. 1991; Wong and Li 2002). Most small UAS (sUAS) systems are integrated with a visible wavelength camera system and a wideband LWIR camera, both of which can prove problematic when imaging wildfires.

113.2.2 Fire Weather Affecting UAS Fire Sensing

Dynamic fire weather conditions exist on every fire and can impact/hinder UAS observation missions. Due to the energy released by a fire, wind conditions can be dangerous to aircraft. Since the plumes over fires are composed of various organic compounds and carbonaceous materials, they pose a significant risk to gas-powered aircraft systems (not significant for electric motor systems). The ingestion of “dirty” air into gas-powered combustion engines can cause significant engine failure or damage internal engine components. This issue also hinders sUAS operations around fire regimes, especially due to their low flight altitude profiles where those constituents are most dense. There are significant updrafts and downdrafts that can affect flight performance and stability of a sUAS platform (or manned platform for that matter) and be a detriment to direct, overhead imaging operations.

As highly energetic fires produce convective systems, those systems can/will contain moisture. The presence of clouds or moisture (fog, rain, etc.) will obscure visible-NIR, MWIR, and LWIR observations of surface conditions and render those channels of limited use for fire observations. This would limit sUAS to less rigorous fire imaging assignments, such as post-fire hot-spot mop-up operations or operations during the night, when general fire weather conditions are usually less intense.

113.2.3 Day vs. Night Fire Behavior Differences Affecting UAS Sensor Operations

Fire behavior is markedly different between day and night. Early afternoon is generally the peak burning period when fires will burn the most intense, spread most rapidly, and tend to exhibit erratic fire behavior, because all of the weather elements are at the point where their influence on fire behavior is the greatest: radiation from the sun is at its maximum when the sun is directly overhead, the fire temperature is at its peak, relative humidity is at its lowest point, wind speed is at its maximum, wind direction is most variable, the atmosphere is the most unstable, and fuel will be the driest. Although this midday period may be the greatest time of need for fire behavior information provided by UAS remote sensing systems, it is also the most hazardous time for operations for small UAS platforms.

At night, the high-risk fire variables mentioned above reduce significantly in severity. Given that tactical aerial operations cease operations at night due to safety, it is a logical time for operations to integrate UAS into a less congested airspace under more benign fire weather conditions. Complex terrain combined with smoky conditions presents a flight safety hazard for nighttime-manned aircraft operations; this is especially true for rotorcraft systems that operate in close proximity to the ground. These operation periods are best handled by sUAS.

113.3 Fire Airspace Issues

The airspace over large wildfires can become very congested with multiple aircraft operating in or transitioning through the fire airspace working environment. Fixed-wing and rotorcraft platforms are used to deliver firefighters and supplies to the fire line in addition to those that are dropping water or retardant on the fire itself. In addition to these platforms, media and law enforcement aircraft are often allowed and present in the airspace as well. Additionally, a lead plane and an air-attack aircraft are almost always dispatched to fires and operate as observation platforms to control aircraft airspace, operating as an air-traffic manager for those fire events.

Most wildfires have segregated airspace designated for them at the onset of the fire, to allow firefighting assets to operate without interference from other aircraft in their vicinity. The FAA routinely grants Temporary Flight Restrictions (TFRs) to segregate aircraft and allow control of the area to the incident Air Operations Unit. Adding UAS into this mix is seen as disruptive to many current wildfire management personnel and other aircraft operators/pilots. How and when UAS are integrated into the airspace above a fire, as well as the altitude regimes, times, and locations of UAS fire flight integration, are still being evaluated by the USFS. To date, most of the UAS support on wildfire events (NASA Ikhana, USAF/Navy Global Hawk, CBP Predator-B) has been “strategic,” with those UAS operating well above the TFR and not interfering with normal wildfire aircraft operational altitudes. By flying at night or under conditions too hazardous for manned aircraft, UAS/manned

Fig. 113.3 The Fire Traffic Area defines when and where firefighting aircraft will contact air attack as well as approximate holding and maneuvering altitudes. The FTA can be expanded and modified as need to accommodate the size of the fire, local terrain, and airspace considerations. UAS integrating into the FTA must be able to maintain separations and follow the required airspace directions and procedures, like any manned aircraft in the FTA (Derived from: Interagency Aviation Management Council 2003)

platform “conflicts” are reduced, and UAS have the ability to satisfy requirements for supplying fire information when it is usually not available to management teams.

The Fire Traffic Area (FTA) developed as a guideline airspace management directive by the USFS Fire and Aviation Management is designed to identify the “rules” regarding general fire airspace separation/operations altitudes of various platforms. The FTA provides a standardized initial attack airspace structure to enhance air-traffic separation over wildland fire (or other) incidents (Interagency Aviation Management Council 2003). The FTA is constructed within the TFR that covers most large wildfires. The FTA separates aircraft horizontally and vertically with clear lines of communication amongst the traffic managers and the flight crews. If UAS are integrated into a FTA while other airborne platforms are present, the UAS pilot will need to communicate with the air attack officer constantly. In addition, pilots of the manned aircraft will need to know where the UAS is operating and avoid that location. As can be seen in Fig. 113.3, there are some key niche areas that sUAS may be able to operate in, between other working manned assets in the FTA.

A common misperception associated with integrating UAS into fire monitoring airspace is that the TFR over a fire “sterilizes” the airspace over that event and that a Certificate of Authorization (COA) from the FAA is not needed for UAS operations. This is erroneous; the TFRs that typically cover fires are defined in FAA regulations, FAR Part 91.137(a), (2) and allow for aircraft that are not participating in fire operations and are not under control of the air-attack supervisor to enter

that TFR. These intrusion allowances include law enforcement aircraft, aircraft on approved instrument flight rules flight plans, accredited news media, and aircraft that are based at airfields within the TFR. In the simplest term, a COA is a project aviation safety plan on how to mitigate the risk associated with operation of a UAS for a very specific location (and type/tail number of UAS). This process is constantly being streamlined, but it is time consuming to collect and enter/provide the required COA application information to the FAA, and it takes approximately 60 days to get approval from the FAA to operate in that region. This is not conducive to fast-moving wildfires and short-term UAS monitoring needs. Once approved, the COA holder can use their existing COA to get an emergency COA for another location with similar airspace approved quickly; NASA was able to obtain an emergency COA within a few hours to support the 2006, 2007, and 2008 California wildfires that were located outside of its original COA area.

As the FAA rules for sUAS are addressed and modified, the relief of operations restrictions should allow a much improved regulatory scenario for UAS operations in support of disaster and law enforcement activities. This will then allow a greater expansion of the role of UAS to support fire events, given that the fire agencies can succinctly identify their own airspace integration plans to avoid conflicts between UAS and manned assets.

113.4 UAS Platform Decisions: Tactical vs. Strategic

The mission requirements and needs for wildfire imaging will dictate the selection of the best UAS for a particular event. There are a number of questions that will have to be addressed prior to inclusion of UAS into operational fire imaging roles traditionally held by manned aircraft assets: Do you really need to use an unmanned platform? Where will you operate (altitude, area of operations of the UAS)? What is your sensor/payload? How will you observe FAA regulations? How much aircraft autonomy do you have/need? All of these questions must be answered to ensure successful operations and utility of information delivery.

If a sensor can fit on a sUAS, it can also fit on a small manned aircraft, and therefore the manned aircraft option should be considered when all other options are of equal importance or value. Often it is technically possible to get the capabilities you want with a sUAS, but cost-effectiveness (of platform utility) needs to be an important and highly regarded index of utility. A sUAS operation may have a large crew, which may increase costs over a manned, single-pilot platform. One must identify the technical components (data, imagery, sensor systems, etc.) that are needed to fulfill their mission requirements in the most efficient and effective means possible (Rango and Laliberte 2010; Zajkowski and Hinkley 2008a, b; Zajkowski et al. 2008a), to ensure cost-effective utility of resources. The following sections describe how these questions and factors need to be evaluated.

Where does one operate a UAS on a fire imaging mission? Wildfire locations are most often a complex mix of extreme environmental conditions (mountainous

terrain, heavy vegetation, and smoky, low-visibility situations), which make it difficult to maintain situational awareness of a fire's location, fire hazards, terrain features, and other inherent fire hazards. These situations can also affect control operations of UAS, especially if operating such out of visual range.

What is the appropriate payload? In addition to fire imaging payloads which are covered in detail in the next section, firefighters have identified another UAS mission for the fire management area, as communications relay platforms. In complex fire environments, terrain masking limits the standard radio linkages between frontline firefighting crews and the incident command teams. Employing a UAS as a “repeater-in-the-sky” can be an effective solution when the establishment of mobile, ground-based radio repeaters is often problematic. Another niche capability for UAS is to serve as meteorological observation aircraft, gathering information on the atmospheric environmental conditions while operating within and around the fire environment. This additional airborne information can supplement/enhance the ground-based meteorological data by providing a mobile measurement of conditions at critical altitude levels above a fire where manned aircraft assets may face fire-induced wind shears, unstable updrafts, and downdrafts. Therefore, the use of UAS within the wildfire operational environment should not be solely limited to image data gathering.

How will you operate the UAS? In fire applications one must take into account the fact that the tactical/sUAS crew may be close to the fire line (within the TFR or FTA), and those crew may have to be fire line qualified so that they do not hinder ground operations. This involves a prequalified level of training in emergency fire operations and protection/safety. Therefore, one cannot simply assume a UAS crew is given access to the interior perimeter of a working fire event without prior training, qualifications, and equipment. If the ground station/crew are not located at the incident and within the TFR/FTA, then one must also plan a robust communications plan and data-link system to communicate both with the aircraft, sensors, and instruments and with the incident command to ensure that the incident management team will receive the necessary data in a timely fashion.

Some of these issues are addressed in the following sections which highlight the differences in platform capabilities and sensor system needs in support of wildfire UAS observations.

113.4.1 Strategic (MALE/HALE) UAS

There are numerous categorizations of UAS, such as by size, weight, capability, altitude, and endurance ranges. For the wildfire imaging application, an identification of UAS by the altitude they operate and their endurance (Polski 2004) is offered. Medium-Altitude Long-Endurance (MALE) and High-Altitude Long-Endurance (HALE) UAS platforms include aircraft such as the MQ-9 Predator-B

(Ikhana) and the RQ-4 Global Hawk. These platforms are considered strategic assets because they would not be controlled operationally by a single fire incident team and would operate outside of the FTA (above) and can support multiple events due to their endurance capabilities. This capability comes at a price: the strategic UAS platform costs can be well into the millions of U.S. dollars and operational costs can be double to triple current manned aircraft operational costs (U.S. dollars/hour of operation). The advantages/situations where strategic UAS can support wildfire observations are:

- Long-endurance data collection flights over remote fire areas, covering a large number of incidents;
- Providing communications link (radio repeater) between incident command (IC) and ground resources;
- Providing real-time day and night sensor imagery of fire behavior to IC;
- Ability to fly above and out of way of all other fire aviation aircraft (out of TFR or FTA).

113.4.2 Tactical (LALE/LASE) UAS

Tactical UAS include Low-Altitude Long-Endurance (LALE) platforms such as the Insitu/Boeing ScanEagle and RQ-7 Shadow and Low-Altitude Short-Endurance (LASE) such as the RQ-11 Raven and RQ-16A T-Hawk and other similar platforms. The designation of “low altitude” is a relative term, where LALE systems are those that typically operate 500–3,000 ft (152–914 m) AGL, while LASE systems, often referred to as “sUAS,” generally operate under 500 ft (152 m) AGL. Larger LALE systems are capable of carrying multiple payloads and could perform missions similar to a strategic UAS over one fire. Most of these tactical/sUAS are hand-launched or catapult-launched and have belly-landing or net-captured recovery systems; therefore, they can be operated from within the wildfire TFR and do not need runway for launch/recovery. LASE or sUAS are typically small enough to be operated by a one-/two-person crew and could be used by “trained” first responders to monitor fire fronts that cannot be seen from their current location. The situations where tactical UAS can support wildfire observations are:

- Fire-line supervisors use to provide real-time photo/video and infrared imagery in tactical situations.
- Direct support of fire-line operations.
- Conditions where manned aircraft cannot operate (i.e., smoke, night, difficult terrain).
- Fire support by sUAS is required immediately and ability to launch quickly.

113.5 UAS Fire Imaging Sensor Characteristics

The use of UAS systems supporting wildfire information management is an issue of matching the appropriate platform characteristics with appropriate sensor systems.

Table 113.2 USFS-Specified Infrared Typing System (From Zajkowski et al. 2011)

| Components | Multiple incidents/large fires | | Single incident | | |
|----------------------------------|--------------------------------|--------|-----------------|----------|-----------|
| | Type 1 | Type 2 | Type 3a | Type 3b | Type 3c |
| Mount | Nadir | Nadir | Gimbaled | Gimbaled | Hand-held |
| Geo-corrected products | Yes | Yes | Yes | Optional | Optional |
| Thermal band(s) | 2+ | 1 | 1 | 1 | 1 |
| Production rate (acres per hour) | 100,000 | 10,000 | 1,000 | 500 | 100 |

First and foremost, the systems design must match the user needs/requirements; second, the UAS/sensor system must be compatible in integration capabilities; third, the system (UAS/sensor) must be able to provide access to the information/imagery collected in near real time; and finally, the UAS system must have cost-efficient operations or show marked improvements to current operations at similar or higher costs than manned aircraft operations.

The USFS has developed a guideline document that defines categories of wildfire airborne (manned) imaging support systems, known as the Infrared Typing System (Zajkowski et al. 2011). The Infrared Typing System can provide guidance on defining the strategic vs. tactical UAS sensor system capabilities. The typing system categorizes the ability of a sensor/platform to acquire either nadir or gimbaled sensor data over fires and further categorizes the ability of the sensor/platform to acquire multiple spectral bands, multiple incident/large fires (or small, single incidents), and the production/acquisition rate, measured in acres imaged per hour. The Infrared Typing System used by the USFS is shown in Table 113.2.

The Infrared Typing Systems can provide a guideline for identifying UAS fire imaging categories, where “strategic” UAS fire imaging operations would fall within the specifications of a Type 1 or 2 system and “tactical” UAS fire imaging operations would fall within the specifications of a Type 3a or 3b systems. The Type 3C category is not relevant to UAS discussions because it focuses on handheld systems operated out the door or window of a manned aircraft. The following subsections highlight examples of both strategic and tactical wildfire imaging systems that have been utilized by the U.S. fire community in UAS evaluations and operational missions.

113.5.1 Strategic Sensor Systems

Strategic systems are defined as providing broad-area coverage of a large single fire/multiple fire events during a single mission profile. The current National Interagency Fire Center (NIFC) National Infrared Operations (NIROPS) program employs two manned aircraft platforms with the wide-area (120° Field of View (FOV)) Phoenix sensor system. The Phoenix sensor on these two aircraft platforms is an example of a strategic acquisition system (<http://nirops.fs.fed.us/>). The Phoenix systems support multiple fires every mission night, providing near-real-time data

from their available MWIR/LWIR channels through a data communications link directly to NIFC where the data is accessed by GIS/interpreters reporting to individual incident teams. Given a longer platform endurance and larger payload capacity, UAS platforms in this category size class can be outfitted with specific-purpose imaging/MWIR/LWIR sensor systems of large size/weight. An example of a strategic UAS fire imaging system is the NASA Autonomous Modular Scanner (AMS) (<http://asapdata.arc.nasa.gov/ams/>), deployed on the NASA Ikhana (Predator-B derivative) UAS platform.

113.5.1.1 NASA AMS Sensor

The Autonomous Modular Sensor (AMS) is an airborne multispectral imaging line scanner capable of semiautonomous operations on both manned and unmanned aircraft that has operated on the NASA Ikhana (Predator-B) UAS. The sensor is able to provide flight endurances + 24 h, collect over multiple fire events, and easily map the entirety of large fire areas during single mission operations. Missions by the Ikhana/AMS generally cover >1,000,000 acres per hour of operation. The system is configured with 16 spectral bands ranging from the visible through near-, mid-, and longwavelength infrared (VIS-NIR-MWIR and LWIR) wavelengths (Fig. 113.4) with $\sim 0.5^{\circ}\text{C}$ temperature discrimination and measurement capabilities up to $\sim 650^{\circ}\text{K}$. The system is configured for onboard processing to derive user-specified products such as fire hot-spot identification from various channel algorithms, post-fire burn severity data, and vegetation vigor analysis. The products are delivered to user-specified locations within 10 min of collection. Product generation can be customized prior to and during flight operations. The AMS overall system weight is ~ 239.5 pounds (109 kg); therefore, the system is most appropriate on larger-class UAS such as a Predator or Global Hawk platform. A sensor pod was constructed to accommodate the AMS on the Ikhana UAS, where it was mounted under the wing.

The AMS is a line scanner imager with a Field of View (FOV) of 86° for 716 pixels across track, resulting in a ~ 3.1 -nmi (5.7 km) swath coverage width from an altitude of 10,000 ft (3,048 m) AGL. The Instantaneous Field of View (IFOV) of 2.50 mrad provides a pixel spatial resolution of ~ 25 ft (7.6 m at altitude 10,000 ft (3,048 m)). An example of AMS data collected over a large fire complex is shown in Fig. 113.5.

113.5.1.2 Wide Area Imager (WAI) Wildfire Sensor

The WAI sensor was developed under a NASA Small Business Innovative Research (SBIR) grant (2008–2012) by Xiomas Technologies, L.L.C., of Ann Arbor, Michigan (Fig. 113.6). The multispectral system is a unique design, incorporating Quantum Well Infrared Photodetector (QWIP) Focal Plane Arrays for the MWIR (4.0–5.0 μm) and LWIR (9.0–10.0 μm) channels that have an IFOV of 300 μrad which can provide a spatial resolution of 3.0 ft (1.0 m) from a platform altitude of 10,000 ft (3,048 m) AGL. Three additional spectral bands cover the visible and NIR wavelength region. The WAI is capable of fully remote/autonomous operations on UAS or adaptable to manned aircraft operations as well. The large area of coverage allows the system to be classified as a strategic asset, able to image 2.9 million

Fig. 113.4 The NASA AMS-Wildfire instrument arranged in the sensor payload pod tray. The scan head is located under the cylindrical white thermal blanket at the *top left* of the pod tray, while the pressure vessel in the center contains the digitizer and electronics. Other components include the power supply and various controlling electronics

acres per hour (1,173,588 hectares per hour) from an aircraft traveling at 300 MPH (260 KTS). The system is able to detect a 10²-in. (25.4²-cm), 600 °C hot spot from an altitude of 40,000 ft (12,192 m) AGL. The onboard processors can integrate positional information from an Applanix Inertial Measurement Unit (IMU) and provide near-real-time geo-rectified fire products through a data telemetry system link. An example of the WAI MWIR data is shown in sensor test and evaluation flight data in Fig. 113.7.

113.5.1.3 Strategic Asset Fire-Mapping Systems Costs

Most of the “strategic” multiple-channel fire imaging sensors in use/evaluation in the United States are one-of-a-kind systems, with high initial investment costs and high maintenance and calibration costs and procedures. The NASA AMS, as an example, is a one-of-a-kind multispectral imaging sensor. Costs for AMS system replication are estimated at \$1.3–\$2 M (U.S.). The market for capable, fully calibrated, wildfire scanning systems with MWIR and LWIR wavelength sensors is small (in comparison to VIS imaging systems), leading to a large development cost structure with little cost-recovery opportunity. The WAI sensor system is similarly developed from new technologies and requires a maintenance and calibration schedule to operate effectively. The cost estimates for replication of the WAI approach \$700 K–\$1.1 M (U.S.), dependent on the components, new (improved) QWIP sensors, and other additional elements.

Fig. 113.5 AMS sensor data collected over the Basin/Indians Fire, Monterey County, CA, on 8 July 2008. This mosaic of flight track collections was geo-rectified and mosaicked in near real time onboard the Ikhana UAS platform and represents a composition of four to five flight segments covering the entirety of the fire, which was the third largest in California history (162,818 acres (65,890 hectares)). These flight segments were collected within a 1-h period. The *thin yellow lines* represent the real-time-derived hot spots of the fire line, while the *purple hues* represent the burned areas of the fire

Fig. 113.6 The Wide Area Imager (WAI) wildfire imaging scanner system developed by Xiomas, L.L.C. The WAI is capable of manned/UAS operations with remote/autonomous operations capabilities. The WAI is designated as a “strategic” fire sensor system able to provide data over greater than 1M acres per hour of operation (Courtesy of J. Green, XIOMAS, L.L.C.)

Fig. 113.7 The Wide Area Imager (WAI) MWIR data collected during test missions over Reno, Nevada, October 2011. The scene on the *left* depicts the geo-rectified data scenes for an entire flight track, automatically mosaiced together. The scene on the *right* is an enlargement covering the Reno, NV airport, showing aircraft on the tarmac and various terminal building thermal properties (Courtesy of J. Green, XIOMAS, L.L.C.)

113.5.2 Tactical Sensor Systems

Tactical systems are those providing small-area coverage of single fire events or portions of a fire to supply near-real-time data directly to fire teams on the ground. Using the Infrared Systems Type Handbook as a guide, tactical systems are those that rely on inexpensive, single band MWIR/LWIR, fixed or gimballed sensors, capable of collecting data at $\sim 1,000$ acres per hour (404 hectares per hour). The sensor systems were generally designed to support non-fire operations (night surveillance operations) and are therefore not optimized for fire, but still useful nonetheless. Some of the UAS platforms/sensors being considered by the fire community are U.S. Department of Defense (DoD) surplus sUAS systems. There are a limited number of private vendors who are developing specific-focus, sUAS/sensor platforms for fire observations, and they are currently engaged in demonstrations and flight trials with the USFS and other civilian agencies.

Fig. 113.8 An

AeroVironment Raven UAS system, operated by the department of Interior, U.S.. Geological Survey to support resource imaging projects, including wildfire imaging. The Raven is a typical small, hand-launched “tactical” UAS that will see expanded use in supporting quick assessments of fire conditions by first-on-scene responder crews, to perform small fire assessments and imaging of residual hot spots during fire mop-up operations (Image courtesy of M. Hutt, USGS)

113.5.2.1 Electro-Optical Video Systems (Gimbaled or Fixed Pointing)

Most of the tactical/sUAS in use today operate with a simple electro-optical video system. The U.S. Department of Interior, Geological Survey (USGS), operates AeroVironment Raven UAS to support various natural resource inventory and mapping efforts as well as their fire-support mapping needs on federal lands (Fig. 113.8). The Raven UAS have an electro-optical, visible-spectrum-range, real-time video sensor, with a LWIR sensor. The newer model Raven aircraft has lightweight, micro-gimbaled “Mantis[©]” VIS and LWIR sensor that provides video data over a communications link. The visible-wavelength E/O systems have limited wildfire use, where smoke precludes clear-acquisition imaging. Nonetheless, they can be an effective, inexpensive tool, useful in fire observations, especially by first responders on wildfire events, as well as utility in post-fire mop-up operations. The models with a LWIR video onboard are more effective sensor platforms for operations within a smoky fire event (Fig. 113.9).

113.5.2.2 Gimbaled LWIR Video Systems

The thermal imaging systems available on most sUAS systems rely on a single band LWIR for hot-spot discrimination. In a single band detection system, sensitivity to small unresolved fire spots is obtained by setting the threshold, or trip level, to a lower apparent temperature. The problem with this method is that warm large-area targets with the same apparent temperature will also be detected as fire hot spots (Hirsch 1971; Hirsch et al. 1971). This can prove problematic for discreet fire detection, as most sUAS thermal imaging systems are optimized for temperature discrimination closer to earth ambient temperatures (~ 300 K). These systems are generally optimized to discern warm objects, slightly above the background temperature of the imaging area, such as a person hiding in a complex brushy terrain or a warm vehicle sitting amongst a cooler camouflaged background. When these systems encounter higher-temperature objects (fire), the

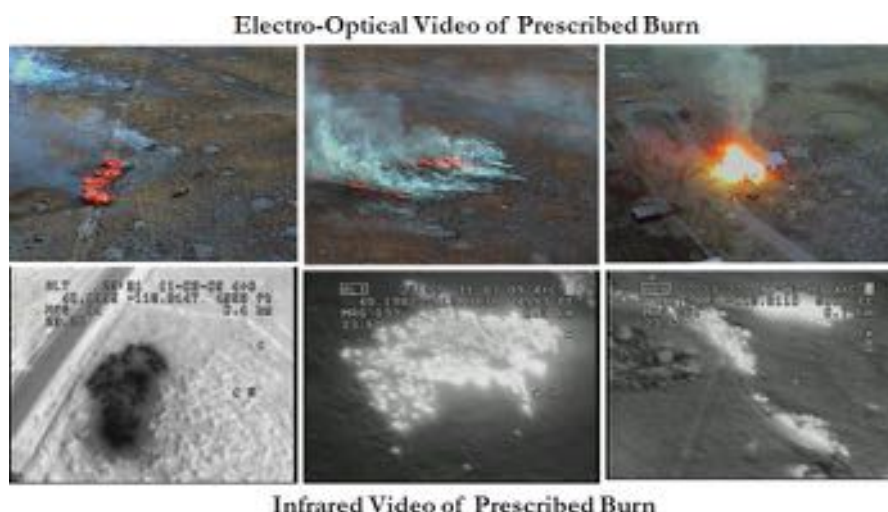

Fig. 113.9 The three images across the *top* are captures of an electro-optical (visible wavelength) video camera system flown on a U.S. Geological Survey Raven UAS. Note the potential for smoke obscuration of the fire in the visible wavelengths. With a larger plume, this can be problematic for fire hot-spot identification. The three images across the *bottom* are captures of a LWIR wavelength video system for three fire areas. The image in *bottom left* is a reverse-mapped scene (dark = warmer temperatures). These three scenes illustrate the sensitivity limitations of simple LWIR systems, where saturation occurs over the fire area and the sensor thermal discrimination capabilities are too low to capture discrete separation from burning and smoldering components. For these missions (quick-look assessment of localized events), these systems are adequate and cost-effective (Images courtesy of M. Hutt, USGS)

sensor becomes “saturated,” which complicates the identification of small hot areas and other features in the data (Fig. 113.10).

Despite their limitations, tactical/sUAS LWIR gimbaled systems are useful for fire support. They allow crews to identify new fire starts, monitor fast-moving fire-fronts, and identify smoldering fires during the mop-up phase. LWIR sensors are also able to detect subsurface heat that is not visible to the human eye such as burning root systems, which can later erupt into surface fire events. The small, LWIR micro-bolometer sensors are constantly improving with the sensor getting smaller, the sensor array sizes getting bigger (increased spatial and pixel resolution), and unit costs decreasing. Several manufactures are working on more efficient and smaller QWIP sensors that can be installed in tactical/sUAS in the near future, which will increase their detection thresholds, spatial resolution, and spatial coverage for each image area while lowering costs. SWIR systems (0.9–1.7 μm) are also being installed on sUAS. As with most LWIR sensors, SWIR systems, optimized for security applications, can be used for fire monitoring. An advantage to SWIR sensors is that the 0.9–1.7- μm wavelength region imagery is easier to interpret than LWIR imagery, especially for the basic-trained image analysts, who are familiar with more commonly available NIR/SWIR image data. One must be cautious with

Fig. 113.10 Subset image of single channel LWIR video of fire in Arizona taken from a DHS-CBP Predator-B UAS. Note the saturation/blooming of pixel response for the hot areas shown in *white*. Not all the area is on fire, but since the sensor is not optimized for high-temperature discrimination, the white areas therefore represent regions which exceed a temperature threshold, usually just 10–50 °C above background ambient temperatures (Courtesy of T. Zajkowski, RedCastle Resources)

Fig. 113.11 A TASE 150, with a FLIR 320 × 120 array Proton sensor, shown mounted in a sUAS payload tray, along with the data-capture computer and electronics board. This model shows the 5-in. (12.7-cm) gimbal unit mounted in a retractable frame, allowing the unit to be retracted during takeoff and landing and in the down (imaging) position during data-acquisition flights. The system weighs 2.3 pounds (1.04 kg) (Image courtesy of D. Yoel, AAAI)

SWIR systems, as they are also more prone to smoke obscuration than MWIR and LWIR systems. An example of a sUAS gimbaled LWIR system, the TASE 150, with a FLIR 320 × 120 array Proton sensor is shown in Fig. 113.11. An image acquired from that system is shown in Fig. 113.12.

113.6 History of Airborne Fire Imaging Systems Utility in United States

The USFS began using manned aircraft for fire patrols in 1917. Early research by Johnson and Thomas (1951) and others reported the value of a Polaroid Land Camera for assessing forest damage due to fire. The camera was used in a near-real-time mode by air dropping prints to fire camps within minutes of acquisition. Since 1964,

Fig. 113.12 Imagery shows an aerial ignition (via air-dropped ignition spheres) of a prescribed fire on the George Washington Jefferson National Forest, Virginia. A curving road with a few fire vehicles on such can be seen running from *top left* to *bottom center* of the image. The linear feature of the aerial ignition fire line can be seen as distinct white lines running parallel to the road (Image courtesy of D. Yoel, AAAI)

the USFS has used airborne thermal infrared line scanner systems to map forest fires. In the 1980s, it began adopting turret-mounted thermal-infrared sensors on aircraft and, specifically, rotorcraft to also observe wildfires. These systems have proven to be very useful for supporting incident teams managing wildfires.

In the early 1960s, the USFS initiated a fire monitoring research program at the Northern Forest Fire Laboratory in Missoula, Montana, with the objective to develop a system capable of detecting and mapping fires through all atmospheric conditions (Hirsch 1963). At the conclusion of this program, Hirsch (1964) listed the attributes of an ideal remote sensing system designed for fire monitoring: including detection of fire in its early stages, effective operation day or night, and the ability to prioritize fires. Hirsch also points out in this report that the most important characteristic of a fire-mapping system is the ability to produce data related to fire-line location and size in relation to topography and road access and communicated in a timely manner.

Between the 1960s and 1970s, the USFS developed a bi-spectral imaging system based on a Daedalus scanner, sensitive in the 3–4 and 8.5–11- μm EM spectrum (Hirsch et al. 1971). System characteristics included the ability to detect small (0.09 m^2), hot (600°C) targets against backgrounds ranging from 0 to 50°C , at altitudes of $5,000\text{ m}$ above ground level. Hirsch (1968) indicated that the information these systems provided was fully integrated into the command and control

process for fire management. Hirsch also listed the limitations of these early systems as (1) non-rectified imagery, (2) slow delivery to fire management personnel, and (3) limited ability to use ancillary data sets such as digital map and digital terrain data. Some of these same limitations still exist today, causing many disaster management agencies to look to new technologies to expand existing capabilities.

In the early 1980s, Daedalus Enterprises, Inc. built the airborne Thematic Mapper Simulator (TMS) scanner for NASA. The TMS was used to simulate the LANDSAT Thematic Mapper satellite sensor system, with 12 VIS/NIR/MWIR/LWIR channels, to support earth science research. In the 1980s the TMS was modified to support fires research and management (Brass et al. 1987; Ambrosia and Brass 1988). Ambrosia (1990) summarized the unique advantages of the TMS, operating on the NASA high-altitude ER-2 aircraft, to cover large fire or multiple fires efficiently and effectively. Various data telemetry systems linked to the TMS on the NASA ER-2 high-altitude aircraft were used to demonstrate data transmission to fire management personnel in near-real-time. These ad hoc wildfire imaging support missions culminated in the 1996 NASA Wildfire Experiment, utilizing a 4-channel scanning sensor (Airborne Infrared Disaster Assessment System (AIRDAS)), demonstrating the utility of real-time data on a prescribed fire (Ambrosia et al. 1998). These experiments and demonstrations, coupled with evolving sensor technologies and improving data telemetry systems, showcased the real-time provision of MWIR and LWIR imagery over wildfire events.

Since 1998, the USFS has utilized the Phoenix imaging system in operational fire imaging. The two Phoenix systems are flown on the USFS manned aircraft (Cessna Citation jet and a Beechcraft B200 King Air). These systems have been improved with the addition of new data telemetry capabilities (Aircell system) and improved electronics.

113.6.1 History of UAS Fire Imaging Systems Developments in the United States

The first documented use of a UAS in support of wildfire intelligence gathering was in 1961 by M. Schroeder of the USFS Forest Fire Laboratory, Riverside California. The low-altitude retrievable probe (LARP) was a modified radio-controlled airplane designed to fly in and around smoke columns to gather fire weather information (Fig. 113.13). The report on the LARP noted that it was difficult to find qualified pilots to conduct the missions (Wilson and Davis 1988).

In October 1996, the USFS demonstrated the Israeli Aircraft Industries (IAI) “Firebird 2001” UAS for fire applications in Missoula, Montana, showcasing fire imaging capabilities with a TV camera and FLIR imaging system onboard (http://www.fire.uni-freiburg.de/iffn/tech/tech_11.htm) (Fig. 113.14). For various reasons the technology was not adopted at the time. Widespread interest in civilian use of UAS technology was not realized until the technological progress and operational experience gained by DoD during military conflicts from the 1990s forward. As systems supporting military intelligence gathering from UAS proliferated, the

Fig. 113.13 The low-altitude retrievable probe (LARP), a radio-controlled “drone” airplane. The LARP was designed to fly in and around the smoke column of a fire, gathering weather information (From Wilson and Davis 1988)

Fig. 113.14 Israeli Aircraft Industries Firebird 2001 UAS during flight demonstration supporting wildfire imaging in Missoula, Montana, October 1996 (Image courtesy of USFS)

broader civilian community embraced the systems for the similar roles that UAS forms could support domestically.

Since 2003, the USFS and NASA have collaborated to enhance wildfire monitoring capabilities through the Wildfire Research and Applications Partnership (WRAP) project (Hinkley and Zajkowski 2011). The WRAP has flown numerous UAS fire imaging missions that have demonstrated their ability to collect/deliver near-real-time intelligence and to serve as communications relay platforms.

Fig. 113.15 *Left to Right:* RNR Products APV-3 UAS, MLB Company Bat-3 UAS, and a modified Yamaha RMAX rotorcraft UAS, on display during fire imaging flight demonstrations at NASA-Ames Research Center, Moffett Field, California, July 2005

The intent of this effort has never been to replace manned, fire aviation assets, but rather to augment such in niche applications that are currently underserved, such as the collection of wildfire tactical intelligence. The objective for the sUAS demonstration series was to develop the Concepts of Operations (CONOPS), Standard Operating Procedures (SOPs), and contracting requirements for UAS integration to operations. This documentation will allow the USFS to phase-in UAS wildfire operation as federal aviation regulations evolve.

113.6.1.1 Small UAS Fire Imaging Demonstration: 2005/2006

The USFS and NASA collaborated on demonstrations of sUAS utility for wildfire support, with the goal to develop UAS operational guidelines, safety standards, and contracting rules so that firefighters can include sUAS in their toolkit. The first demonstrations took place at the NASA the Ames Research Center in July 2005. Three UAS systems, an MLB Company Bat-3 UAS, the RNR Products APV-3 UAS, and a modified Yamaha RMAX rotorcraft UAS, demonstrated imaging capabilities over a small fire hot spot (Fig. 113.15). The demonstration proved successful and led to expanded demonstration capabilities in 2006.

A second UAS fire-support demonstration was conducted in June 2006 in the Military Operations Area (MOA) of Fort Hunter Liggett, near King City, California

Fig. 113.16 UAS in June 2006 USFS/NASA Fire Imaging Demonstration, Ft. Hunter Liggett, CA (*Upper left*) APV-3 UAS used as an over-the-horizon communications relay platform; (*upper right*) In Situ (Boeing) A-20 ScanEagle on catapult launch assembly; (*lower left*) AeroVironment Puma, hand-launched UAS; and (*lower right*) IntelliTech Vector-P UAS, in preflight tarmac test

(Fig. 113.16). This demonstration required UAS to operate day/night over a large controlled burn, 5 mi (8 km) from the UAS airfield, and transmit that imagery back in near-real-time. The UAS included an AeroVironment Puma, an In Situ (Boeing) ScanEagle, an RnR APV-3 (communications relay platform), and an IntelliTech Vector-P. The 2006 demonstrations helped inform the UAS community of the requirements of fire management personnel to operate safely and efficiently in a wildfire scenario. The UAS commercial-provider community demonstrated their capabilities at their own costs and provided a wealth of information allowing the fire community to evaluate the use of UAS for fire imaging support and communications relay. It also allowed the agency to initialize policy objectives for integration of UAS into operational utility in support of wildfire management efforts.

113.6.1.2 NASA Altair and Ikhana (Predator-B) Western States UAS Fire Imaging Missions: 2006–2009

In 2006, NASA-ARC, the USFS, and NASA-Dryden Flight Research Center (DFRC) collaborated to demonstrate capabilities of long-endurance UAS and sensors to support near-real-time wildfire information data provision over numerous wildfires in the western United States. The missions were designed to evaluate the capabilities of the NASA Altair and the Ikhana (Predator-B) UAS. In 2006, the partners relied on the Altair UAS to support fire imaging demonstrations, while

Fig. 113.17 (a & b) (top) The NASA Altair UAS (modified Predator-B) platform in flight during 2006 Western States UAS Fire Imaging Mission Series. The AMS sensor was carried in the pod mounted below the fuselage. (bottom) The NASA Ikhana UAS (Predator-B) platform in flight during the 2007 Western States UAS Fire Imaging Mission Series. The AMS sensor was carried in the pod mounted under the wing (Images courtesy of NASA)

the Ikhana was prepared for delivery to NASA. The Altair, shown in Fig. 113.17a, is a higher-altitude version of the Predator-B. The Ikhana (Fig. 113.17b), flown in support of fire imaging missions in 2007–2009, housed the AMS sensor, to support wildfire observations with onboard, real-time, fire-derived product generation (Merlin 2009; Ambrosia et al. 2011a, b).

During the Western States UAS Fire Imaging Missions, the Ikhana flew over 20 missions in the western United States over 60 fires, demonstrating UAS/sensor capabilities (Fig. 113.18). Near-real-time, geo-rectified AMS fire imagery was delivered to wildfire incident management teams within 10–15 min of acquisition (Zajkowski et al. 2008b). This allowed an improved understanding of fire conditions by the incident teams resulting in maximization of firefighting resources. The Ikhana was also the first public-use UAS to receive a Certificate of Authorization (COA) to operate in extensive segments of the U.S. National Airspace System (NAS) without requirements for chase aircraft or ground observers. The Ikhana was operated in coordination with six FAA Air Route Traffic Control Centers (ARTCC) covering the entire western U.S.. The platform was given FAA COA support during the October 2007 Southern California firestorms that burned over 500,000 acres

Fig. 113.18 The NASA Ikhana UAS Western States UAS Fire Imaging Mission flight tracks overlain in GoogleEarth. The four missions, spread throughout the summer of 2007, ranged in duration of 9.5–20 h, and covered from 1,400 to 3,200 nmi for each mission

(770 mi², 2,000 km²), caused the evacuation of ~500,000 people, took 9 lives, and injured 85 others. During that mission period (October 24–28), the Ikhana was granted access to airspace over densely populated regions of southern California, an event never before allowed by the FAA. The Ikhana flew at a constant altitude of FL230 (7,000 m), under control of a NASA pilot through some of the world's busiest airspace, supporting image data collection over wildfires near the San Diego and Los Angeles metropolitan areas (Fig. 113.19).

This mission series demonstrated the safe operations of MALE UAS in support of wildfire/disaster event monitoring. The collaborations with the FAA allowing access to the NAS provided new opportunities for UAS to support national disaster events and have helped spur the UAS developments of other agencies. Table 113.3 lists the wildfire imaging support missions flown by the Altair and the Ikhana UAS during the Western States UAS Fire Imaging Mission's 2006–2009 fire seasons.

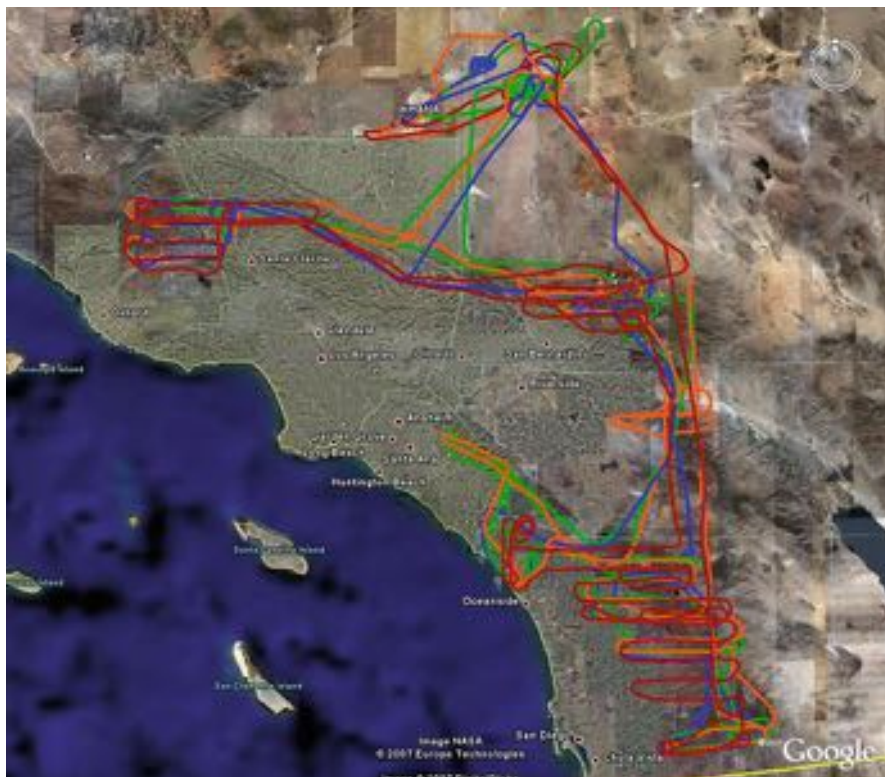

Fig. 113.19 Four days of aircraft tracks of the NASA Ikhana (Predator-B) UAS covering the October 2007 Southern California Fire Storm region. At least 11 fires were overflown every day (some twice a day), and imagery was delivered in real time from the AMS sensor on the Ikhana to incident command centers on the ground. The Ikhana UAS missions originated at NASA Dryden Flight Research Center (DFRC) at Edwards Air Force Base (EAFB), California, located in the *upper center* of the map image

113.6.1.3 DoD Predator-B UAS Fire Mission Support: 2008

In June 2008, numerous dry thunderstorms started thousands of wildfires, most occurring in northern California forestlands. At its peak, over 2,700 fires were burning throughout northern California, straining available resources. In addition to the NASA Ikhana UAS, the U.S. Air Force and U.S. Navy flew fire imaging support mission with their RQ-4 Global Hawk UAS platforms, operating from Beale Air Force Base, near Marysville, California. In addition to providing intelligence on wildfires, these mission were the groundbreaking collaboration element between the DoD and the national disaster management community, which helped forge agreements and procedures for sharing wildfire management needs/requirements between the DoD and civilian agencies.

Table 113.3 Summary of Western (United States) States Fire Mission (WSFM) flights, 2006–2009

| Year | Aircraft | Flights | Hours | Fires flown |
|------|----------|---------|-------|---|
| 2006 | Altair | 4 | 68 | Mono Lake Prescribed Fire, Esperanza Fire (CA) |
| 2007 | Ikhana | 12 | 89 | Zaca, Tar, Colby, Babcock, Jackrabbit, Butler, North, Fairmont, Grouse, Lick, Bald, Moonlight, Zaca, Trapper Ridge, Castle Rock(ID); WH Fire (MT); Columbine, Hardscrabble, Granite Creek (WY); GW Fire, Big Basin (OR); Domke Lake, South Omak (WA); SoCal Firestorm Complex (Witch Creek, Harris, Poomacha, Horno/Ammo, McCoy, Rice, Ranch, Buckweed, Santiago, Slide, Grass Valley, Magic) |
| 2008 | Ikhana | 4 | 21 | Piute, Clover, Silver, North Mountain, American River, Cub Complex, Canyon Complex, Basin, Gap, Camp, Cascadel, Hidden (CA) |
| 2009 | Ikhana | 2 | 11 | Piute, Station Fire (CA; post-burn assessments) |

Note: CA California, ID Idaho, MT Montana, WY Wyoming, OR Oregon, WA Washington

113.6.1.4 AUVSI Fire Fighting Table Top Exercises: 2009–2010

The USFS collaborated with the Association of Unmanned Vehicle Systems International (AUVSI), the Naval Postgraduate School (Monterey, CA), and U.S. Army Dugway Proving Grounds (Dugway, UT) to host two Firefighting Table Top Exercises (FF-TTX) in 2009 (CA) and 2010 (UT). These exercises provided an exercise for wildland fire personnel to assess the integration of UAS into fire management operations and allowed the unmanned systems community and firefighters to directly interact with each other in conditions similar to those found in an actual wildfire. The firefighters were able to interact with the UAS operators, giving them the opportunity to get hands-on training to direct sensors or give commands to UAS autopilots. In return, the UAS community received valuable direct feedback from the firefighters on UAS integration issues in the wildfire airspace. The TTX workshops exposed both communities to the issues and capabilities involved in supporting operational wildland fire events and the difficulties encountered on wildfires given safety and shifting situational environments (AUVSI 2010).

113.6.1.5 Fort Pickett UAS Fire Imaging Demonstration: 2010

A USFS-led UAS fire imaging demonstration project at the U.S. Army National Guard Maneuver Training Center, at Fort Pickett, Blackstone Virginia in 2010, concentrated on a UAS Long-Endurance Data Collection and Relay Mission. The UAS flight provided the incident commander multiple looks of a remote fire area to maintain situational awareness of a fire’s location, hazards, and terrain features, providing tactical/strategic information. The demonstration exemplified the capabilities of sUAS to provide improved, near-real-time fire-line safety information and fire behavior data to the incident team/first responders.

Fig. 113.20 The University of Alaska Fairbanks InSitu ScanEagle UAS being prepared for a fire observation mission over the Crazy Mountain Complex fires north of Fairbanks, Alaska, on 5 August 2009. The ScanEagle supported the fire management personnel when manned aircraft were grounded due to the flight hazard created by the large smoke pall. Note the background, hazy conditions caused by the smoke plume in the background (Image courtesy of K. Rich (UAF))

113.6.1.6 University of Alaska Fairbanks/Alaska Fire Service UAS Fire Missions, Crazy Mtn. Fire: 2009

In 2009, one of the four InSitu ScanEagle UAS owned by the University of Alaska Fairbanks supported the 447,000-acre (180,894-hectare) Crazy Mountain Complex fires burning north of Fairbanks. A large smoke pall covering the region had grounded manned aircraft assets for safety reasons, so there was no opportunity to track fire progression except for the UAF ScanEagle UAS. The ScanEagle, with a 10-foot wingspan, weighs about 40 pounds (18.14 kg), is capable of speeds between 40 and 70 MPH (64–113 KPH), and has an endurance of ~20 h and a ceiling of ~16,000 ft (~4,877 m) AGL (Fig. 113.20).

The operational use of the ScanEagle sensors allowed the incident management team to assess the fire position relative to a critical natural fuel break (stream); this assessment saved aircraft retardant drops and ground-crew firefighting efforts, by showing that the fire had not crossed the stream into heavy fire-prone areas. The UAF UAS Program is based at Poker Flat Research Range and is currently working with the Alaska Fire Service and federal land management agencies in Alaska to support more wildfire assessment needs into the future.

113.6.1.7 USGS Fire Imaging Demonstrations

Established in 2008, the USGS National Unmanned Aircraft Systems Project Office has made significant contributions in operational utility of UAS platforms supporting the U.S. Department of Interior (DOI) agencies in resource inventories, hazards assessments, and disaster imaging support on federal lands managed by DOI. Using RQ-11 Raven sUAS, the Office has flown prescribed fires over Dugway Proving Grounds in Utah (2009) and Eglin Air Force Base in Florida (2010). The USGS UAS Program Office has transitioned their UAS fire mission operations capabilities to the DOI Aviation Management Directorate, which is currently developing procedures to fly operational mission. These shared-agency developments will help improve guidelines and operational procedures with common language, objectives, goals, and directions for integration of UAS into operational utility within the federal government. It will also provide the framework for state-level agencies to build and develop their capabilities, based on these agency models.

113.7 Concluding Remarks

In the United States, the USFS and other federal agencies are testing and evaluating UAS systems on wildfire incidents, developing UAS “Roadmap” documents directing future adaptation of UAS into operational utility. The first step of that adaptation-into-operations framework is to evaluate system capabilities and appropriateness for use in various situations. The USFS has partnered in evaluation of strategic systems for national observation capabilities and is also evaluating small/tactical UAS systems. Given the expense of strategic UAS operations, the focus in strategic observations will be on continuing usage of the manned aircraft platforms/sensors and sharing usage on partner agency strategic UAS assets. Many of the capabilities demonstrated during those strategic UAS mission operations (autonomous sensor operations/processing, real-time data communication strategies) are being leveraged and adapted to manned aircraft assets, showcasing dramatic improvements in wildfire observation capabilities. When the larger, strategic assets reach a higher level of operational maturity, as well as an improved price point, they will see increased use, possibly as “shared” assets amongst a consortium of civilian agency users.

The U.S. wildfire management agencies are focusing their UAS integration to operations on tactical/sUAS platforms. Their focus is based on their mission requirements for “over-the-hill” tactical data supporting fire operations, needs for nighttime operations when manned assets are grounded/unavailable, and cost structures similar to/cheaper than their current manned aircraft (typically rotorcraft) cost structure. The USFS is also evaluating the cost trade-offs of owning/operating their own fleet of UAS vs. contracting for UAS services. Current FAA regulations favor “public-use” UAS in the NAS, but those regulations are being modified and could change dramatically within the year. When that occurs, there will likely be a surge of private UAS service providers moving towards capturing a larger market share of the federal/state agency airborne fire imaging/disaster imaging community.

Whether the wildfire management agencies decide on “in-house” or contracted UAS capabilities, that wildfire community will have to be further educated and informed of UAS capabilities and limitations, as well as the role they can play in their operational structure.

The use of UAS to support wildfire observations must be primarily dictated by the observation objectives of the fire incident team: strategic or tactical observations. These decisions then must be tempered by the capabilities of the sensors and the platforms, their ability to meet the needs of the missions, and the expected costs vs. benefit of the UAS operations. There are a number of critical factors that should be part of the needs evaluation for UAS support to wildfire events including UAS selection based upon mission needs (strategic observations, tactical, post-fire assessments of residual burning, etc.); sensor requirements (payload mass/volume, spatial coverage and spatial resolution, electrical load of sensors on UAS, communications, go/no-go criteria); and, on-station requirements (ferry distance from launch/recovery to fire area), measurement duration, weather considerations, and many more, including cost considerations.

Each of these factors should be on every checklist for determining UAS/sensor viability to support wildfire imaging. The UAS and sensor community would do well to remember that the driving objectives of the missions are to *support wildfire observations and intelligence gathering in the safest and most efficient methods possible*. If any of the criteria listed above is not “optimized” for a particular UAS use, then the mission should not be undertaken. Remembering that the role of the firefighter is to manage wildfire events with the best and most effective tools in his/her toolbox is of utmost importance. By objectively addressing the needs, requirements, capabilities, timeliness, efficiency, costs, and effectiveness of using UAS/sensor systems, the community will readily adopt UAS and associated technologies in support of wildfire “intelligence” gathering.

The way forward in UAS use for wildfire agencies is through collaboration, since no single entity currently has the assets or knowledge to support large operational UAS wildfire imaging programs. But together, the agencies can pool assets, leverage resources, and develop standard tasking, processing, exploitation, and data dissemination procedures. They can also share awareness of capabilities with each other and work cohesively to collect the data necessary to develop UAS operating plans and procedures with the FAA. Only then will UAS be readily integrated into operational wildfire imaging support environments.

Abstract

The applications of Unmanned Aerial Systems (UAS) are typically related to information exchanges that are useful in the context of surveillance, mapping, target tracking, and similar tasks presented in other chapters of this handbook such as forest fires, environment monitoring, measurements in volcanic environments, and maritime applications. However, other applications of interest can involve physical interactions between UAS and environmental objects as well as between several UAS. This chapter presents the state of the art in two branches of this novel research area: aerial manipulation and load transportation. In addition, the particular case of using autonomous helicopters equipped with robotic arms for aerial manipulation is detailed. Finally, recent field experiments of joint load transportation with multiple autonomous helicopters are presented.

114.1 Introduction

The applications of Unmanned Aerial Systems (UAS) are typically related to information exchanges of the UAS with objects in the environment, with ground stations, and between several UAS. These information exchanges are very useful for applications such as surveillance, mapping, target tracking, and the ones presented in other chapters. However, other UAS applications can be envisaged. These include applications that involve physical interactions between several UAS and between UAS and objects on ground. This chapter is devoted to these applications that can be considered as a natural progression of the abovementioned UAS applications related to information exchanges. The level of maturity of the functionalities required to support these applications is still low, and only prototypes have been designed. However, the potentialities are very high.

Physical interactions between aircrafts are today performed in applications such as the in-flight refueling or air-air refueling between manned aircrafts. Increasing the endurance of the missions is also an objective to be achieved in the UAS field. This could be performed in the same way by means of linking manned and UAS or UAS to UAS (Mammarella et al. 2008). In all these applications, the interactions are in the air.

Another strategy is the application of perching on rods or beams allowing UAS to increase the endurance of their missions if perches are equipped with battery charging stations. In this second case, the interactions are between the UAS and elements fixed on the ground. In Doyle et al. (2011), a bio-inspired concept and prototype that allow helicopters passive perching on cylindrical-type surfaces are presented.

Another functionality carried out by means of manned aircrafts, mainly helicopters, is the slung load transportation. This functionality is used in many applications such the transportation of line towers in remote areas or in the logging industry that use helicopters to transport logs in areas inaccessible by ground.

The slung load transportation has been also performed by means of unmanned helicopters (Bernard and Kondak 2009). The weight of the load is critical because the cost of the UAS increases exponentially with this load. In order to avoid this limitation, the joint transportation of a single load by several helicopters was proposed and demonstrated with three helicopters in the project AWARE funded by the European Commission (Bernard et al. 2011). Notice that in this case the physical coupling between UAS is involved through direct interactions of each unmanned aerial vehicle with the joint load.

Load transportation and deployment by one and several helicopters are very useful for many applications including the delivery of first-aid packages to isolated victims in disasters (floods, earthquakes, fires, industrial disasters, and many others) and are also basic technologies for other future applications, such as the building of platforms for evacuation of people in rescue operations and the installation of platforms in uneven terrains for landing of manned and unmanned VTOL aircrafts. This later application would first require the installation of the supporting units defining the horizontal surface and later the installation of the surface itself.

There are other possible applications such as the remote inspection by contact that have been targeted by the European AIRobots (2010) project. Also there are applications that involve aerial manipulation in sites that are very difficult to be accessed by ground. These include collecting samples of materials or inspection and maintenance tasks that can be solved by a UAS equipped with a special device or with a robotic arm.

Another application is the cleaning of windows or walls by applying forces while maintaining flight stability. In Albers et al. (2010), an additional actuator was added to generate forces in physical contact while the UAV stays horizontal.

The next step is to provide the aerial robots with assembly and manipulation capabilities. The assembly functionality of an aerial robot could be useful to replace parts in inaccessible sites. Another application is the construction of structures. In some of these applications, the limitation of payload is a significant drawback that could be avoided by using the cooperative assembly and manipulation. Moreover, this cooperation enables applications that require physical intervention in more than one place at the same time. The development of a Cooperative Assembly System by means of aerial robots equipped with robotic arms is the main subject of the ARCAS (2011) integrated project recently launched by the European Commission.

The on-orbit servicing and the assembly of space structures have been also the subject of research over the last two decades and include free-flying servicer concepts for handling and assembling and a few theoretical studies concerning the dynamics and control of the motion of grasped bodies in space (Moosavian and Papadopoulos 2007). However, only simplified practical demonstrations of these free-flying manipulators have been developed.

Figure 114.1 shows potential UAS applications involving physical contacts between UAS or between UAS and ground.

In many of the above applications, the use of piloted helicopters is very risky or even impossible. Moreover, the use of multiple manned helicopters is also problematic, and only simple operations, like load transportation with two

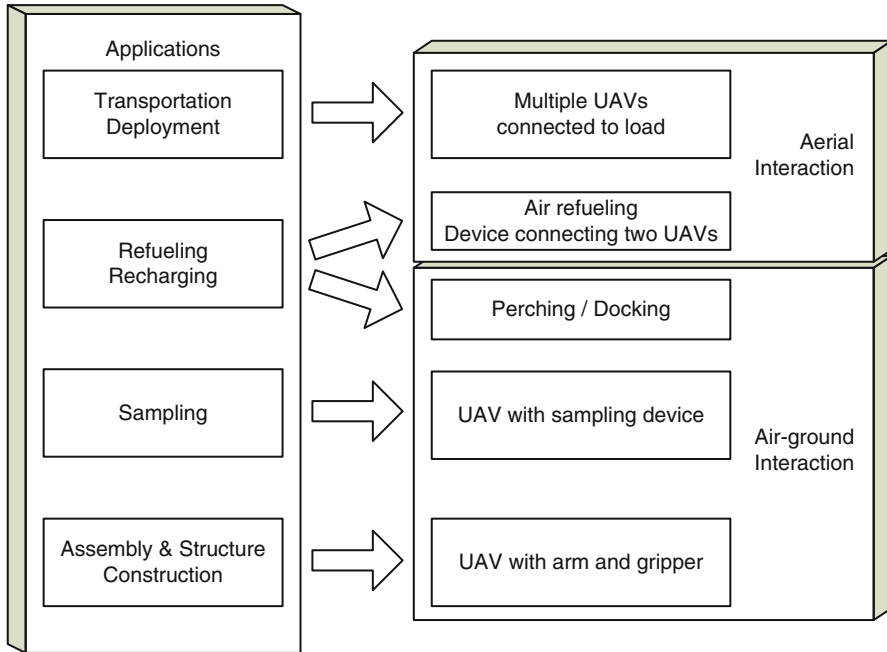

Fig. 114.1 Applications of UAS physically interacting

helicopters, can be performed by extremely skillful and experienced pilots. The level of stress is usually very high, and practical applications are therefore rarely possible.

The next section of this chapter presents a general framework for the cooperation of multiple UAS that includes possible physical interactions. The following sections are devoted to two relevant cases involving physical interactions. Thus, Sect. 114.3 presents aerial robot manipulation as an application of interest for the UAS equipped with a robotic arm and gripper in Fig. 114.1. Section 114.4 deals with load transportation and deployment, as an exemplary case of physical interaction between multiple UAS connected to a load. Finally, the last two sections are devoted to the conclusions and references.

114.2 Model for the Interaction

Robotic systems composed of a physical process and a decisional and control system can be modeled as hybrid systems (Fierro et al. 2002; Chaimowicz et al. 2004; Fagiolini et al. 2007; Li et al. 2008). Figure 114.2 shows a simplified hybrid model of a robot interacting with the environment and/or other robots.

Let us consider that the robot can perform k different tasks $\Omega = \{\tau^1, \tau^2, \dots, \tau^k\}$ with n logical conditions requiring a change of task in the current plan. Let

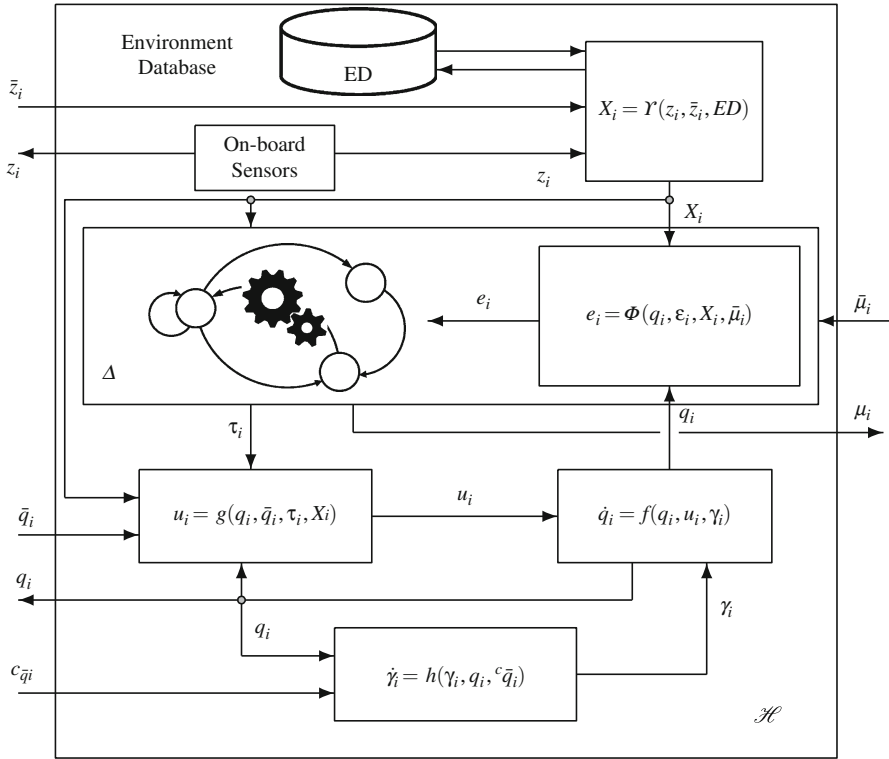

Fig. 114.2 General blocks and interactions considered in the hybrid model of each robot

$\mathcal{E} = \{e^1, e^2, \dots, e^n\}$ be a set of discrete events associated with n logical conditions requiring a change of task during the execution. The i th robot's current task has a discrete dynamics $\delta : \Omega \times \mathcal{E} \rightarrow \Omega$, i.e.,

$$\tau_i^+ = \delta(\tau_i, e_i), \quad (114.1)$$

where $e_i \in \mathcal{E}$ is an event (internal or external) requiring a change of task from τ_i to τ_i^+ , both from the set of tasks Ω . As an example, for the aerial manipulation of an object, the following sequence of tasks should be executed:

- τ^1 : approach from home
- τ^2 : precise positioning for manipulation
- τ^3 : grasping and manipulation
- τ^4 : departure
- τ^5 : return to home

It should be noticed that each task can have a different control algorithm or a different set of parameters for the same controller. The control reconfiguration

is triggered in the transition between tasks associated to different events. Event activation is generated by

$$e_i = \Phi(q_i, \varepsilon_i, X_i, \bar{\mu}_i), \quad (114.2)$$

where ε_i represents the internal events (such as changes in the execution states of the tasks) and $\bar{\mu}_i$ is a vector $\bar{\mu}_i = (\mu_{i1}, \mu_{i2}, \dots, \mu_{iN_m})$ containing the messages coming from N_m robots cooperating with the i th robot. Those messages are used for example in the negotiation processes involved in the task allocation mechanisms and are generated in each robot by a decisional module Δ (see Fig. 114.2). This module encompasses high-level reasoning and planning, synchronization among different robots, negotiation protocols for task allocation and conflict resolution purposes, task management and supervision, complex task decomposition, etc. Following the previous example, the transition from τ^1 to τ^2 will be triggered by the module Δ once the aerial robot is hovering in a suitable location for the manipulation of the object.

The information about the objects in the environment will be inferred from all the measurements z_i taken by the sensors onboard the robots and \bar{z}_i gathered by the fleet of N_s robots that can communicate with the i th robot $\{\bar{z}_j, j = 1, \dots, N_s\}$. The latter vector can be completed with the measurements from sensors located around the environment such as static cameras or sensors deployed in the area of interest. In addition, a database ED with “a priori” knowledge about the environment, including static obstacles, objects of interest and threats can be available and updated with the new information gathered. Notice that z_i also contains the forces/torques derived from the interaction with the environment that are measured with the sensors on board.

On the other hand, let $q_i \in \Theta$ be a vector describing the state of the i th robot taking values in the configuration space Θ , and let $\tau_i \in \Omega$ be the task τ that the i th robot is currently executing. This robot’s configuration q_i has a continuous dynamics

$$\dot{q}_i = f(q_i, u_i, \gamma_i), \quad (114.3)$$

where $u_i \in \mathcal{U}$ is a control input and $\gamma_i \in \Gamma$ models the dynamics associated to the possible physical interaction with the environment and/or other robots

$$\dot{\gamma}_i = h(\gamma_i, q_i, {}^c\bar{q}_i), \quad (114.4)$$

with vector ${}^c\bar{q}_i = (q_{i1}, q_{i2}, \dots, q_{iN_c})$ containing the configurations of the N_c neighbors physically connected to the i th robot. Then, $\gamma_i \neq 0$ only if there is physical interaction.

Regarding u_i , it is a feedback law generated by a low-level controller $g : \Theta \times \bar{\Theta} \times \Omega \times \Upsilon \rightarrow \mathcal{U}$, i.e.,

$$u_i = g(q_i, \bar{q}_i, \tau_i, X_i), \quad (114.5)$$

so that the robot's trajectory $q_i(t)$ corresponds to the desired current task τ_i taking into account the configurations of the N neighbors $\bar{q}_i = (q_{i_1}, q_{i_2}, \dots, q_{i_N})$ with influence in the control of the i th robot. This influence can be found, for example, in the control problem of swarms and formations. On the other hand, Eq. (114.5) also includes the vector $X_i \in \mathcal{Y}$ taking values in the environment model space \mathcal{Y} that encompasses estimations about forces/torques derived from the interaction with the environment, targets to be tracked, obstacles detected during the mission and/or known "a priori," threats to be avoided, etc.

In conclusion, the hybrid dynamics \mathcal{H} of the i th robot shown in Fig. 114.2 has \bar{z}_i , $\bar{\mu}_i$, \bar{q}_i , and ${}^c\bar{q}_i$ as inputs and z_i , μ_i , and q_i as outputs. This diagram is not intended to be exhaustive or to cover all the possible architectures and existing systems. Instead, it is aimed at providing a general overview of all the possible interactions in order to put into context the approaches presented in the next sections of the chapter.

114.3 Aerial Manipulation

In this section, a brief summary of the state of the art in the aerial manipulation area is presented. The main part of the section details the particular case of an autonomous helicopter equipped with a robotic arm for aerial manipulation. The approach presented fits well in the general scheme described in Sect. 114.2 and provides useful insights into the complexity of the associated control problem.

114.3.1 Existing Work

In the following, existing work on interactions between Unmanned Aerial Systems and objects in the environment is reviewed. The quadrotor in Albers et al. (2010) is able to carry a tool, such as a cleaning brush, and apply contact forces to a wall. An extra propeller in the quadrotor provides horizontal thrust to flight in close proximity to a wall. In addition to the quadrotor flying control system, a microcontroller is used to collect and process the data from the ultrasonic ranger to the wall and implement the control loops for the horizontal propeller. The setpoint is given by the pilot, and the basic automatic flight stabilization stays active.

In the video (Pounds and Dollar 2010), a small RC helicopter with a gripper is able to grasp an object while in flight. The gripper mechanism is mounted ventrally between the aircraft's skids; the landing gear is raised during grasping to avoid contact with the ground or target objects. The underactuated compliant gripper allows for positional errors between the helicopter and the target object. To acquire an object, the helicopter approaches the target, descends vertically to hover over the target, and then closes its gripper. Once a solid grasp is achieved, the helicopter ascends with the object. In Pounds et al. (2011), the stability of the helicopter in contact with the object and/or the ground is studied. Particularly, the longitudinal dynamics is studied, and the payload effect is modeled by means of a pitch moment. The stability analysis is carried out by considering the effect of the payload on the

mass of the helicopter, the rotational inertia of the helicopter, and the height of the rotor plane above the Center of gravity. The adjusted parameters are calculated and the stability is assured by applying the Routh-Hurwitz criterion. The paper also examines the hovering grasping as the helicopter picks up objects from the ground. The task consists of the hovering coupled to a fixed object, the transition to a free flight, and the object retrieval while hovering.

Grasping and cooperative transporting loads with quadrotors are also presented in Mellinger et al. (2010). In Mellinger et al. (2011), several lightweight, low-complexity grippers that allow quadrotors to grasp and perch on branches or beams and pick up and transport payloads are presented. The inertial parameters of the grasped object are estimated and used to adapt the controller and improve performance during flight. The next subsections also describe an autonomous electric helicopter with a hand that can be used for general manipulation tasks.

Korpela et al. (2012) presents the progress and results toward a design and physical system to emulate mobile manipulation by an unmanned aerial vehicle with dexterous arms and end effectors. An hybrid quadrotor-blimp prototype to test some manipulation concepts is presented.

Autonomous construction by means of autonomous systems has been also the subject of research work. Thus, decentralized algorithms for the cooperative assembly of 3D objects that consist of multiple types of parts, using a networked team of ground robots, have been presented (Kook Yun et al. 2009). Recently, construction experiments have been carried out with indoor quadrotors (Lindsey et al. 2011). This research did not include joint manipulation in the air, 3D positioning of the parts, and other cooperative assembly functionalities.

In the following, the particular case of an autonomous helicopter equipped with a robotic arm for aerial manipulation is detailed. The approach presented provides useful insights into the complexity of the associated control problem.

114.3.2 General Considerations

Let us consider systems which are similar to the one shown in Fig. 114.3. This system is composed of four main components: a helicopter, a manipulator mounted on the fuselage, sensor (e.g., a camera) to track the position and orientation of a manipulation object, and the object itself. Further, the helicopter is equipped with a position sensor (e.g., GPS) and an orientation sensor (e.g., IMU) for estimation of the fuselage position and orientation in an inertial frame. The task of this system is to fly closely enough to the object, to activate the sensor for object tracking, to go closer to the object, and, in the last phase, to perform a manipulation task. The manipulation task depends on the application and can range from taking sole probes and picking up objects to performing force interaction with an object like for assembly operations. The control of the helicopter and manipulator in the last phase can be realized using one of the following approaches or their combinations:

- Completely decoupled control
- Coupling on the kinematical level
- Coupling on the dynamical level

Fig. 114.3 Scheme of the system for aerial manipulation based on an autonomous helicopter

In case of completely decoupled control, the helicopter and the manipulator are controlled independently. Usually, the helicopter will try to maintain a hovering position trying to compensate the disturbances from the manipulator; the manipulator will try to keep the tool center point (TCP) on the object compensating the disturbances caused by the helicopter movement around the hovering position. In case of kinematical coupling, the controller for helicopter and manipulator is coupled by the positions and velocities of both subsystems. In the case of dynamical coupling, the overall controller for both subsystems considers the dynamical model of the whole system. The last case is, of course, the most general one and potentially will provide the best possible performance from the theoretical point of view. However, the practical considerations make this general conclusion not obvious. Some of the reasons for that are:

- The quality of the sensor signals, often, does not allow precise state estimation of the coupled system.
- The dynamical model of the coupled system is complicated, and the model-based controller will be usually sensitive to system parameters, non-modeled effects, and disturbances.
- For some system setups, where the masses of a helicopter are much higher than the mass of a manipulator, the dynamical coupling cannot improve the performance of the whole system significantly.

It is very likely that for different system setups, different approaches should be chosen. For example, the system composed of the helicopter with the take-off mass of 100 kg and of a 7DoF, high-dynamic, lightweight robotic manipulator with the mass of 15 kg could be controlled using the first and second approaches. On the other hand, the system composed of a helicopter with a take-off mass of 10 kg and a 5DoF degenerated manipulator could be better controlled in case of force interaction using dynamical coupling approach between the helicopter and the manipulator. Therefore, the decision about the control approach depends also on the particular system setup and application.

Regardless of the fact which control approach and which system setup will be chosen, the following aspects should be investigated in order to design a particular control scheme and to estimate the achievable control performance:

- Precision control of the helicopter
- Force interaction between helicopter and environment
- Movement of the center of gravity (CoG) due to the manipulator movement

The understanding of the above-listed aspects constitutes a base for further development of approaches and technologies for aerial manipulation. In the following subsections, each of these aspects is described in more detail. Based on presented considerations, a control approach with coupling on kinematical level is suggested. Some preliminary experimental results are also presented.

114.3.3 Precision Control of the Helicopter

The objective to reduce the take-off weight implies manipulator constructions with reduced working space or even with less than six DoF. Therefore, it is desirable to increase the helicopter positioning precision in order to facilitate the manipulation task. In same system setups, it could be even required to realize some DoF of TCP by moving the helicopter fuselage.

A suitable approach for precise placement of the helicopters relatively to the grasping object is to use a local sensor for object tracking. In Fig. 114.4, an experimental setup for investigating the performance of our helicopter control for precision positioning is shown. This setup is composed of an aerial robot with the DLR lightweight robotic arm (LWR III). This robotic arm has seven degrees of freedom for manipulation and a mass of 15 kg. The flight platform which has been additionally equipped with onboard sensor devices (IMU, GPS, etc.) is a proprietary platform and experimental system based on the Swiss UAV helicopter with a mass of 90 kg with fuel. The system has a total take-off mass of 120 kg, a rotor diameter of 3 m (3 blades), and an engine-turbine with 16 kW and 1,100 RPM. A vision-based object tracking system is integrated on the helicopter. The control scheme implemented in the system is shown in Fig. 114.5. The main controller is composed of an inner loop for orientation control, \mathbf{R}_{ori} , and an outer loop for position control, \mathbf{R}_{pos} . The output of the vision system – position of the object relative to the helicopter – is integrated at the input side of the outer loop. The performance of the whole system is given by the performance of the main controller. The combination of linear controller with nonlinear dynamical and kinematical inversion blocks is used. More detail on the main controller can be found in Kondak et al. (2007).

Using this setup, flight experiments were used to validate that the grasping of a simple object is even possible without translational movement of TCP relative to the helicopter fuselage. In the first phase of this grasping experiment, the helicopter is controlled using only the DGPS and is guided to some position not far from the object. In the second phase, the vision system is switched on and starts to track the object position. The vision system calculates the position of the object relative to the helicopter. This position is used to guide the helicopter to the specified state where the grasping is possible. In our experiments, the DGPS was used as sensor for absolute position in both phases. The output of the vision system was used only to calculate the appropriate desired position of the helicopter, as shown in Fig. 114.5.

Fig. 114.4 Experimental setup for precision control with integrated vision system. This is the first worldwide setup in outdoors involving an autonomous helicopter equipped with a robotic arm for manipulation

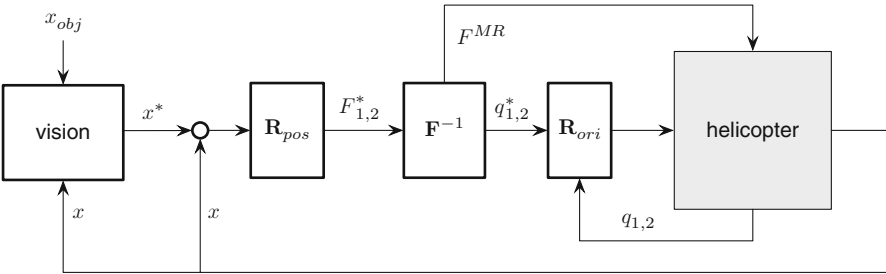

Fig. 114.5 Control scheme used for experimental setup

This was due to the higher reliability of the DGPS on our test ground compared to the vision system which had well-known problems with different light conditions and shadows in outdoor environment. With ideal weather conditions, a precision of TCP positioning up to 1 cm could be achieved.

114.3.4 Force Interaction Between Helicopter and Environment

A manipulator or other grasping device imposes forces and torques on the helicopter fuselage which influence the helicopter motion. This is illustrated on Fig. 114.6. The description and analysis of the interaction between helicopter and manipulator are complicated. The translational movement of the helicopter generates the interaction forces between manipulator and the fuselage. These forces change the orientation of the fuselage and the main rotor plane which again results in changes of the translational movement. Please note that the dynamical equations for translation and

Fig. 114.6 Force torque interaction between manipulator and helicopter fuselage

orientation of the helicopter without manipulator are coupled only in one direction. It means that the equations for the rotation are independent from translational movement, e.g., see Eqs. (114.6). The translation depends, of course, on the orientation of the main rotor plane. For the system composed of a helicopter with a manipulator, there is coupling between translational and rotational dynamics in both directions. The equations of rotational dynamic depend on the translational movement. This fact makes the analysis of the system and, therefore, the model-based controller design complicated. Regarding Fig. 114.2, $\gamma_i \neq 0$ if the manipulated object has some dynamics. The term X_i in Eq. 114.5 includes the measurements from the onboard force/torque sensors required to compute the control law.

Thus, in the scheme depicted in Fig. 114.2, there is a term $\gamma_i \neq 0$ in this case. These dynamics should be taken into account in the design of the controller. The term X_i in Eq. 114.5 includes the measurements from the onboard force/torque sensors required to compute the control law.

The same approach developed by the authors for the load transportation system based on autonomous helicopters is also proposed here. The key element in this approach is the orientation controller in the inner loop. As it is shown in Kondak et al. (2006), the rotation dynamics for a single helicopter, represented by two rigid bodies for the fuselage and the main rotor, can be expressed by the following equations:

$$\begin{aligned} T_1^{MR} + K_{12}u_2 + K_{11}\dot{u}_1 &= 0, \\ T_2^{MR} + K_{21}u_1 + K_{22}\dot{u}_2 &= 0, \end{aligned} \quad (114.6)$$

the position vector connecting sensor attaching point m and CoG of the system. The resulting orientation controller is composed of the orientation controller for a helicopter without manipulator and the compensator block **C** (see Fig. 114.7), where \mathbf{T}_r is calculated and subtracted from torques calculated in **D**. The usage of the compensator **C** has the following main advantages:

- The closed-loop system becomes very robust against variation of system parameters and disturbances.
- The orientation controller for such complicated system becomes quite simple.

There are two reasons for the robustness of the proposed orientation controller: first, the actual influence of the manipulator on the fuselage is measured through $\mathbf{F}_{\text{inter}}$, $\mathbf{T}_{\text{inter}}$, and, therefore, the compensation becomes independent from the parameters and state of the manipulator. Second, as long as the orientation of the helicopter is known, the calculated compensation torque is always in the correct phase.

Two types of influences imposed on the helicopter from a manipulator are distinguished: coherent and noncoherent influence. In case of coherent influence, the forces and torques imposed on the helicopter by the manipulator change with frequencies close to those of the helicopter movement, whereby in case of noncoherent influence, they do not change in time significantly or change with frequencies different to those of the helicopter movement.

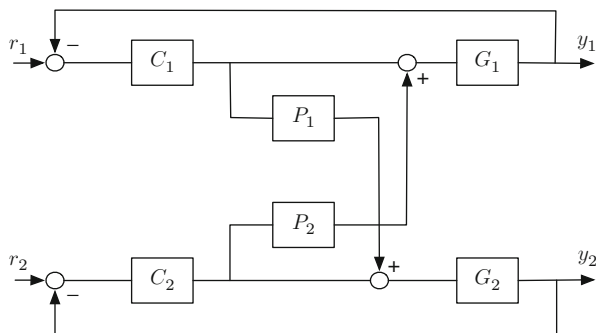

The small-size helicopters are insensitive to the noncoherent influences. This can be verified in simulation or by analysis of the dynamical equations as well as in flight experiments. Even large noncoherent torques imposed on the fuselage are compensated by the proposed controller with compensator **C**.

The opposite is the case for the coherent influence. Even small interaction forces imposed on the fuselage periodically in proper phase could yield to low-frequency instabilities and oscillations, so-called phase circles. Unfortunately, these phase circles appear often in the case when manipulator is compensating the helicopter movement in hovering, as explained in Sect. 114.3.6 in more detail. In this case, the proposed controller with compensator **C** works only with a perfectly modeled system. Therefore, for practical applications, in addition to this controller, a coupling between the helicopter and manipulator controllers should be used in order to prevent phase circles.

114.3.5 Phase Circles

Let us consider two feedback controlled systems S_1 and S_2 with plants G_1 , G_2 and controllers C_1 , C_2 , as shown in Fig. 114.8. These feedback systems can correspond to two separate physical systems or be two parts of one physical system. For example, a helicopter with position control allowing an independent motion in x - and y -directions can be considered as composed of two systems with $y_1 = x$ and $y_2 = y$. Often, especially in case where S_1 and S_2 belong to one physical system, there is a coupling between these two systems, as denoted in Fig. 114.8 with blocks P_1 and P_2 . This undesirable coupling can be caused by model parameter

Fig. 114.8 Scheme of the system with a coupling between two outputs y_1 and y_2

uncertainties, by systematic errors in the sensors, or by non-modeled physical interconnections between systems S_1 and S_2 . This coupling can lead to periodic or coherent energy flow into the systems and induce low-frequency oscillations in S_1 and S_2 . This is demonstrated for the linear case in the following. Let us consider the transfer function $G_{11} = y_1/r_1$ for the coupled systems in Fig. 114.8. It can be shown that

$$G_{11} = \frac{T}{1 + T}$$

with

$$T = G_1 C_1 - G_1 C_2 P_2 \frac{G_2 C_1 P_1}{1 + G_2 C_2}.$$

Considering symmetric systems with $G_1 = G_2 = G$, $C_1 = C_2 = C$,

$$G_{11} = \frac{GC (1 + GC (1 - P_1 P_2))}{1 + 2GC + G^2 C^2 (1 - P_1 P_2)}, \quad (114.7)$$

where only the product of both coupling blocks $P_1 P_2$ has influence on the system behavior. If one of the blocks, P_1 or P_2 , is zero, the system behavior is the same found without coupling

$$G_{11} = \frac{GC}{1 + GC}.$$

In this case, the influence from the second system can be considered as a disturbance.

On the other hand, it can be seen from the denominator in Eq. (114.7) that by increasing the gains in blocks P_1 and P_2 , the product $P_1 P_2$ can move the system poles to the right half of the s-plane, which means the existence of the oscillations in the form

$$y_1 = e^{\lambda t} \cos(\omega t),$$

$$y_2 = e^{\lambda t} \sin(\omega t).$$

If the outputs y_1, y_2 are the coordinates x, y , then the system moves in cycles with increasing radius for $\lambda > 0$ and with the period $T = \omega/2\pi$. Often, the existence of P_1 and P_2 is caused by the same physical phenomenon, and both transfer functions differ only in their phase. These are reasons for calling this type of oscillations in context of the moving platforms phase circles.

One well-known example for phase circles is the low-frequency diverging oscillations of hovering UAVs caused by the compass offset. In hovering, the compass offset induces the phase circles, and the movement of an UAV is similar to the one shown in Fig. 114.12.

The phase cycles could also appear as a result of the movement of the manipulator connected to the helicopter platform as it is described in the next paragraph in more detail.

114.3.6 Movement of the CoG

The setup for aerial manipulation shown in Fig. 114.3 is considered in the following. Let us imagine that the TCP is fixed on the object (does not move relative to the ground) and the manipulator is compensating the movement of the helicopter caused by a wind gust or the ground effect; see Fig. 114.9. The displacement of the fuselage Δx_F is compensated by the manipulator fixing the TCP at the same position $x_{TCP} = 0$. The resulting displacement of the manipulator CoG Δx_{CoG} causes additional torque on the helicopter fuselage ΔT . This additional torque changes the orientation of the helicopter, which yields to some further displacement of the fuselage Δy_F . The particular issue of a small-size helicopter with a single main rotor is that the torque applied to the fuselage yields the displacement in the same axis as a torque vector or, in our example, perpendicular to the direction of Δx_F . The fact that $\Delta y_F \perp \Delta x_F$ is important because this is the reason for existence of the phase circles as it will be shown later.

To see that $\Delta y_F \perp \Delta x_F$, it is considered the solution of the Eqs. (114.6) for constant input torques T_1^{MR} and T_2^{MR} which is given by

$$\begin{aligned} u_1(t) &= -\frac{T_2^{MR}}{2\beta} + [C_1 \cos(\tilde{\alpha}t) - C_2 \sin(\tilde{\alpha}t)], \\ u_2(t) &= \frac{T_1^{MR}}{2\beta} + [C_2 \cos(\tilde{\alpha}t) + C_1 \sin(\tilde{\alpha}t)]. \end{aligned} \quad (114.8)$$

Here, β depends on the rotor properties and its rotation speed around the rotor axis (which is assumed to be constant). Furthermore,

$$\tilde{\alpha} = 2\omega_{MR}\gamma,$$

where γ is a function of mass and geometry properties of the fuselage and the rotor and ω_{MR} is the rotation speed of the rotor. Depending on the particular system or its

Fig. 114.9 Movement of the manipulator CoG while compensating the displacement of the helicopter

value of γ , the oscillations in Eqs. (114.8) can be neglected or not. In any case, the first part

$$\begin{aligned} u_1 &= -\frac{T_2^{MR}}{2\beta} \\ u_2 &= \frac{T_1^{MR}}{2\beta} \end{aligned} \quad (114.9)$$

shows that, due to the gyroscopic effect of the main rotor, the applied torque induces the rotation speed of the fuselage in perpendicular direction, e.g., $T_2^{MR} \rightarrow u_1$, and the corresponding change in the orientation generates additional component of the lifting force or acceleration a_2 which is perpendicular to the axis of u_1 . Therefore, the complete chain in our example is the following:

$$\Delta x_F \rightarrow \Delta T_2 \rightarrow u_1 \rightarrow q_1 \rightarrow a_2 \rightarrow \Delta y_F, \quad (114.10)$$

where coordinates x, y correspond to axes 1, 2 and q_1 is the orientation angle around axis 1.

Taking into account that $\Delta y_F \perp \Delta x_F$ and the chain (Eq. 114.10), the interaction between the helicopter and manipulator by fixing TCP relatively to some object in the environment could be described by the scheme shown in Fig. 114.10. Without the blocks P_1^* and P_2^* , this scheme represents the motion of a controlled helicopter along x - and y -axis. Here, a simplified form for rotational dynamics represented by one integrator is used. $C'_{1,2}$ are orientation controllers and $C'_{1,2}$ are translation

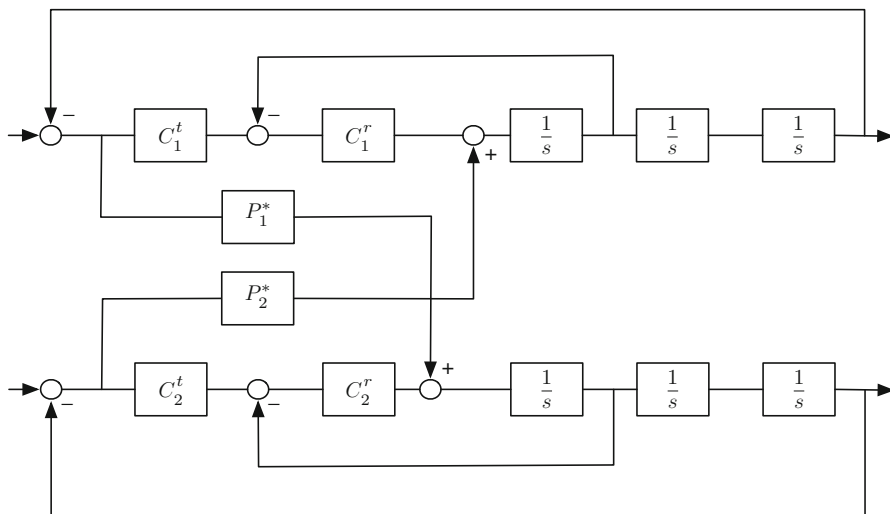

Fig. 114.10 Simplified scheme of the helicopter with manipulator using decoupled control

controllers for axes 1, 2. Using this scheme, whether the phase circles exist in this case will be investigated.

To get the transfer function G_{11} , Eq. (114.7) can be used replacing P_1 and P_2 by

$$P_1 = \frac{1}{C_2^r} \frac{1}{C_1^t} P_1^*,$$

$$P_2 = \frac{1}{C_1^r} \frac{1}{C_2^t} P_2^*.$$

The resulting expression for G_{11} in case of symmetric system with $C_1^{r,t} = C_2^{r,t}$ is then

$$G_{11} = \frac{C^r C^t s^3 + (C^r)^2 C^{tr} s^2 + (C^r C^t)^2 - P_1^* P_2^*}{s^6 + 2C^r s^5 + (C^r)^2 s^4 + 2(C^r C^t)^2 s^3 + 2(C^r)^2 C^t s^2 + (C^r C^t)^2 - P_1^* P_2^*}.$$

Using for $C^r = K_q$, for $C^t = K_d s + K_p$ with $K_q = 3$, $K_d = 2$, $K_p = 1$, the following G_{11} transfer function is obtained:

$$G_{11} = \frac{3(3 + 12s + 15s^2 + 7s^3 + 2s^4) - P_1^* P_2^*}{(3 + 6s + 3s^2 + s^3)^2 - P_1^* P_2^*}.$$

Like in (Eq. 114.7), $P_1^* P_2^*$ has influence on system poles. In Fig. 114.11, the poles movement for the gain of $P_1 P_2$, changing in interval $[-40; 40]$, is shown. As it can be seen in points $Re(P_1^* P_2^*) = -25$ and $Re(P_1^* P_2^*) = 9$, one of the system

Fig. 114.11 Movement of system poles λ while increasing gains in $P_1 P_2$

Fig. 114.12 Movement of the helicopter induced by a manipulator which moves its CoG in two dimensions (horizontal plain)

poles gets positive real part or moves to the right half of the s -plane. This means that the system starts to move on the phase circles as explained in Sect. 114.3.5. In Fig. 114.12, an example of such movement is shown. The different sign of the two points $Re(P_1^* P_2^*) = -25$ and $Re(P_1^* P_2^*) = 9$ means that phase circles can appear for P_1^* and P_2^* with the same as well as with a different sign.

One possible solution to avoid phase circles is to set P_1^* or P_2^* to zero. In our case, it can be done by restricting the motion of manipulator CoG by setting

$$\Delta y_{\text{CoG}} = 0. \quad (114.11)$$

This means that manipulator CoG moves only in xz -plane, so $P_2^* = 0$ and the phase circles cannot appear for any set of system parameters. The condition (Eq. 114.11) can be realized, e.g., using a manipulator with 7DoF.

In Fig. 114.12, the two horizontal coordinates (x , y) of a helicopter moving in a simulation experiment are shown. In this experiment, the TCP position is fixed in an inertial frame, and the manipulator compensates the movement of the helicopter. The helicopter and the manipulator are controlled independently, and condition (Eq. 114.11) is not satisfied. As it can be seen, the phase circles appear, and the helicopter controller is not able to stabilize its hovering configuration. In Fig. 114.13, the motion of the same system in simulation is shown. Different to previous case, here condition (Eq. 114.11) is satisfied, and the manipulator CoG is moving only along the x -axis. The helicopter controller stabilizes the hovering configuration, and the phase circles do not appear.

Please note that even if the displacement of the manipulator CoG and the corresponding torques acting on fuselage are small, compared to torques generated by the main rotor, they act in the phase with the fuselage movement and can induce phase circles. The disturbance torque, imposed on the fuselage, which is not changing in the phase with the fuselage movement, e.g., static displacement of the CoG, does not cause the phase circles described above and can be rejected by helicopter controller well even if its absolute value is comparable with the torques generated by the main rotor.

Condition (Eq. 114.11) and the results from the second simulation experiment shown in Fig. 114.13 are verified in flight experiments using the setup shown in Fig. 114.14. An electrical helicopter with the take-off weight of 15 kg is equipped with a pendulum, which can move a mass of 1 kg along the roll axis of the fuselage. The distance between the pendulum CoG and its rotation point is 0.12 m. The displacement of the pendulum CoG, while hovering, did not induce the oscillations as shown in Fig. 114.12.

114.3.7 Summary

Considering the aerial manipulation, three important aspects have been described: precision positioning control for helicopters, force interaction between helicopter and environment, as well as movement of the manipulator CoG. The simplified scheme was proposed to study the principal behavior of a complex system composed of a helicopter and a manipulator. It has been shown that a completely decoupled control of helicopter and manipulator is problematic if manipulator has enough DoF to move the TCP along x - and y -axis independently. The low-frequency diverging oscillations, so-called phase circles, can appear even for systems where manipulator movement is negligible in a static case. Therefore, at least a coupling on kinematical level between helicopter and manipulator controllers is needed. One possibility to couple the controllers in order to avoid phase circles is to restrict the motion of manipulator CoG in one direction. In addition to simulations, some experimental

Fig. 114.13 Movement of the helicopter induced by a manipulator which moves its CoG only along one dimension

Fig. 114.14 Experimental platform with pendulum for displacement of the helicopter CoG

results were presented. An integral experiment with 7DoF manipulator mounted on helicopter is being currently prepared.

114.4 Load Transportation and Deployment

In this section, the load transportation by using autonomous helicopters is considered. The cases of single and multiple helicopters connected to the load by means of flexible ropes are considered. In both cases, helicopters experience force influence from the rope caused by dynamics of the load and its interaction with the environment or with other helicopters connected to the load. First, a brief summary of the state of the art in load transportation is presented. The main part of the section details the particular case of the load transportation by one or several autonomous helicopters. Using autonomous small-size helicopters, a load transportation system was implemented, which was successfully used for sensor node deployment in areas with a difficult access. The control approaches presented also fit well in the general scheme described in Sect. 114.2, and several field experiments using this system are presented.

114.4.1 Existing Work

The single-lift configuration, whereat a long rope couples one helicopter and one load, is the only configuration commercially utilized for the transportation of slung loads. Several textbooks (see, e.g., Wagendonk (2006)) provide information about the correct attachment of the slung loads and important safety procedures. However, the manual maneuvering of a helicopter with an attached slung load is very difficult and requires a skillful and experienced pilot. In particular, the active damping of load oscillations is a difficult task, which most pilots avoid. Instead, the pilots stabilize only the helicopter and wait for the load oscillation to die down. To support manual-piloted slung load operations, the iMAR GmbH and the German Aerospace Center DLR developed the “iSLD-IVC” (iMAR Slung Load Damping based on inertial stabilized vision control) system, which uses an artificial horizon instrument to guide the pilot. The authors are not aware of a completely autonomous system for full-size helicopters. The system presented in this work provides the full autonomous control of single-lift slung load configurations (based on small-size helicopters), including the active damping of load oscillations.

The load transportation by several autonomous systems involves physical interactions between these systems. The joint transportation of a large and heavy object by means of several ground robots has been proposed and demonstrated since the 1990s. The coordinated control of the motion of the ground robots should consider the involved forces.

A suitable approach for the coordinated control is the leader-follower scheme. In this scheme, the desired trajectory is the trajectory of the leader. The followers estimate the motion of the leader by themselves through the motion of the transported

object. This approach can be extended to multiple followers and to robots with non-holonomic constraints (see Kosuge and Sato 1999) by means of decentralized compliant motion control algorithms. The method has been implemented in an experimental system with three tracked mobile robots with a force sensor. In Sugar and Kumar (1998), the decentralized control of cooperating mobile manipulators is studied with a designated lead robot being responsible for task planning. The control of each robot is decomposed (mechanically decoupled) into the control of the gross trajectory and the control of the grasp. The excessive forces caused by robot positioning errors and odometry errors are accommodated by the compliant arms. In Borenstein (2000), the Omnimate system which uses a compliant linkage platform between two differential drive mobile robots (Labmate) is presented. In Huntsberger et al. (2004), distributed coordinated control of two rovers carrying a 2.5-m-long mockup of a photovoltaic tent is presented and demonstrated as an example of the CAMPOUT behavior-based control architecture.

Lifting and transportation of loads by using multiple helicopters has been also a research topic for many years motivated by the payload constraints of these vehicles and the high cost of helicopters with significant payload. Particularly, the lifting and transportation by two helicopters (twin lift) has been studied since the beginning of the 1990s by means of nonlinear adaptive control (Mittal et al. 1991) and H_∞ control (Reynolds and Rodriguez 1992). This research work has been done only in simulation. In Lim et al. (1999), an interactive Modeling, Simulation, Animation, and Real-Time Control (MoSART) tool to study the twin-lift helicopter system is presented. However, until recently, only simulation experiments have been presented. In December 2007, lifting and transportation of loads by means of three helicopters was demonstrated experimentally in the framework of the AWARE project. The authors presented in Bernard et al. (2011), the field experiments involving the lifting and transportation of loads by means of one (single-lift) and three (multi-lift) autonomous helicopters. Experimental results with a team of aerial robots to manipulate and transport a payload in three dimensions via cables have been recently presented (Michael et al. 2011). The authors propose two quality measures for motion plan design that minimize individual robot motion and maximize payload stability along the trajectory.

The joint transportation of a single load by means of several manned, manual piloted helicopters has been also proposed in the literature. In experiments with two manned helicopters, it was determined that the control of two coupled helicopters is a very challenging task, which emphasizes the need of automatic helicopter stabilization.

114.4.2 Load Transportation and Deployment by Several Helicopters

The coordinated control of the motion of each helicopter should consider the involved forces induced by the other helicopters and the load itself. The transported object moves with a dynamic behavior that can be expressed by means of Eq. 114.4.

Thus, in the scheme depicted in Fig. 114.2, there is a term $\gamma_i \neq 0$ in this case. These dynamics should be taken into account in the design of the controller. The term X_i in Eq. 114.5 includes the measurements from the onboard force/torque sensors required to compute the control law. For example, a force sensor in the rope can provide a measurement of the influence of the other helicopters and the load being transported as proposed by the authors.

The orientation controller proposed in Bernard et al. (2011) features a measurement-based torque compensation and is applicable for single-, dual-, and multi-lift load transportation. Therefore, the theoretical results of this work are applicable to all the configurations presented in Cicolani and Kanning (1992), except for the twin rotor helicopter configurations, which require an adaptation of the used helicopter model. The load is connected to the helicopters using ropes, and the orientation controller follows the scheme depicted in Fig. 114.7. In this case, the inputs used in the compensator block are the measured rope force \mathbf{F}_r and the helicopter angles $q_{1,2,3}$. The block estimates the disturbance torques T_{r1}, T_{r2} that allow to decouple the orientation control for each helicopter from the rest of the system. This makes the use of the same orientation controller, independent of the number of coupled helicopters, possible. In the following, the field experiments carried out using this orientation controller are summarized.

The first successful experiment was conducted in Berlin, December 2007, in the framework of the AWARE project. For these flight experiments, three identical helicopters were equipped with a multi-UAV modular autopilot system developed at TUB. The rope is attached to the helicopter by means of the so-called load transportation device (LTD), which is mounted between the landing skids (see Fig. 114.15). A load of 4 kg was transported by means of three helicopters. In this experiment, ropes with a length of 13 m were used. The helicopters were arranged as an equilateral triangle on the ground, with a distance of 8 m between the helicopters. In Fig. 114.16, the coordinates of all three helicopters during the whole flight are shown. The x_{h123} and y_{h123} coordinates describe the horizontal motion of the helicopters, and the z_{h123} coordinates describe the vertical motion. The coordinates of the helicopters are shown in different ground-fixed frames, which have the same orientation but different origins (take-off position of each helicopter); therefore, there are no offsets between the helicopter trajectories. The mapping of helicopters and line colors is ambiguous. This is acceptable, since the motions of the helicopters are only discussed together and not individually.

The load was lifted when the helicopters reached approximate 12.4 m. The weight of the load was not considered in the controller, and therefore a small disturbance in the z_{h123} trajectories can be observed at the moment the load was lifted from the ground as well as during strong acceleration in x , y -direction. A position error of each helicopter in hovering was approx. ± 0.3 m. During the whole flight, the triangular formation of the helicopters with a precision of about ± 0.3 m and the load was moved very smoothly. To our knowledge, these were the very first successful flight experiments to transport a load using multiple autonomous helicopters.

Fig. 114.15 Detail of the so-called load transportation device (LTD) onboard each helicopter. The device is equipped with a force sensor to estimate the influence of the other helicopters and the load itself – term γ_i in Eq. 114.4

Another experiment was carried out in May 2009 within the scope of the AWARE project: A fire alarm had been declared in a building, and the objective was to place a wireless camera with pan-tilt on the top floor. The camera could provide continuous real-time video to monitor the operations of the firemen and the health status of the victims on the roof of the building. Several coupled helicopters were required for this task, since the camera, together with its associated communication equipment and batteries, was too heavy for a single helicopter. To the best of the authors knowledge, this was the first field experiment involving the transportation of a load from the ground to the roof of a building with three autonomous helicopters.

The experiment was executed as follows: The load transportation system (LTS), composed of three autonomous helicopters and the coupled payload, was ready for operation, and the helicopters were waiting on the three take-off and landing pads. The platform user specified a load transportation task to deploy the wireless pan-tilt camera on the top floor, and a plan builder module generated the full set of ordered tasks for the LTS.

It should be noted that the enormous complexity of the load transportation system composed by three helicopters was hidden to the user, who only needed to specify the deployment task, by providing the desired GPS location of the load deployment. The altitude specified for the deployment was several meters above the top floor of the building. The autonomous decision-making software of the platform had access to the map of the area in order to plan the deployment task decomposition properly,

Fig. 114.16 Motion of three helicopters transporting one load of 4 kg. The load was lifted when the helicopters reached approximate 12.4 m. The coordinates of the helicopters are shown in different ground-fixed frames, which have the same orientation but different origins (take-off position of each helicopter); therefore, there are no offsets between the helicopter trajectories. The x_{h123} and y_{h123} coordinates describe the horizontal motion of the helicopters, and the z_{h123} coordinates describe the vertical motion

taking into account parameters of the system and of the environment like building altitude and the length of the ropes.

Figure 114.17 shows a 2D view of the trajectories followed by the three autonomous helicopters and the transported pan-tilt camera unit. The formation of the helicopters was similar to the formation used for the experiment conducted on December 2007: an equilateral triangle, with a distance of 8 m between the helicopters. The weight of the payload composed of camera, transportation housing, and batteries was approximately 5 kg, where the payload of each helicopter, due to additional electronic equipment, was about 2 kg. The trajectories of the helicopters are plotted in gray, and the trajectory of the camera is plotted in black. The estimated rope positions are plotted as gray lines, whereat a time step of 1 s elapsed between two successive estimations. The arrow indicates direction of the load transportation. It is noteworthy that despite the stormy weather conditions, the load stayed clearly within the extends of the roof during the deployment.

Figure 114.18 complements the flight data presented in Fig. 114.17, by depicting the values of the x , y and z coordinates of the helicopters and the load during the flight. The motion of the load is depicted from the moment the load was lifted

Fig. 114.17 Path followed by the three helicopters transporting the load in the $x - y$ plane. The trajectories of the load and the helicopters are in *black* and *gray*, respectively. The *arrow* indicates direction of the load transportation. The formation of the helicopters was a equilateral triangle, with a distance of 8 m between the helicopters

Fig. 114.18 Values of the x , y and z coordinates of the helicopters (*left*) and the load (*right*) during the flight. The coordinates of each helicopter and the load are given relative to one global Newtonian reference frame, but for each helicopter and for the load, the coordinates were plotted with respect to a relative origin (the take-off position of the respective helicopter or the lift-off position of the load). The trajectories of the helicopters show almost no deviation relative to each other

off the ground to the moment it was deployed on the roof. The coordinates of each helicopter and the load are given relative to one global Newtonian reference frame, but for each helicopter and for the load, the coordinates were plotted with respect to a relative origin (the take-off position of the respective helicopter or the lift-off position of the load). The mapping of helicopters and line colors is ambiguous, but similar to Fig. 114.16, the motions of the helicopters are only discussed together. The trajectories of the helicopters show almost no deviation relative to each other. Therefore, the helicopters preserved their relative formation during the whole flight. To demonstrate the robustness of the translation controller, the additional weight of the load was neglected during the experiment. Therefore, in the interval [120 s, 140 s], the strong acceleration of the helicopters caused a height deviation. However, beside this deviation, no additional side effects were noticeable. During the return flight [240 s, 260 s], after the load deployment, no disturbance of the height is visible. It should be mentioned that during the execution, wind gusts around 35 km/h were registered. These velocities are close to the maximum speed of the helicopters. Therefore, the performance of the coupled load transportation system is considered very good.

Finally, several photographs of the LTS during the execution of the mission are shown in Fig. 114.19. A fourth helicopter used to acquire airborne video footage of the mission can be seen in two pictures.

114.4.3 Load Transportation and Deployment by a Single Helicopter

As in the case of multiple helicopters, the rope connected to the fuselage imposes forces on it. The same control scheme for orientation controller (see Fig. 114.7) can be used in order to compensate the influence of the rope using direct force measurement. However, the position control for single helicopter transporting a load is more challenging compared to the case with three and more helicopters. The helicopter movement should actively compensate the movement of the load on a flexible rope. The task for a load transportation system is usually specified in terms of desired load movement. The required movement of the helicopter is in general more complicated than the movement of the load.

In addition to more complicated position control, the estimation of the load position could cause difficulties. In our experimental setup, the two encoders on cardan joint axes in LTD (see Fig. 114.15) were used to estimate the movement of the load. The direct calculation of the load position by multiplying angles with the rope length is problematic. Assuming normal flight conditions, the ropes are tautened between helicopter and the payload, similar to a string of a music instrument. Therefore, external disturbances (like wind gusts) or high accelerations can stimulate a natural oscillation of the ropes. This behavior has been observed in real flight experiments several times. The load motion calculated from the angle

Fig. 114.19 Three UAVs transporting a pan-tilt wireless camera to the roof of a building with a height of 12 m in Utrera (Spain) in May 2009. The images show the mission during the take-off (*top picture*) and shortly before (*bottom picture*) the load deployment. On two pictures, a fourth helicopter is visible, which was used to acquire airborne video footage of the mission

encoders during these oscillations does not correspond to the real movement of the load. The oscillating angles lead to strong responses of the controller and, in the worst case, to the further excitation of the oscillations. This can happen also in the case of load transportation with multiple helicopters. But the position control for multiple helicopters is more robust and can reject these disturbances. In case of a single helicopter, a special model-based observer should be used for motion estimation of the load. More details about this observer and positioning control for single helicopter transporting the load as well as experimental results can be found in Bernard et al. (2011).

114.5 Conclusions

The applications of Unmanned Aerial Systems (UAS) are typically related to information exchanges that are useful in the context of surveillance, mapping, target tracking, and similar tasks presented in other chapters. However, other applications of interest can involve physical interactions between several UAS and other objects. In this chapter, two branches of this novel research area have been presented: aerial manipulation and load transportation. Different types of physical interactions between UAVs as well as between an UAV and an environmental object can be represented with a general scheme as explained in Sect. 114.2. But for practical relevant cases, the models are complicated due to dynamic coupling between different systems. This was illustrated on particular case of autonomous helicopters used for aerial manipulation and load transportation. It was also shown that for analysis and control design, simplifications could be found which lead to practical relevant solutions. Preliminary results for aerial manipulation and more advanced achievements for load transportation, applied for sensor node deployment, were presented and discussed. The first results, which have been already achieved in the research community, demonstrate the big potential for UAS applications involving direct contact and force interaction.

Abstract

Current practices and major trends in unmanned aircraft systems (UAS) for maritime operations are presented along with projections of future UAS maritime applications. First, various aspects of UAS program management, including organization, operator responsibilities, program operation, and overall program costs, are reviewed. Next, maritime aircraft missions and required capabilities are outlined, and current practices for both manned and unmanned aircraft are described. Technological trends relating to UAS are also discussed, focusing on developments relevant to maritime UAS operations. This information provides a background for assessing potential future maritime UAS operations. Trends including miniaturization of sensors and computer systems, high energy density of power sources, and increased subsystem standardization and modularity will have important effects in the future. However, another significant trend is towards increased system autonomy via new command and control frameworks that facilitate integration of UAS into higher level maritime observing systems through new concepts of operation for networked systems and new business models.

115.1 Introduction

Unmanned aircraft systems (UAS) are here to stay. The focus has been more on military UAS. This has to do with clear operational needs and established certification protocols. However, recent trends in UAS technology developments and certification procedures may pave the way for an expanding range of UAS uses for nonmilitary purposes.

Investment in UAS has been steadily increasing. The U.S. Department of Defense (USDOD) alone increased its expenditures on UAS from \$284 million in 2000 to a staggering U.S.\$3.3 bn in 2010 (Gertler 2012). The annual global world expenditures on these systems are expected to rise to double digits (U.S.\$ bn) by 2020. This rise has been enabled by technological developments in materials, computers, sensors, and command and control. Currently, the trend is towards onboard autonomy. Autonomy paves the way for operations in remote locations where data links to remote operators may not be available or when the cost of communications is prohibitive.

Onboard autonomy basically means that deliberation takes place onboard without human intervention. In other words, the typical sense-deliberate-act cycle is intrinsic

in contrast to what happens with automated vehicles, where sense and acting are mediated by scripted control procedures:

Autonomous means that a system has a choice to make free of outside influence... Automatic means that a system will do exactly as programmed, it has no choice (Clough 2002).

Maritime deployments present added challenges for UAS design and operations because of marine environmental conditions and more complicated communication requirements. Additionally, the lack of ground support and large areas of ocean imply either land-based access corridors with greater UAS endurance and range requirements or UAS ship or water launch and recovery mechanisms. The realities of routine maritime UAS operation can also mean additional certification issues for integration into ship systems in addition to UAS coordination with other maritime assets, including manned aircraft.

The paper discusses current practices and trends in UAS for maritime operations. This is not a roadmap and does not address issues specific to countries or organizations. It is a focused overview of maritime UAS systems complementing and summarizing information available from multiple sources including roadmaps, standards, regulations, and essays. By this means some concept of future UAS maritime operations can be better understood.

The conceptual framework for the discussion is presented in the next two sections. First, UAS background is reviewed. The conceptual framework stems from a notational work breakdown structure (WBS), which is a standard method for understanding systems. Operations and support, levels of automation, operator functions, interoperability, certification, cost structure, missions, and required capabilities are then discussed in this framework. Life cycle management concerns are also emphasized because UAS are rapidly evolving technologies, and obsolescence is a major concern. The discussion uses information available from disparate sources and provides a framework targeted at maritime operations. Second, maritime aircraft missions and required capabilities and current practices for both manned and unmanned aircraft (UA) are discussed in this framework.

Trends in maritime operations and in technological developments pertaining to UAS cost and capabilities are briefly discussed before enumerating how these may affect future maritime aircraft operations. This will entail a paradigm shift: from single vehicle to multi-vehicle networked operations.

115.2 UAS Background

An UAS is a pilotless aircraft. Piloting is done by onboard computers and remote pilots. This makes dull, dirty, and dangerous (3D) missions one of the main reasons for operational use of UAS, notably in military operations.

UAS come in several shapes, sizes, configurations, and categories. Extreme examples include the *QinetiQ Zephyr Solar Electric* UAS (QinetiQ 2009) and the *Micromechanical Flying Insect* (Fearing 2007).

Table 115.1 UAS categories (Adapted from DOD 2009)

| UAS category | Maximum gross takeoff weight (lbs) | Normal operating altitude (ft) | Speed (kts) | Representative UAS |
|--------------|------------------------------------|---------------------------------|--------------|--------------------------------|
| Group 1 | 0–20 | <1,200 Above ground level (AGL) | 100 | <i>WASP III, Pointe</i> |
| Group 2 | 21–55 | <3,500 AGL | <250 | <i>Silver Fox, ScanEagle</i> |
| Group 3 | <1,320 | <18,000 Mean sea level (MSL) | | <i>RQ-7B</i> |
| Group 4 | >1,320 | | Any airspeed | <i>MQ-5B, MQ-8B</i> |
| Group 5 | | >18,000 MSL | | <i>MQ-9A, RQ-4 Global Hawk</i> |

In spite of UAS diversity, it is important to have commonly accepted and understood UAS categories. The categorization methodology introduced by the USDOD (DOD 2009) is based on three enduring UA attributes: weight, altitude, and speed. The five resulting categories are reproduced in Table 115.1.

A different categorization has to do with roles of aircraft. The U.S. military has a *Tier* system to designate roles of individual aircraft in a usage plan for integrated operations. Different branches have their own tier systems. The U.S. Air Force tiers are the following:

Tier N/A: Small/micro unmanned aircraft vehicle (UAV)

Tier I: Low altitude, long endurance

Tier II: Medium altitude, long endurance (MALE)

Tier II+: High altitude, long endurance conventional UAV (or HALE UAV)

Tier III-: High altitude, long endurance low-observable UAV

A few definitions, taken from Hagan 2009, are needed at this stage:

Capability. The ability to achieve a desired effect under specified standards and conditions through combinations of ways and means to perform a set of tasks.

Mission. The objective or task, together with the purpose, which clearly indicates the action to be taken.

Process. The combination of people, equipment, materials, methods, and environment that produces output – a given product or service.

System. The organization of hardware, software, material, facilities, personnel, data, and services needed to perform a designated function with specified results, such as the gathering of specified data, its processing, and delivery to users.

Subsystem. A functional grouping of components that combine to perform a major function within an element such as electrical power, attitude control, and propulsion.

Work Breakdown Structure. An organized method to break down a project into logical subdivisions or subprojects at lower and lower levels of details.

Technological trends, capabilities, costs, operations, and missions are better understood in terms of UAS product structure and main life cycle processes – acquisition/development, operation, and support – affecting life cycle management

Table 115.2 UAS product structure (Adapted from DOD.a 2011)

| Level 1 | Level 2 |
|----------------|--|
| Air vehicle | Airframe (may include subsystem for taking off and landing in water) |
| | Propulsion (includes power/thrust to propel the vehicle; may include energy harvesting subsystems) |
| | Communications/identification |
| | Navigation/guidance |
| | Central computer |
| | Auxiliary equipment |
| | Air vehicle application software |
| Payload | Air vehicle system software |
| | Survivability (may include subsystems specific to maritime operations) |
| | Reconnaissance |
| | Electronic warfare |
| | Armament |
| | Weapons |
| | Remote Sensor System Delivery (may include subsystems for the delivery of sensors/actuators) |
| Ground segment | Payload application software |
| | Payload system software |
| | Ground Control Systems (may include stand-alone communication systems or networks; may include subsystems for mounting communication devices such as buoys or aerostats) |
| | Command and Control Subsystem |
| | Launch and recovery equipment (may include subsystems for launch and recovery from ships, land, or the ocean) |
| | Transport system components |
| | Ground segment application software |
| | Ground segment system software |

(LCM), a management process, applied throughout the life of a system, that bases all programmatic decisions on the anticipated mission-related and economic benefits derived over the life of the system (Hagan 2009).

The USDOD has a reference WBS handbook for the acquisition process (DOD.a 2011). The WBS provides a standard method for structuring systems, and their products, into logical subdivisions and levels. However, there is no standard WBS for UAS. A notational product structure for maritime UAS adapted from the reference WBS (DOD.a 2011) is presented in Table 115.2. The table concerns only levels 1–2 of the UAS product structure and does not include level 1 WBS items which are relevant, for example, to cost analysis. These level 1 items include system integration, systems engineering, system test, and evaluation; training; data; support equipment; operational/site activation; industrial facilities; and initial spares and repair parts.

Typically, the operation of a single UA requires at least one ground station, several operators, and a data link to the UA. In the simplest remotely piloted aircraft (RPA), the data link allows the pilot to operate the aircraft from the ground station. More advanced UAS have some degree of onboard automation (e.g., waypoint tracking and vision tracking of targets) to facilitate interactions with operators on the ground station and to reduce dependence on high-speed communication links.

Table 115.3 Levels of automation (Adapted from Clough 2002)

| Level | Level descriptor |
|-------|--|
| 10 | Fully autonomous |
| 9 | Battlespace swarm cognizance |
| 8 | Battlespace cognizance |
| 7 | Battlespace knowledge |
| 6 | Real-time multi-vehicle cooperation |
| 5 | Real-time multi-vehicle coordination |

Several taxonomies for levels of automation have been proposed; the one proposed in Clough (2002) is presented in Table 115.3. Currently, the level of onboard automation for most UAS is quite low (at most Level 4); higher level functions are currently performed by remote operators. Examples of these higher level functions, taken from C.E. Nehme et al. 2006, are the following: monitoring (weapon status, network communications, health and status of UA, sensor activity); negotiating with other stakeholders; notifying relevant stakeholders; optimal position supervision; path planning supervision; perceiving/interpreting images; perceiving/interpreting other sensor data; analyzing images; analyzing other sensor data; positive target identification; resource allocation; and scheduling and tracking target.

Several standards have been developed for interfacing with a UAS control system. These standards are targeted at facilitating interoperability among software components from multiple vendors. The North Atlantic Treaty Organization (NATO) Joint Capability Group UAV (JCGUAV) developed the Standardization Agreement (STANAG) 4586 via a standard set of messages between the air vehicles and the control stations and the control stations and external command, control, communications, computers, and intelligence (C4I) nodes (NATO 2007) and began the development of STANAG 4660 for an Interoperable Command and Control Data Link (IC2DL) to meet the need for a low bandwidth command and control link (Seagle 2011). The Joint Architecture for Unmanned Systems (JAUS) was originally an initiative promoted by the USDOD to develop an open architecture for unmanned systems (Joint Architecture for Unmanned Systems (JAUS n.d.)); several standards for a service-based framework evolved from it. Currently, it is unclear how the existing standards will address levels of automation beyond the current state of the art in UAS usage. Moreover, the role of experienced human operators in planning and execution control procedures, termed mixed-initiative planning and execution control, is still to be determined in future concepts of operation.

Open systems architecture concepts have been advocated in several unmanned air/surface/ground/underwater vehicle system (UXS) roadmaps to address the problem of interoperability (DOD.b 2011). This is because open architectures (OA) utilize a common set of interfaces and services, associated data models, robust,

standard data busses, and methods for sharing information to facilitate development. The expectations are that OA will reduce life cycle costs, enhance competition, and open new markets. Observe that the true goal of interoperability entails more than software interoperability:

The interoperability goal for Unmanned Systems is an ability to provide data, information, material, and services to and accept the same from other systems, units, or forces ... and to use the exchanged data, information, material, and services to enable them to operate effectively together. (DOD.b 2011).

Current legislation and standards only allow UAS to fly in segregated airspace. The integration of UAS into nonsegregated airspace is one of the main challenges facing UAS development and operations (Dalamagkidis et al. 2009).

In the USA the access to the National Airspace System (NAS) can only be obtained through a temporary Certificate of Authorization (COA) from the Federal Aviation Administration (FAA) or through a certification of the aircraft. A COA may take up to 60 days to obtain, thus precluding fast access to NAS through the so-called “file-and-fly” system used for piloted aircraft. Access to NAS will basically require an UA to be airworthy; to be operated by a qualified pilot/operator; and to comply with operating rules, standards, and procedures. Airworthiness is the basic requirement for any aircraft system, manned or unmanned, to enter the National Air Space (NAS). Airworthiness will require certification of the UAS.

The primary guidance for USDOD airworthiness certification is DOD (2005). The USDOD is expanding this guidance to include criteria that address UAS specific issues. UAS-unique standards are derived from NATO STANAG (2007, 2012). UAS operators will have to respond in a timely manner to commands from air traffic control, while the UAS should also have airborne collision avoidance system (ACAS) and contingency management capabilities. Regulatory compliance for UAS needs definition in national and international regulatory guidelines and standards. This is one of the reasons why some UAS manufacturers have developed hybrid manned UAS, which are basically manned aircraft with UAS capabilities, to allow rapid testing and demonstration (with a pilot onboard). The USDOD UAS Airspace Integration Plan (DOD.c 2011) outlines DOD’s approach, which is summarized by four overarching precepts: apply USA world-leading aviation expertise to UAS; conform where possible, create where needed; leverage DOD authorities and equities; and engage as one. This is an incremental approach to provide UAS critical access to a given operations profile prior to implementing a full dynamic operation solution. The end state is routine NAS access comparable to manned aircraft for all DOD UAS operational, training, and support missions. The National Aeronautics and Space Administration (NASA) *UAS Integration in the NAS Project* leverages current NASA investments to contribute capabilities that reduce technical barriers related to the safety and operational challenges associated with enabling routine UAS access to the NAS (Griner 2011). UAS access to international and foreign national airspace faces similar challenges. There are several initiatives underway worldwide to address the problem of integration in civilian airspace.

The Australian Civil Aviation Safety Authority has been very active in this area. The Civil Aviation Safety Regulations (CASR) – Part 101 Unmanned Aircraft

and Rocket Operations consolidates the rules governing all unmanned aeronautical activities into one body of legislation (Civil Aviation Safety Authority [n.d.](#)).

Europe has also been active in this field. The key civil aviation entities are the European Joint Aviation Authorities (JAA) with the European Organization for the Safety of Air Navigation (EUROCONTROL); the European Aviation Safety Agency (EASA), defined as the legal edifice for civil aviation in Europe, like its North American counterpart, the FAA; the European Organization for Civil Aviation Equipment (EUROCAE); and the Civil Aviation Authorities (CAAs) for each country. The European Defence Agency (EDA) and NATO are the most representative organizations concerning military aviation. In 2004, experts from JAA and EUROCONTROL submitted the report entitled *UAV Task Force Final Report* (UAV TASK-FORCE [2004](#)) about the regulation of civilian UAS. One year later, EASA issued an *Advance Notice for Proposed Amendment* of this document (EASA [2005](#)). In January 2007, the International Civil Aviation Organization (ICAO) started the UAS Study Group (UASSG) with the aim of developing Standards and Recommended Practices (SARPs) (ICAO [2006](#), [2007](#)). In February 2008, the United Kingdom (UK) presented the third edition of its Civil Aviation Publication CAP 722 entitled *Unmanned Aerial Vehicle Operations in UK Airspace – Guidance*. The fifth edition of CAP 722 was issued in 2012 and incorporates amendments to legislation introduced in the *Air Navigation Order* (ANO) (Civil Aviation Authority [2012](#)). In early 2011, ICAO published new recommendations to provide the fundamental international regulatory framework (ICAO [2011](#)). In 2004, the *European Military Aviation Authorities Group* (EMAAG) was established at the annual *International Military Aviation Authorities Conference*. In 2008, a forum for military airworthiness authorities – the *European Military Airworthiness Authorities* – was created under the aegis of the EDA. In January 2005, the *Délégation Générale de l'Armement* (DGA) presented version 3.0 of *UAS Systems Airworthiness Requirements* (USAR) (FMOD/DGA [2005](#)). The document was later adopted by NATO as the basis for STANAG 4671. In 2005, NATO established the JCGUAV working group which is organized into several subgroups and activities. *Flight in Nonsegregated Airspace* (FINAS) is one of those subgroups which concerns the definition of airworthiness requirements for UAV. This group approved the first draft of STANAG 4671 (NATO STANAG [2007](#)). More recently, the STANAG 4703 (for light UAS) has been developed, being also under ratification (NATO STANAG [2012](#)). In the UK, a working group created under the purview of the *Society of British Aerospace Companies* – involving industry members and representatives from CAA air traffic control (ATC) – issued, in November 1991, the document entitled *A Guide to the Procurement Design and Operation of UAV Systems*. This document provided guidelines for the development of UAS in the UK and has been used by the UK Ministry Of Defence (MOD) as the basis for the *Defence Standard 00-970 part 9*. EDA is responsible for the workgroup *Mid Air Collision Avoidance System* (MIDCAS) that has an ongoing project namesake. It has been active in what concerns integration of UAS into nonsegregated airspace, being more dedicated to the issues of detect, sense, and avoid (DS&A) technology.

Life cycle cost has been another major challenge for UAS development, operations, and support. There are several reasons for this. First, the UAS field is relatively new but it is evolving quite fast, especially in some UAS categories. Systems, capabilities, and associated cost have been changing significantly over time; and there is no standard way to estimate and report costs. Second, the distribution of UAS cost across acquisition, operation, and support categories differs significantly from that of manned aircraft making comparison between UAS and manned aircraft complicated. In addition, some UAS, notably those in the small UAS categories, enable new applications for which there is no experience in manned aviation. Moreover, existing cost comparisons between manned and unmanned aircraft have not been necessarily favorable to UAS. Third, the diversity of UAS, ranging in size from a few millimeters to tens of meters, precludes uniform cost metrics. Common cost metrics, such as weight and endurance or pound-hour per thousand dollars (pound-hour/\$k) (DOD.a 2005) fail to capture the highly nonlinear dependence on UAS diversity (Valerdi et al. 2005). Additionally, cost-per-hour quotes for UA use are often misleading in that they address only the recurring costs of actually flying the vehicle. However, nonrecurring costs, which typically include engineering, fabrication, test and integration, payload integration, vehicle transport, support team travel, and aircraft acquisition costs, must also be considered. This state of affairs makes it hard to determine cost estimation relationships (CERS) for UAS. Fourth, the unprecedented pace of technological development of key components, such as sensors and communications devices, requires unprecedented models of development with special emphasis on upgrades with short life spans. Moreover, developmental UAS have demonstrated their worth in both military (e.g., the *Global Hawk*) and scientific operations (NASA.a 2006; NASA.b 2006). In fact, UA technologies have been transitioned to operations, especially to the battlefield, at an unprecedented rate making it hard to draw the line between development and operations. New acquisition and business models may be needed. Finally, UAS technology enables new concepts of operation, notably those concerning the higher levels of automation from Table 115.3. However, the economics of coordination and cooperation for heterogeneous systems of systems is still poorly understood.

115.3 Maritime Missions

115.3.1 Taxonomy

A general taxonomy of current and future airborne maritime missions is presented in Tables 115.4 and 115.5. In spite of the large number of different missions, there is one segment that is the cornerstone of current airborne operations in the maritime domain: air maritime surveillance. Other types of missions also present new opportunities for future UAS operations.

Maritime surveillance encompasses the systematic and continuous observation of the maritime domain to achieve effective situational awareness

Table 115.4 Civilian maritime missions (Adapted from NASA.b 2006)

| Earth sciences missions | Coastal and oceanic missions | Security missions |
|---|---|--|
| Repeat pass interferometry for surface deformation | Coastal management | Search and rescue (SAR) |
| Cloud and aerosol measurements | Coastal water quality | Marine safety |
| Stratospheric ozone chemistry | Identification and tracking of marine species | Alien migrant interdiction operations |
| Tropospheric pollution and air quality | Shallow water benthic ecosystem | Ports, waterways, and coastal security |
| Water vapor and total water measurements | Wildlife habitat change | Marine environmental protection (e.g., oil spill response, marine debris) |
| Coastal ocean observations | Carbon dioxide flux | Aids to navigation |
| O2 and CO2 flux measurements | Disaster: real-time comm. predict, measure, reducing risk to responder, pre- and post-event monitoring and assessment | Drug interdiction |
| Aerosol, cloud, and precipitation distribution | | Defense readiness |
| Glacier and ice sheet dynamics | | Living marine resources (e.g., fisheries, endangered species & whale/marine mammal protection) |
| Vertical profiles of shortwave atmospheric heating rates | | Other law enforcement |
| Ice sheet thickness and surface deformation | | Ice operations |
| Imaging spectroscopy | | |
| Gravitational acceleration measurements | | |
| Antarctic exploration surveyor | | |
| Magnetic fields measurements | | |
| Cloud properties | | |
| River discharge | | |
| Cloud microphysics/properties | | |
| Focused observations – extreme weather | | |
| Forecast initialization | | |
| Hurricane genesis, evolution, and landfall | | |
| Physical oceanography, meteorology, and atmospheric chemistry | | |
| Tracking long distance transport and evolution of pollution | | |
| Cloud systems: clouds/aerosol/gas/radiation interactions | | |
| Long time scale vertical profiling of atmosphere | | |
| Global three dimensions continuous measurement of environmentally important species for assimilation in global models | | |
| Transport and chemical evolution in the troposphere | | |

Table 115.5 Military maritime missions (Adapted from Nehme et al. 2006)

| Military |
|--|
| Intelligence/reconnaissance (mapping, battle damage assessment, target acquisition, target designation) |
| Drones (target practice, decoy) |
| Transport |
| Surveillance (listening; geospatial surveillance; nuclear, biological, and chemical (NBC) sensing) |
| Communications |
| Extraction: payload extraction from a specified target. In the military, insertions typically involve cargo and/or personnel (search and rescue would fall here) |
| Insertion (payload delivery, electronic warfare) |
| Maritime security |
| Surface warfare |
| Special operations forces support |
| Maritime interdiction operations (MIO) support |

(del Pozo et al. 2010). It is one of the main applications of aerial vehicles for intelligence, surveillance, and reconnaissance (ISR). This is because maritime spaces are immense, with no physical or functional boundaries. Moreover, the average speed of any type of maritime vessel is quite low, and regions of interest extend well beyond the typical land-based electromagnetic horizon. This means that for proper surveillance and reconnaissance, one has necessarily to resort to the speed and endurance provided by airborne platforms. Also, satellite-based ISR has its own limitations. For example, detection of typical objects/activities may be difficult, if not impossible, from high orbit satellites and, notably, from geostationary assets.

Air maritime surveillance permeates military and civilian roles, covering a wide range of missions that are performed by a comprehensive set of systems operated by military forces, law enforcement agencies, and civilian organizations. Even though the requirements for long-range antisubmarine/surface aircraft have somehow diminished after the Cold War, there is an increasing growth in the number of smaller multi-mission capable platforms. This is in mainly due to the increasing demand for persistent wide area surveillance in the exclusive economic zones (EEZ), in the coastal areas, and in the planned extensions of the continental shelves of coastal countries. The relevance of air maritime surveillance has, therefore, increased over recent years. Its main roles are indicated in Table 115.6.

The importance of some of these roles is better understood by considering the fact that the economic value of the marine ecosystem has been estimated in the vicinity of U.S.\$21 tn (Costanza et al. 1997); that the global opiate and cocaine markets are valued above U.S.\$140 bn (UN 2011) – a considerable part of which is trafficked by sea; or that maritime piracy has an annual cost impact of U.S.\$7 bn to U.S.\$12 bn (Bowden et al. 2010).

Table 115.6 Maritime patrol/surveillance roles

| Maritime patrol/surveillance roles | |
|---|--|
| Military | Civilian/military |
| Intelligence, surveillance and reconnaissance | Search and rescue |
| communications, command, and control | Exclusive economic zone |
| Antisubmarine warfare | Outer continental shelf patrol |
| Anti-surface warfare | Maritime patrol and assistance |
| | Vessel monitoring and tracking |
| | Shipping lane protection and security |
| | Law enforcement |
| | Port security |
| | Environment preservation (pollution control) |
| | Customs and border control |
| | Immigration control |
| | Fisheries control |
| | Natural disaster management |

115.3.2 Current Practice

115.3.2.1 Manned Aircraft

Air maritime surveillance is traditionally performed by manned maritime patrol/surveillance aircraft (MPA/MSA). These platforms, capable of deploying an impressive array of sensors, enable wide area surveillance and thus provide an operational advantage over surface vessels.

Adding to the surveillance capabilities, MPA also provide an attack option when equipped to deliver bombs, missiles, mines, depth charges, and torpedoes. The antisubmarine warfare (ASW) and anti-surface warfare (ASuW) missions concern high-end combat roles performed by specialized, complex, and more expensive military aircraft that require extended loiter time and specialized sensor suites and weapons to engage surface and subsurface targets. Even though these aircraft can also perform the less demanding maritime surveillance missions (safety and security), their employment is considerable more expensive than that of short-/medium-range platforms.

According to the ISR Special Report 2009 (Flight Insight 2009), the role of MPA/MSA accounted for 39 % of the global share, totalling 787 aircraft worldwide, as shown in Table 115.7.

The layered maritime surveillance roles involve a tiered organization of aircraft capabilities. The first tier includes the long-range MPA, capable of weapon delivery, only available to the military forces of a selected group of countries. Aircrafts in this category include the *Boeing P-8 Poseidon*, the *Lockheed P-3 Orion*, the *Dassault Atlantique*, and the *CASA C-295MP*. The second-tier platforms include medium-range MSA, such as the *ATR-42* or the *CASA CN-235*, which can perform a variety of roles and are widely used by armed forces and coast guards. The third tier involves short range, light aircraft, designed for coastal surveillance, such as the *Dornier Do228*, the *Beechcraft King Air 200*, and the *CASA C-212*.

Table 115.7 Worldwide
ISR active fleet per region
(Adapted from Flight Insight
2009)

| Region | MPA/MSA | ISR |
|------------------------|------------|--------------|
| North America | 214 | 857 |
| South America | 55 | 112 |
| Europe | 242 | 549 |
| Africa | 9 | 42 |
| Middle East | 8 | 84 |
| Asia-Pacific | 259 | 377 |
| Total aircrafts | 787 | 2,021 |

In this decade, the USA is expected to remain the global leader in the procurement of MPA/MSA aircraft, although countries in Asia and Middle East are expected to increase their procurement for MPA/MSA as well. However, the high-end capabilities of these new multi-mission maritime aircraft come with a high price tag, not affordable to the majority of the users. Even the modernization of legacy systems like the P-3 can be quite expensive. For instance, the P-8 cost per platform is eight times higher than that of the CN-235 that equips the U.S. Coast Guard (Robertson 2012).

Even though this is an era of budget cuts, the demand for ISR aircraft seems likely to increase. *Visiongain* estimates the global airborne ISR market, including new acquisitions and upgrades, to be worth U.S.\$17.3 bn in 2011 (Visiongain 2011). The segment of maritime patrol alone is estimated to have a robust growth of more than U.S.\$6.5 bn per year, totalling U.S.\$78 bn throughout the 10-year period. Therefore, opportunity and necessity are some of the drivers that indicate significant growth opportunities in the maritime patrol/surveillance segment.

115.3.2.2 Unmanned Vehicle Systems

The proliferation of maritime missions opens new opportunities for short-/medium-range platforms dedicated to coastal/exclusive economic zone/Outer Continental Shelf (OCS) patrol. In addition, countries with ambitions to maintain some degree of sovereignty over their maritime domains may resort to short-/medium-range platforms instead of costly high-end MPAs. Considering the technological advances in the unmanned arena, namely, modularity and miniaturization of sensors and mission management information systems, there is a growing interest in the development and employment of UAS for maritime applications. This is discussed next.

Tier II MALE/HALE UA require airfields for takeoff/landing and are therefore operated from land. Those systems have increased range, loiter time, and larger payload when compared to smaller shipborne organic UAS. In addition, the employment of such platforms avoids challenging launch and recovery operations from ships in high seas. However land-based UA have some limitations for maritime operations. One of their main limitations is the compromise between the necessary

detection capability and the required capability for area coverage. Small, low-contrast (even for multispectral cameras) targets (e.g., the head of a survivor at sea) impose zoom/altitude requirements which are quite different from those pertaining to the wide area coverage requirements arising in broader maritime surveillance.

The maritime MALE segment includes systems as the *Guardian* UAS, a maritime-configured *Predator B* operated by the U.S. Department of Homeland Security, which has proven to be effective in supporting operations against several maritime threats, including counter-narcotics efforts against fast boats and submersibles. Other maritime capable MALE platforms include the Israeli-produced *Heron* UAS and the *Hermes 900* UAS equipped with a variety of sensors, with extended range, and loiter time of up to 40 h.

The most important, complex, and expensive UAS program in the HALE segment is the U.S. Navy *MQ-4C Broad Area Maritime Surveillance* (BAMS). The BAMS UAS is based upon the *Global Hawk* UAS and will provide persistent maritime and littoral ISR to naval forces up to a range of 2,000 nautical miles, complementing manned platforms such as the *P-8 Poseidon*. It is expected to achieve initial operational capability by 2016.

On the lower end of the maritime missions, there are small tactical UAS typically used as organic assets of surface vessels, which can easily be deployed to investigate contacts (typically over-the-horizon-targeting (OTHT) distance of 20/30 miles). Due to the low altitude of flight, the problem of autonomous flight in nonsegregated airspace does not arise in this tier. The main technical challenges on this tier are related to the small size of these UAS (reduced payload capabilities) and the need for launch and recovery systems. Automatic (or manual, for that purpose) recovery of these UAS from a medium-sized ship operating in rough seas is not a trivial task. Typically, this requires small, lightweight, fast, and inexpensive vehicles. This is also one of the reasons behind the development of shipboard rotary-wing UAS capable of vertical takeoff and landing (VTOL) operations.

The *ScanEagle* UAS, launched from a pneumatic catapult, is one of the most successful tactical systems used in maritime missions such as ISR, sea-lane escort and convoy protection, search and rescue, border security, communications, video, and data relay. After accomplishing the mission, it is autonomously recovered using a folding “skyhook” and catch line. In service with the U.S. Navy since 2005, the *ScanEagle* has flown nearly 250,000 h under the Naval Air Systems Command’s ISR services contract (U.S. Navy 2012).

Finally, there is a growing interest in the high-end maritime capabilities of unmanned combat air vehicles. The U.S. Navy requirement for persistent carrier-based ISR coverage to be performed by UAS capable of operating in contested airspace and performing deep penetrating strike has led to the development of an Unmanned Carrier-Launched Surveillance and Strike Aircraft (UCLASS) demonstrator program. One of the contenders, the *Northrop Grumman X-47B* Unmanned Combat Air System (UCAS) demonstrator, successfully completed its first land-based catapult launch in November 29, 2012, marking the dawn of a new era for naval aviation (Naval Air Systems Command Public Affairs 2012). In 2013, it is expected to perform autonomous carrier-based launches and recoveries.

115.4 Current Trends and How These Will Affect UAS for Maritime Operations

115.4.1 Ocean Observation and Global Sustainability

Currently, there is a pressing need for a sustained, persistent, and affordable presence in the oceans that will help us to understand and monitor how key issues such as climate change, ocean acidification, unsustainable fishing, pollution, waste, loss of habitats and biodiversity, shipping, security, and mining are affecting global ocean sustainability and stewardship (IOC/UNESCO 2011). This is not an easy endeavor. First, the oceans cover 71 % of the Earth and contain 96 % of the Earth's living space thus making ocean observation a problem at the planetary scale. Second, the oceans are still largely inaccessible, not only to humans but also to man-made devices. Third, the oceans are a communication-challenged environment: land-based communications have limited range and satellite communications are quite expensive. Fourth, although ships have been the mainstay of seagoing ocean sciences, a ship can only be at one place at a time, can only carry a small number of scientists, and can only stay at sea for limited time. In addition, ship time is very expensive. Fifth, the interior of the ocean changes faster than it can be measured with traditional sampling devices, such as shipborne sensors and drifters (Bellingham and Rajan 2007).

A sustained, persistent, and affordable presence in the oceans require innovative approaches to systems development, operations, and management. This can only be achieved with an incremental and multidimensional approach. First, there is a need to increase the number of systems (buoys, drifters, floats, etc.) in operation in the oceans and to develop and deploy new fleets of robotic vehicles for ocean observation with unprecedented spatial and temporal resolution. Second, it is necessary to network existing systems and new robotic vehicle systems for coordinated adaptation to observational needs. This entails being able to command and control networks of manned and unmanned vessels which, in turn, may form ad hoc communication networks allowing extended and cost-effective communications coverage. Observe that presently most systems at sea lack basic networking capabilities. These capabilities would allow, for example, commercial ships to act as opportunistic sensor and communication platforms, as well as "data mules" ferrying data collected by other systems that they may encounter at sea. Third, there is a need to develop unmanned vehicles capable of long duration/range missions for cost-effective spatial and temporal coverage. Fourth, there is a need for new organizational frameworks to manage and coordinate the system(s) of systems that will result from these networking trends and associated cost benefits. This poses unprecedented technological and organizational challenges to countries and international organizations. Some efforts are underway to address these challenges. For example, a network of national observatories is being coordinated to provide ocean data for the Global Ocean Observing System (GOOS, <http://www.ioc.goos.org>). Many observatories are surface or seafloor moorings with sensor arrays. Where moorings are cabled to shore for power, a few observatories

Table 115.8 Payload trends

| | |
|---|--|
| Payload | |
| Modular/standard payload mechanical, electrical, and signal interfaces will facilitate the integration of new payloads and will reduce overall costs. | |
| Survivability | Stand-alone localization components will facilitate finding downed UA at sea and may lead to new concepts of operation. Design for survivability will improve reliability and reduce costs. |
| Reconnaissance/electronic warfare | Advances in miniaturization and sensor development will lead to new sensor capabilities for small UA. |
| Remote sensor system delivery/retrieval | Developments in stand-alone ocean sensor and communication nodes will enable delivery of nodes in remote locations where ad hoc networks may be formed. In addition, UAS may revisit these locations to collect stored data and ferry it to base stations. This may reduce the cost of communications. Retrieval of devices (e.g., sensors or containers with water samples) from the ocean will lead to unprecedented fast response to episodic events (e.g., underwater volcanic eruption). |
| Payload application and system software | Developments in low-power and high-performance computer systems will enable advanced onboard intelligent data handling and processing and advanced sensor fusion algorithms. This will reduce the need for high-speed data links (for remote processing of sensor data) and also for operator's intervention. Open architecture development paradigms will enable rapid testing and prototyping and will reduce development costs. |

include buoyancy gliders as observing system components. Discussions have been underway to further develop Integrated Ocean Observing Systems (IOOS) which also include propeller-driven autonomous underwater vehicles (AUV), autonomous surface vessels (ASV), and UAS. These networking concepts are applicable to other domains such as surveillance and maritime security, where the role of UAS becomes even more relevant (McGillivray et al. 2012) (Tables 115.9 and 115.10).

115.4.2 Technological Trends

Technological trends relevant to maritime UAS in groups 1–3 from Table 115.1 are discussed next (trends for groups 4–5 are expected to follow closely those for manned aircraft and are not discussed here). This is done with respect to the UAS product structure presented in Table 115.2.

115.4.3 UAS Capabilities and Life Cycle Management

The trends discussed so far in this section will lead to new UAS capabilities and will significantly affect certification and interoperability, operations and support, and cost structures. This poses significant challenges to LCM processes.

Table 115.9 Trends affecting components of the air vehicle

| | |
|---|---|
| Air vehicle | |
| Modular/standard mechanical, electrical, and computational subsystems will facilitate systems integration and will reduce overall costs | |
| Airframe | <p>Developments in composite materials, nanotechnologies, and intelligent structures will decrease weight and improve aerodynamic performance.</p> <p>Ruggedized airframes will allow launch and recovery from the ocean, from maritime assets (e.g., ships, submarines, offshore platforms, and autonomous surface crafts), and from remote locations (e.g., islands or ice). Operations from remote locations will also be enabled by autonomous recharging and/or refuelling.</p> <p>Specialized airframe designs will allow energy harvesting from atmospheric phenomena, such as wind, and/or from the sun.</p> <p>Air-to-air refuelling subsystems will enable long duration missions and persistence.</p> <p>Design for survivability will make a major impact on overall reliability. This will be done in conjunction with advanced fault identification and handling algorithms.</p> <p>Developments in mechanical standardization will allow interoperability of launch and recovery systems.</p> <p>Developments in anti-icing and related technologies will enable UAS to operate in remote regions, especially in the high latitudes.</p> |
| Propulsion/energy storage | <p>VTOL and short takeoff and landing (STOL) technologies will facilitate deployment from maritime assets and remote areas.</p> <p>Developments in high energy density power sources, namely, hydrogen and fuel cell technologies, are expected to increase flight time, even for UA equipped with combustion engines.</p> <p>Laser and microwave technologies are expected to allow recharging of batteries on the fly for small UAS.</p> |
| Communications/identification | <p>Advances in communication standards will reduce development and operational costs.</p> <p>Trends in network-centric communication will facilitate integration in system(s) of systems frameworks.</p> <p>Advances in cognitive radio technologies and in heterogeneous communication devices will enable “smart” communications with heterogeneous assets (e.g., manned and unmanned aircraft, offshore platforms, buoys, tagged animals) through interoperated networks.</p> <p>Advanced relaying technologies, data compression, and network coding techniques are expected to increase effective communication data rates over extended ranges thus alleviating dependence on satellite communication (SATCOM) and enabling over-the-horizon communication. Aerostats and other aerial assets will allow sustained beyond line-of-sight (BLOS) communications. In addition, multiple UAS and other maritime assets may be required to form communication networks to provide communications coverage in remote environments.</p> <p>Disruptive tolerant networking (DTN) protocols will enable the delivery of data and commands in communications challenged environments. This allows for priority messaging when several transports, including SATCOM, are available. Data mules will transport low priority messages between nodes which may not be in direct communications.</p> |

(continued)

Table 115.9 (continued)

| | |
|---|--|
| Air vehicle | <p>Secure protocols and encryption will allow secure access control and control handover for networked operations.</p> <p>Identification standards will enable operations over wide geographic areas, including international waters, where assets from different countries and organizations may be present.</p> |
| Navigation/ guidance | <p>New satellite services for global positioning will complement and improve existing services through better integration and coverage.</p> <p>Developments in microelectromechanical systems (MEMS) technologies will enable the development of tactical grade low-cost inertial measurement units.</p> <p>Navigation aids mounted on naval assets will assist navigation in remote locations, in high latitudes, or in Global Positioning System (GPS)-denied environments.</p> <p>Guidance systems for energy harvesting from atmospheric phenomena will allow persistent operations.</p> |
| Central computer | <p>Miniaturization, multi-core computer architectures, and dedicated computing units will enable demanding onboard computations, such as those related to data fusion, deliberative planning, and higher levels of autonomy.</p> |
| Air vehicle application and system software | <p>Interoperability standards and open architecture frameworks will reduce development costs and facilitate true interoperability with heterogeneous assets. Interoperability will be extended to interactions with ship-based systems and with other maritime assets. This will reduce integration and certification costs.</p> <p>Developments in cyber-physical systems technologies and frameworks will enable the development of application software targeted at system of systems integration.</p> <p>Improvements in software development techniques and tight integration with onboard computer systems, with special emphasis on redundancy, will lead to more reliable flight systems.</p> <p>Advances in control design will lead to standardized maneuvers with special emphasis on maneuvers with performance and safety guarantees. Libraries of maneuvers are expected to grow with time to deliver new capabilities, namely, those concerning interactions with other assets (e.g., refuelling, forming a communications network, tracking a vessel, interacting with manned aircraft). This will allow developers to continuously extend the command set for existing UA platforms. In addition, advances in networked controls will allow tight motion coordination of multiple UAS over unreliable communication channels. All of these developments will pose new challenges to certification.</p> <p>Advances in collision avoidance technologies and concepts, together with advances in collision detection capabilities, will also facilitate certification and air worthiness.</p> <p>Advances in fault identification, intelligent system health monitoring, contingency management, and fault recovery and in controls for degraded modes of operation will improve reliability and reduce associated costs. This will lead to more reliable flight systems.</p> |

Table 115.10 Trends affecting the off-board components

| | |
|---|---|
| Ground/ocean segment | |
| The ground/ocean segment will expand dramatically allowing multiple ground and maritime systems to interact with UAS. This will be facilitated by advances in interoperability and standardization. | |
| Ground control systems | Trends towards networking and system of systems will enable UAS to interact with heterogeneous ground/ocean control systems ranging from more “traditional” control stations to hand-held devices, to unattended buoys in the ocean, or to other unmanned vessels. This will allow either direct real-time control or the anticipation of future interactions (e.g., new UAS mission plans may be uploaded to an ocean buoy for downloads by UAS operating in the region). |
| Command and control subsystem | <p>Advances in onboard autonomy and interoperability will allow UAS to become “more operable” thus facilitating the task of human operators and reducing training cost. Moreover, these advances are expected to enable one operator to control UAS teams, which may involve other types of maritime assets. This will be done through the specification of high level objectives and extended UAS command sets.</p> <p>Interoperability standards and open architecture frameworks will reduce development costs and facilitate interoperability with heterogeneous assets.</p> <p>Advances in command and control frameworks for system of systems frameworks will facilitate integration of UAS into higher level maritime observing systems. This will enable new concepts of operation and new business models.</p> <p>Developments in human factors technologies will allow the optimization of mixed-initiative interactions by providing better integration of human operators in system of systems frameworks.</p> |
| Launch and recovery equipment | <p>Standards for modular launch and recovery systems will facilitate operations from heterogeneous maritime assets and remote locations and will enable new concepts of operation taking advantage of geographically distributed launch and recovery locations. These may entail launch, or at least recovery, from the ocean.</p> <p>Standards and certification procedures will be developed to enable operations from maritime assets.</p> |

Table 115.10 (continued)

| | |
|--|--|
| Ground/ocean segment | |
| Transport system components | Standardized components will facilitate transportation and minimize the cost of spare parts. |
| Ground segment application and system software | Advances in archival of data in a searchable manner, in the semantic web, and in intelligent data handling and processing techniques for high volumes of data will enable unprecedented real-time data analysis capabilities. Cloud computing technologies will provide unprecedented computational power for intensive data handling and processing techniques Advances in data fusion and visualization techniques will significantly improve situational awareness capabilities (e.g., overlay of video on top of satellite imagery from the same spot if not at the same time) Advances in interoperability will enable interactions with external systems required for the operation of UAS. |

The challenges come from the rapid pace of technological developments and from a paradigm shift in maritime operations: from single vehicle to multi-vehicle networked operations. The fast pace of technological developments, especially those affecting the software subsystems from Table 115.2, is bound to significantly affect LCM for UAS in groups 1–3 (Table 115.1) because frequent upgrades will be required to prevent obsolescence. Moreover, frequent upgrades will be facilitated by simpler certification requirements for UAS in groups 1–3. The paradigm shift will mean that UAS will become nodes in system of system networks. This will significantly change UAS maritime operations.

Several countries and organizations are developing technological roadmaps to address capabilities development in a systematic fashion and within an appropriate organizational framework. The technology roadmap (DOD.b 2011) is quite comprehensive and presents key capabilities, organized around seven themes, to be developed for the continued integration of unmanned systems into the USDOD. The projected evolution of key capabilities for each of these themes is briefly summarized next (Table 115.11).

Capabilities specific to UAS maritime operations will include ship-based and ocean-based launch and recovery (McGillivray 2010) and also retrieval of systems from the ocean. These will pose additional legal challenges, namely, when it concerns operations in international waters and classification of maritime assets (Kraska 2010).

The problem of reducing UAS life cycle costs is addressed in UAS assessment reports (Subcommittee on Unmanned Systems 2011) and roadmaps (DOD.b 2011). Several steps towards reducing the cost associated to the UAS life cycle are briefly discussed next with respect to the traditional decomposition of cost into recurring and nonrecurring costs (NASA.a 2006).

Payload integration, which is one of the largest nonrecurring costs for UAS, can be decreased through standardized interfaces. The cost of support personnel

| | Multifunctional antennas (2018–2019) |
| Training | Environmental-based adaptive dynamic system changes (2019–2025+) |
| | Pre-deployment training/lessons learned before arriving the area of operations (2014) |
| | Surrogate UAS support/training improvement plan (2016–2017) |
| | Universal pilots and operators (2018–2019) |
| Propulsion and power | HP/LP power extraction (2016–2017) |
| | Extreme endurance (2018–2019) |
| Manned-unmanned teaming | Payload control (2013–2014) |
| | Control of UAV from other aircraft (2015) |
| | Unmanned wingman (2016) |
| | Manned-unmanned scout/ATK teaming (2017–2018) |
| | Unmanned scout/ATK teaming (2018–2019) |

that must accompany the UAS can be reduced by making UAS more “operable.” This requires access to NAS on a “file-and-fly” basis, simple deploy and launch mechanisms and procedures, minimal preflight and post-flight procedures, high system reliability, and increased levels of automation for flight plan development. The cost of acquisition, especially for the larger UAS, may be prohibitive for most users and countries. This opens a market for UAS service providers. On the other hand, organizations that have a constantly recurring mission (e.g., U.S. Coast Guard) would need to include acquisition costs in the mission cost. Modularity and standardization will contribute to the reduction of development costs. This will also reduce the cost of UAS upgrades. In addition, UAS will benefit from developments in autonomy, interoperability, and sensor integration for other unmanned systems.

Recurring costs are those that are directly proportional to the number of hours the UAV actually flies and include direct costs, insurance, communication support, mission planning, and data analysis. The cost of ground operators will be significantly reduced with the expected increase in levels of onboard and off-board automation. Interoperability standards will have the same impact. Interagency

coordination, asset pools, and consolidated operations centers should also contribute to cost savings (Subcommittee on Unmanned Systems 2011). New concepts of operation involving networked vehicles and launch and recovery from ships and remote locations will contribute to the reduction of transportation costs. The cost of insurance has been one of the major components of the cost per flight hour. Improvements in reliability and fault tolerance, competition, and specialized insurance policies may bring these costs down. The cost of communications is significant, especially for long-range missions where SATCOM seem to be the only available solution. Increased onboard autonomy reduces bandwidth requirements for command and control. But this does not solve the problem of the increasing bandwidth requirements arising from more sophisticated payloads. Disruptive tolerant networking (DTN) communication protocols and networked vehicles will help solve the problem of beyond line-of-sight (BLOS) communications. The cost of data analysis may still increase in the near future as sophisticated payloads become available. Automation is the answer. Developments in archival of data in a searchable manner and in algorithms for analyzing high bandwidth data streams are expected to reduce this cost.

115.5 Potential Future UAS Maritime Operations

Future UAS maritime operations will differ significantly from what is done today. This is because technological trends and projected developments of capabilities will entail a paradigm shift from single UAS operations to UAS integration into system(s) of systems. New concepts of operation will revolve around interactions, teaming, persistence, services, network behavior, and dynamic reconfiguration.

Tier II maritime MALE/HALE UAS will be operated from land, eventually from remote locations located closer to areas of interest. In the first stage of development, UAS will provide direct observation and communication services to manned and unmanned sea-based and airborne assets through encrypted communication channels. Later, teamed operations involving HALE and MALE UAS, and possibly smaller UAS, equipped with complementary sensors and communication devices and operating at different heights will provide services with adaptation of spatial and temporal resolution to observational needs, thus bridging the gap between wide area coverage requirements arising in broader maritime surveillance and detailed inspection of features of interest. In addition, the inclusion of UAS into operations including manned ships, as well as ocean observation surface buoys and underwater observation networks, enables a wider range of data collection relevant to ocean monitoring than previously possible. At a later development stage, dynamic reconfiguration of interactions and of UAS teams will allow dynamic missions in persistent operations with heterogeneous UAS.

Small tactical maritime UAS will be used as organic assets of surface vessels and submarines. Extreme endurance will allow UAS to be launched and recovered from different assets at different locations. This will enable transportation, delivery, and recovery (from the ocean) services. Additional sensing and communications

services will be provided to manned aircraft and ships. This will allow loyal wingman operations in manned-manned teaming for SAR missions, as well as in MIO support.

115.6 Conclusions

Current practices and trends in UAS for maritime operations are presented along with projections of future UAS maritime operations. This is discussed in the conceptual framework of a notational work breakdown structure (WBS), which is a standard method for understanding systems. First, a taxonomy of maritime aircraft missions and required capabilities is presented along with current practices for both manned and unmanned aircraft. Second, trends in ocean observation and in technological developments pertaining to UAS cost and capabilities are presented before discussing how these may affect future UAS capabilities and life cycle management. Third, projections of potential future UAS maritime operations are discussed, with special emphasis on new concepts of operation.

Technological trends and projected developments of capabilities will entail a paradigm shift from single UAS operations to UAS integration into system(s) of systems. The new UAS capabilities will allow concepts of operation which could have not been imagined before. These, in turn, will pose new organizational and legal challenges. For example, interoperable UAS will be capable of launch and recovery from assets from different countries. Networking is the future. The question is how?

Abstract

This chapter presents an Unmanned Aircraft System (UAS) which consists of a helicopter, a fixed wing Unmanned Aerial Vehicles (UAVs), and their supporting infrastructure. This UAS, which was used in a number of environmental research experiments focused on autonomous remote sensing, detection, classification, and management of invasive species, weeds, in Australia.

The annual cost of weeds to the Australian economy is estimated at A\$4 billion. Over the last few years, experiments have been performed at three geographically distant regions of Australia to evaluate if the UAS can be used as a cost-effective tool in management of invasive species. In these experiments

three distinct families of weeds, growing on three different types of terrain were investigated.

In the first group of experiments, a helicopter UAV equipped with a high-resolution imaging payload was flown over difficult to reach water channels and wetlands for detection of aquatic weeds. The second set of experiments was performed in large, relatively flat rangelands to map woody weed infestations. A low-flying fixed-wing UAV platform was also operated over a designated cattle grazing area and collected high-resolution aerial imagery. Weed infestation maps were produced from aerial imagery using machine learning techniques. By incorporating the human subject matter experts and farmers into the decision-making process, weed management plans produced. An autonomous helicopter was then tasked with spraying herbicides on aquatic weeds and dispensing granular herbicides on top of the selected woody weeds. The third set of experiments was focused on the airborne detection of wheel cacti on remote mountainous terrain using fixed-wing aircraft. Cacti infestation maps were generated and compared with data collected by weed experts on the ground. Successful results of these experiments are encouraging and suggest that robotic aircrafts in a properly designed UAS can play an important role in environmental robotic science.

116.1 Introduction

Unmanned Aerial Vehicles (UAVs) have been used in the military domain since the First World War (Cook 2007). Wide use of UAVs and other robotic platforms in conflict zones has resulted in a substantial military robotics industry (Singer 2009). On the other hand, the commercial and civilian applications of UAVs are rapidly evolving. Market forecasts indicate that currently limited market share of civilian UAVs is promising to have a sustainable growth for foreseeable future (Cox et al. 2004). Precision agriculture (Herwitz et al. 2002), environmental monitoring (Dunbabin and Marques 2012), wildlife surveying (Körner et al. 2010; Watts et al. 2010), Antarctic ecology research (Lucieer et al. 2010), rangeland management (Rango et al. 2006), agronomical research and crop health assessment (Nebiker et al. 2008), and weed detection, classification, and management are some of the civilian areas in which UAVs have proven to have potential uses (Bryson et al. 2011b; Göktoğan et al. 2010).

Introduction of non-native plants to Australia has threatened the ecological environment, rangeland and primary production industries. Invasive species have major impact on the environment; they destruct the native habitats, hinder the growth of the native species, cause land degradation, and significantly reduce the agricultural, horticultural, and forestry productivity. Australia has a fragmented landscape, thus the indigenous ecosystems are at a higher risk of being overcome by the invasive species or weeds (Nuberg et al. 2009). Weeds are rapidly spreading invasive plants that have an adverse effect on the environment and can have serious economic impacts. Although some native plants can also become weeds if the right conditions arise, the overwhelming majority of weeds in Australia are those which are introduced into Australia from other continents, mainly due to human activities.

The annual cost of invasive species or weeds to the Australian economy as a loss in agricultural revenue is in the order of A\$4 billion (Pash 2007; Sinden et al. 2004). Besides the major economic effect, natural fauna, flora, biodiversity, native landscape, and irrigation also suffer from rapidly spreading invasive species. This is why management of invasive species, weeds, has national significance (NRMMC 2007). Work presented in this chapter is focused on surveillance and management of three different families of weeds: (a) aquatic weeds, (b) woody weeds, and (c) cacti.

In parallel with an increasing public environmental awareness and education, there is an increasing trend toward development and utilization of new technologies for better environmental monitoring and management (Dunbabin and Marques 2012). Management strategies of invasive species can be grouped into three categories (a) prevention, (b) early detection and rapid assessment, and (c) control, containment, or eradication (Virtue et al. 2001).

In recent years, commercial satellite imagery for civilian use has become more accessible and is being used in assessing natural resources. Typical satellite imagery available to the civilian domain has approximately 2–45 m resolution per pixel. These images are useful for a high-level overview of large landscapes. It is even possible to detect large weed infestations from using satellite imagery (Everitt et al. 2008). However, weed management strategies aim for early detection of weed patches before they turn into problematic weed infestations. Current satellite imagery cannot offer the needed spatial and temporal resolution for early detection and rapid assessment of small weed clusters.

On the other hand, aerial imagery from human piloted aircrafts can provide better than 1 m spatial resolution imagery, which can be useful for providing ground truth for the satellite data as well as investigation of relatively large rangelands. Using higher-resolution cameras and flying at lower altitudes can yield even higher-resolution imagery. However, it is not safe to operate human-piloted aircrafts in narrow corridors around natural obstacles such as valleys, trees, or bushes, even if ultralight aircraft are used (Grigg et al. 1997). High-resolution aerial imagery from human-piloted aircraft is being successfully used for weed detection and assessment, particularly at late weed phenological stages (Yang and Everitt 2010; López-Granados 2011). Furthermore, human piloted agricultural crop-dusting airplanes have a long history of being used in pest insect and weed management since the end of the First World War (Eldon and Lemmer 1965). However, the high operational cost of human piloted aircraft is an important limiting factor for weed management practices.

Therefore, when a centimetre or better resolution is desired in aerial imagery, UAVs can be tasked with intelligent and adaptive sampling for an effective *close sensing* mission without putting human operators into risk (Watts et al. 2010; Göktoğan et al. 2010). As it is addressed in the following sections, robotic aircraft as a part of an appropriately designed Unmanned Aircraft System (UAS), can play an important roles in all three categories of weed management strategies. In the context of this chapter, the term UAS refers to not only the UAV platform but also all entities utilized in UAS operations such as all onboard avionics, communication subsystems, the ground control station (GCS), data analysis tools, as well as human operators.

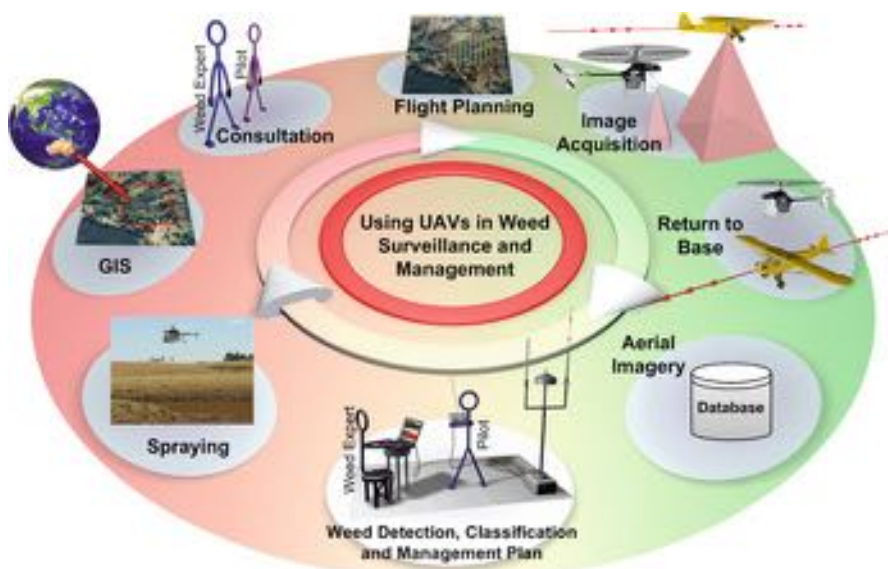

Fig. 116.1 System life cycle of using UAVs in weed surveillance and management

This chapter addresses a set of novel applications of autonomous remote sensing of invasive species from robotic aircrafts and presents the overall system view. The emphasis is on the system perspective and the focus on the connections, interactions and dependencies between components, rather than the UAV platforms and data processing algorithms as a disconnected set (Fig. 116.1).

116.2 Weed Surveillance and Management Life Cycle

As illustrated in Fig. 116.1, the lifecycle of a typical weed surveillance mission starts with some a-priori estimate of the weed location provided by land owners, farmers and weed experts. Weed experts generally keep this information in their geographical information system (GIS).

Prior to UAV flights, weed experts and UAV operators identify the regions of interest. Initial planning is based on the data from GIS, environmental conditions, weed sightings, and/or data from satellite imagery, aerial imagery obtained from manned flights, but above all, it is based on the tacit knowledge of the subject matter experts.

UAVs must be operated in accordance with the rules and regulations applicable to the particular type of UAV and the operation region. Hence, during the mission and flight planning phase, UAV operators must work closely with the Civil Aviation Safety Authority (CASA). Based on the draft situation model and environmental constraints, such as topography of the region, obstacles, wind directions, and so forth, flight plans are prepared on the ground and uploaded to the UAV autopilot for

autonomous surveillance. Alternatively, for small line-of-sight operations, a human pilot may remotely control the UAV to fly over the suspected regions for data collection. In a typical image acquisition mission, system attributes such as flight paths, flight height, flight speed, focal length of the camera, and image acquisition rate, desired image overlap between image frames of geographically close regions etc. are all closely related with each other. Mission planning is therefore a multi criteria decision making process optimising the flight plan and system configuration. It aims to maximise the return from the UAS, while minimizing the fuel, flight time and risk associated with the flight operation. Once each UAV image acquisition flight over a specified region is finished, and the UAVs have returned to the base, data is downloaded to aerial imagery databases at the ground station for processing.

The initial phase of the data processing pipeline is image registration/geo-referencing. This process identifies the relation between image pixels and geographical coordinates. It can utilise accurately surveyed control points on the ground and/or the position and orientation estimates of the airborne camera at the time of image capture. Ground control points may confer higher accuracy compared to a direct method of geo-referencing airborne images using logged navigation data. However, as it is mentioned in the following sections, manual ground surveying of weed-infested aquatic habitats and steep cliffs of cacti infestations on hilly terrains would not always be practically possible. Compared to larger manned aircraft, small UAVs are limited in options of carrying highly accurate sensors. These limitations can be reconciled in UAV flight planning by aiming to achieve relatively smooth and repeatable flights and acquiring more overlapped aerial imagery.

Current civil aviation rules and regulations imposed by the CASA have tight restrictions on the spraying of chemicals or dispensing of herbicide granules from aircrafts. The relevant acts provide details about the endorsement of the aircraft and onboard human pilot for the spraying operations. Although these rules may not be directly applicable to unmanned operations, it is difficult to reach a conclusion in relation to UAV operations for spraying or dispensing herbicides. Thus, in order to demonstrate the proof-of-concept, a water-soluble non-toxic dye is used for spraying operation and non-toxic granules dispensed instead of real herbicides.

Other regulatory and operational challenges are mainly related to the integration of new unmanned systems into existing regulated airspace. Currently, sharing the same civilian airspace between manned and unmanned aircrafts is not routine. Therefore, rules and regulations in relation to UAS operations are conservative to safeguard public safety. Although it may take many years to come, it is envisaged that prolonged safety records of new UASs will help to change existing regulations to allow regular UAS operations without compromising overall aviation and public safety.

116.3 Avionics Architecture

Avionics systems used both in the helicopter and fixed-wing UAV platforms have the same high-level system architecture. Figure 116.2 illustrates the major architectural building blocks. UAVs are fitted with an autopilot module, a navigation computer,

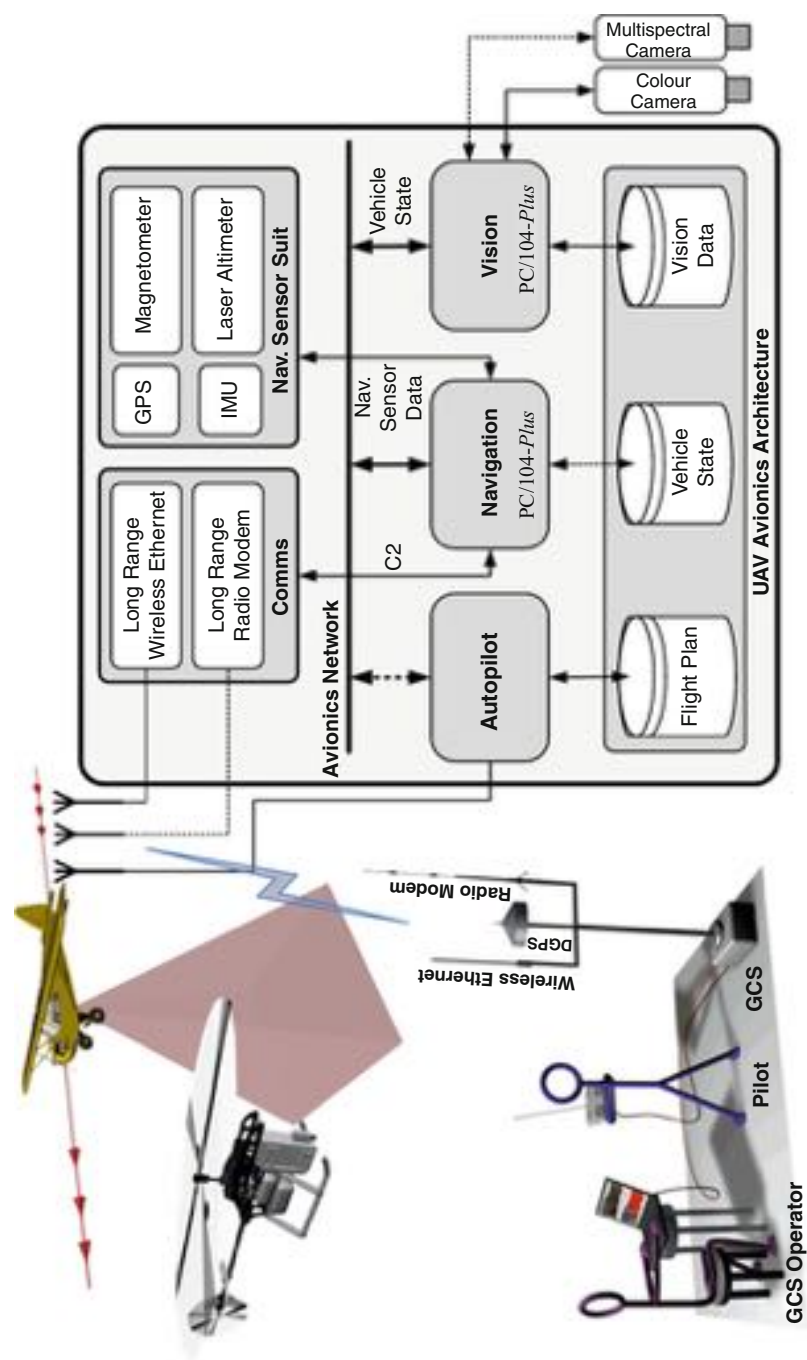

Fig. 116.2 Typical high-level avionics system architecture for UAVs used in weed surveillance and management experiments

and a vision computer. The navigation and vision computers are both in PC/104-*Plus* form factor, and the autopilot module is built around an embedded microcontroller board. They are linked together via an onboard network, and they are also able to communicate to the GCS via the communication subsystem.

In order to accurately localise and geo-reference the weeds and other feature of interests (FoI) in the aerial imagery, an accurate estimate of the UAV position and orientation, i.e., attitude are needed. The navigation computer provides the position and attitude estimate at a rate of up to 20 Hz by fusing sensor data from the navigation sensor suite. Optionally, a downward pointed laser range finder can be used as a laser altimeter, and its readings can be incorporated into the navigation solution to better estimate the flight height above ground. Both the raw sensor data and the navigation solution are logged on onboard solid-state disks. All the logged data is accurately time stamped for further analysis. The navigation solution is published on the avionics network for other subsystems. The navigation data is also available to the GCS. The GCS uses the navigation solution to update the GCS screen in real time to indicate the position and attitude of the RUAV to maximise the situation awareness of the GCS operator and the pilot (Göktoğan and Sukkarieh 2009).

The vision subsystem is tasked to control vision cameras, acquire image frames, time stamp each frame, and save them into solid-state disk for further analysis. The UAVs vision subsystem consists of a PC/104-*Plus* computer and a digital video camera interfaced via IEEE 1394 (FireWire). Optionally, an additional multispectral camera can be added to the vision subsystem.

Presented UAVs are equipped with two separate wireless communication subsystems. The long-range radio modem establishes a full-duplex link between UAV and the GCS. It is mainly used for the transfer of telemetry, command, and control (C2) packages. If this communication link is lost for a predefined period of time, then the autopilot switches its mode and initiates a communication recovery procedure. This procedure consists of loitering over a predefined place with a predefined path so that it can try to re-establish communications. If communication cannot be established after a communications time-out period, either the flight abort procedures or auto-landing procedures can be executed.

The wireless Ethernet link between a UAV and the GCS provides wider bandwidth compared to the radio modem link. However, this link has shorter communication range, and it is subject to frequent dropouts. Hence, flight and mission critical data are not transmitted via wireless Ethernet, but via a long-range radio modem unit. Wireless Ethernet link generally utilised for the transmission of high bandwidth sensor data such as sample image frames.

116.4 Aquatic Weeds Surveillance and Management Using Helicopter UAV

Aquatic weeds, as the name implies, often spread in aquatic habitats. However, they can also survive in land habitats for long duration of time and thrive in the right conditions. Two particular aquatic weeds, namely the alligator weed (*Alternanthera*

Fig. 116.3 An irrigation channel blocked by aquatic weeds (a) alligator weed (*Alternanthera philoxeroides*) and (b) salvinia (*Salvinia molesta*)

philoxeroides) and salvinia (*Salvinia molesta*) (Sainty and Jacobs 2003), are studied. As shown in Fig. 116.3, by creating thick blankets of vegetation across the water surface, these weeds decrease oxygen concentrations in water to a level that is ultimately be detrimental to bottom-growing native vegetation and fish populations.

Alligator weed is extremely invasive, and has a high potential for rapid spreading over large areas. Furthermore, it can also invade both aquatic and land habitats. Salvinia can cause devastating environmental effects and severely affect riparian ecosystems, water quality, wildlife, and the surrounding primary industries. Given the right conditions, salvinia exhibits an extraordinary growth rate; it can double its dry weight in two and a half days. Holm and East-West Center (Holm and Center 1977) describes salvinia as one of the world's worst weed.

Fig. 116.4 (a) Close-up view of the UAV frame with the payload box and onboard electronics, (b) G18 helicopter UAV flying over the salvinia-infested aquatic habitat

Compared to fixed-wing UAV platforms, helicopters provide better manoeuvrability over irregularly shaped aquatic habitats (Australia Law 2009). A modified G18 helicopter UAV platform was used in surveillance of aquatic weed infestations in the Killarney Chain of Ponds in Pitt Town, New South Wales. The same platform was later equipped with a spraying mechanism to spray water-soluble non-toxic dye to demonstrate the capability of spraying herbicides on selected regions (Sukkarieh et al. 2009; Göktoğan et al. 2010; Sukkarieh 2008, 2009, b).

116.4.1 Helicopter UAV

The helicopter UAV used in the presented applications is based on a locally manufactured, commercially off the shelf (COTS), G18 industrial helicopter platform (Fig. 116.4). In order to increase its robustness for field experiments in remote locations, a range of major modifications have been made to increase its reliability, endurance, and payload capacity (Göktoğan et al. 2010).

The basic specifications of a modified G18 based helicopter UAV is tabulated in Table 116.1. With its 1.8 m main rotor diameter, and 15 kg maximum take-off weight (MTOW), this platform can be classified as small-to-midsize helicopter. Depending on the vision payload and/or the herbicide carried onboard, the endurance varies between 20–120 minutes. This flight time is sufficient and well suited to existing operational practices of weed management personnel.

As shown in Fig. 116.4, the front section of the platform is modified to accommodate the mission payload which consists of a navigation computer, autonomous flight control system, image processing equipment, vision camera, and the radio communication units. The entire payload is placed in a custom-made enclosure and mounted to the main body using vibration isolation mounts. The isolators had to be symmetrically located around the centre of gravity of the payload to ensure the rolling and pitching motions were not introduced by the vibration.

Table 116.1 Basic specifications of modified G18 helicopter UAV

| Helicopter UAV | |
|---------------------|-----------------------------------|
| Overall length | 2.0 m |
| Overall height | 0.63 m |
| Main rotor diameter | 1.8 m |
| Max takeoff weight | 15 kg |
| Engine | 26cc Zenoah (modified) |
| Speed | 0–100 km/h |
| Endurance | 20 min to 2 h (payload dependant) |

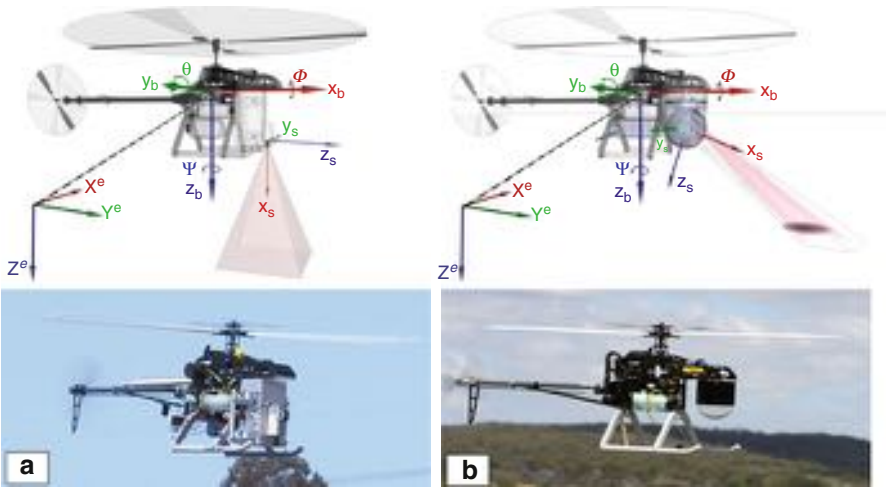

Fig. 116.5 Helicopter UAV in two different configurations. (a) UAV carrying the payload box and a fixed, downward-looking monocular camera. (b) UAV without payload box, with a gimbaled camera. Upper illustrations show the Earth, body, and sensor coordinate reference frames and how camera frustum and image footprint are related

Additional mounting points were also installed for the Global Positioning System (GPS) antenna, the magnetometer, and the communications antenna.

The G18 helicopter has a large frontal volume that can be utilised to carry different vision payloads (Fig. 116.4). For aerial image acquisition operations, two different types of camera attachments have been tested. Figure 116.5 illustrates that, in the first configuration, a downward-looking monocular vision camera is mounted in front of the payload box. This is the most commonly used configuration as it provides images with minimum slant angle. Alternatively a gimbaled camera can be mounted to the payload bay for more flexible camera-pointing applications, in which the feature of interest can be observed without hovering above the target. Coordinate reference frames used to geo-reference the acquired imagery are illustrated in Fig. 116.5.

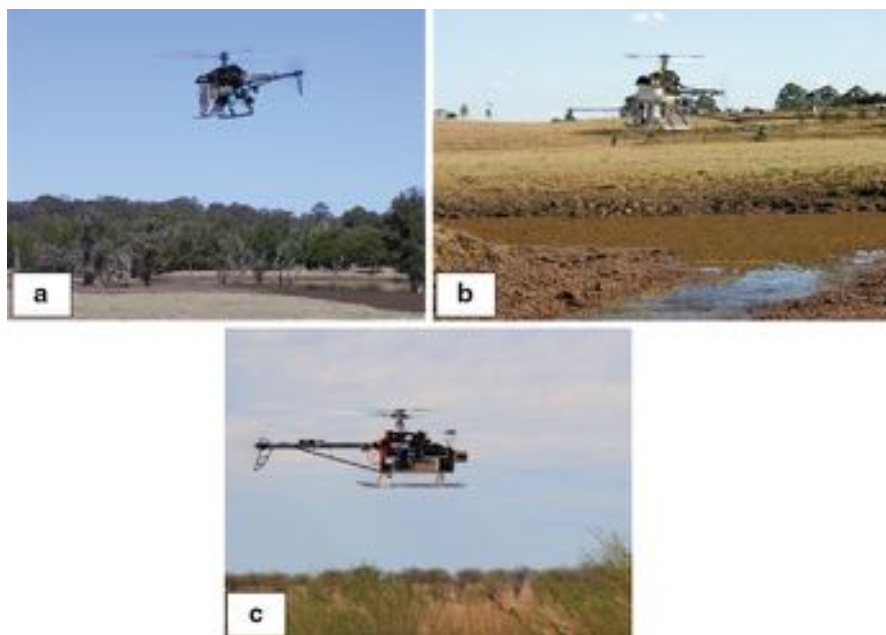

Fig. 116.6 (a) Helicopter UAV equipped with vision payload and downward-looking camera, flying over aquatic habitat for an aerial image acquisition mission, (b) the same helicopter with spraying booms attached, flying low over salvinia-infested water channel spraying a water-soluble non-toxic dye, and (c) helicopter without vision payload, reconfigured with granule dispenser, flying over woody weeds

In addition to two alternative vision payload configurations, the presented helicopter UAV can be easily configured for different missions. As shown in Fig. 116.6, it can be configured to carry a high-resolution, downward-looking monocular camera along with a high-accuracy navigation sensor for aerial image acquisition missions. Logged navigation data can later be used for geo-referencing the captured images. In this configuration, spray booms can also be attached to each side of the helicopter.

The booms are designed to reduce vibration caused by the rotor down draft. Ball joints were installed and the boom hinges to allow for movement of the spray booms when in contact with the ground during takeoff and landing. As shown in Fig. 116.4, the spray liquid tank, spray pump, control system, and power supply are positioned located under the centre of gravity of the helicopter. Hence, changing weight due to spraying operation does not have adverse effects on flight stability. For the proof-of-concept demonstrations, a dye was added to water to enable visualisation of the spray patterns and area covered.

For granule-dispensing missions, the vision payload box can be replaced with a controlled droplet applicator (CDA). The CDA unit consists of a plastic granule flask and an electromechanically driven, custom-designed dosage controller valve and dispensing outlet. In a woody weed management mission, the helicopter can

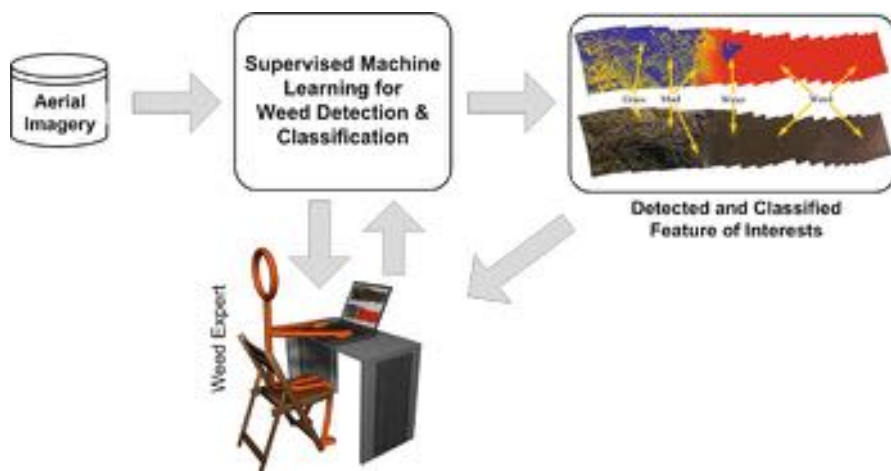

Fig. 116.7 Supervised learning process for weed detection and classification processes

be tasked to hover over the targeted weed cluster and the onboard computer can activate the CDA unit for dispensing predetermined doses of granule herbicides. Weed experts often prescribe just a few grams of weed killer, granular herbicide for a reasonable size woody weed. Thus, the helicopter UAV can be used to target large number of woody weeds in each flight. As has been mentioned in previous sections, due to existing civil aviation rules and regulations in relation to UAV operations, non-toxic granules were dispensed instead of real herbicides.

116.4.2 Weed Detection and Classification

As it is highlighted in Fig. 116.1, keeping a human in the loop, particularly in decision-making tasks, is an important feature of the weed surveillance and management life cycle. Utilisation of weed experts' input into the weed detection, classification, and mapping process is an important requirement for the presented works. In order to utilize the tacit knowledge of weed experts, supervised machine learning techniques are used. In supervised learning the user provides input and the corresponding output data to the machine learning system. The aim of the system is to establish (i.e., learn) a model for the relationships between input and output data sets. The learnt model can then be used to predict the output for any new input data.

Figure 116.7 illustrates the role of the human weed expert in the supervision of the weed detection and classification process. In this process, using a small set of aerial imagery, the weed expert interactively marks a number of regions as FoI and labels them as alligator weed, salvinia, water, mud, etc. The supervised machine learning algorithm takes these labelled learning samples and processes the rest of the aerial imagery to detect the same or similar FoIs.

Fig. 116.8 (a) The helicopter UAV over a weed-infested water channel acquiring aerial imagery. (b) Stitched mosaic of images. (c) The result of the offline weed classification process performed on the same stitched image mosaic. Colors represent the weed probability; *red* indicates high probability; *yellow* is medium probability; and *blue* is low probability

For the aquatic weed detection and classification mission, Support Vector Machine (SVM) technique has been applied to the geo-referenced and stitched aerial image mosaic. The SVM has also been used in a number of different ecological studies (Trebar and Steele 2008; Huang et al. 2002). The aim of the SVM is to map input vector into a multidimensional feature space and locate optimal hyperplane boundaries between classes (Göktoğan et al. 2010; Christopher 1998; Vapnik 2000). Classification results are presented to weed experts in the form of color-coded the probability distributions maps (Fig. 116.8). Weed management plans are made based on these infestation maps. Comparison of the ground truth with the output of classification results proved that the SVM can be used as an effective method for aquatic weed detection. However, further experiments should be performed to develop more effective ways for human-machine interfaces and tuning of the machine learning system.

116.5 Woody Weed Surveillance and Management Using Fixed-Wing and Helicopter UAVs

Woody weed infestations that cover large open rangeland areas are difficult to control, and their management is very costly and time-consuming (Bryson and Sukkarieh 2011b; Reid et al. 2011; Hung et al. 2010, 2012). In the second case study presented in this chapter, mesquite (*mesquite prosopis*), parkinsonia (*Parkinsonia aculeata*), and prickly acacia (*Acacia nilotica*) infestations around Williams Outstation and Carrum in the Julia Creek region of Northwest Queensland are targeted (Fig. 116.9).

Mesquites have a major impact on pastoral and grazing rangelands. They generally grow on floodplains, along watercourses, and aggressively replace grasslands.

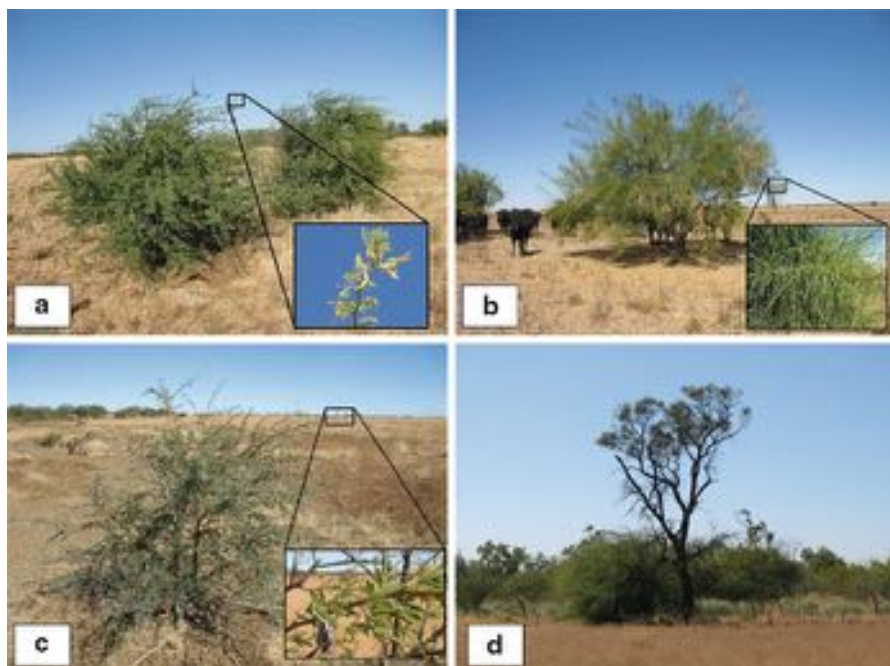

Fig. 116.9 Woody weeds: (a) mesquite (*mesquite prosopis*), (b) parkinsonia (*parkinsonia aculeata*), (c) prickly acacia (*acacia nilotica*), and (d) a native tree around Julia Creek, in Northwest Queensland

They can form impenetrable, thorny, dense bushes around watercourses and restrict native animals' and stock access to water. Feral animals can easily spread mesquite seeds. Parkinsonia is also a thorny woody weed, and its floating seeds can easily spread over large distances in wet seasons. Prickly acacia is introduced to Australia from India and Pakistan as an ornamental. It is dispersed by stock and human activities. These woody weeds outcompete native vegetation which is a major concern to the grazing industry.

In this work, 3D maps of the woody weed infestations are created. The 3D map of the terrain is generated by triangulating a set of dense feature points between subsequent image frames based on the optimal pose data. The pose estimation done by processing IMU and GPS data using an Extended Kalman Filter (EKF) for each image frame captured. Image frames were processed for to extract scale-invariant feature transform (SIFT) features. The extracted SIFT features were matched between consecutive image frames. Identified species are labelled in the infestation maps. Both a fixed-wing and a helicopter UAV platform are used for the surveillance and management missions. A fixed-wing UAV performed broad acre surveillance, and a helicopter UAV performed precision targeting around the weed (Bryson et al. 2011a).

Fig. 116.10 The fixed-wing, 1:3 scale J3 Cup UAV platform used in woody weed and wheel cacti surveillance missions. (a) Typical GCS setup in a remote country site in Northwest Queensland. (b) The UAV taking off, under a human pilot control, from an unsealed road in the bush. (c) The UAV in autonomous flight. (d) The UAV landing onto an unsealed road

116.5.1 Fixed-Wing UAV

A majority of weed surveillance and management UAV missions are performed in remote locations in the Australian bush without dedicated runway. Thus the selected UAV platform must be able to take-off from and land on a dirt surface. Figure 116.10 shows a typical rangeland in Northwest Queensland in which woody weed surveillance and management UAV missions are performed.

With its conventional tractor configuration, the J3 Cub aircraft is a suitable platform for short field operations on rough surfaces such as unsealed roads in unimproved areas. Furthermore, the J3 Cub has a large-size and weight-carrying capability which were required for the payload. Hence, a COTS, 1:3 scale J3 Cub airframe was chosen for use in the performed weed surveillance missions. It then underwent a series of extensive modifications. The main sensor and navigation payload is mounted in the upper fuselage (Fig. 116.11). To isolate it from the engine vibration, isolator mounts were selected based on the vibration frequency, payload mass, and desired level of isolation. This was necessary to isolate the payload from the vibration to increase the reliability of the electronics, improve the quality of the inertial measurement data, and permit the video camera to use slower shutter speeds without motion blur. The fuselage was widened with custom-made fibreglass fairings to incorporate the new mounts and to allow the required movement of the payload.

The internal payload camera required a section of the fuselage bottom to be removed. This was replaced with a Perspex window. A special mounting was made so this could be installed exactly perpendicular to the camera's optical axis to reduce

Fig. 116.11 (a) The fixed-wing 1:3 scale J3 Cub UAV platform with the onboard avionics and downward-pointing color camera, (b) The UAV flying over woody weed infestation

Table 116.2 Basic specifications of modified 1:3 scale J3 Cub fixed-wing UAV

| Fixed-wing UAV | |
|--------------------|---------------------------------------|
| Wing span | 3.58 m |
| Max takeoff weight | 27 kg |
| Engine | Desert aircraft 100cc (twin cylinder) |
| Cruise speed | 90 km/h |
| Max speed | 145 km/h |
| Endurance | 2 h |

reflections. It was also designed to be easily removable for cleaning or to enable the camera lens to be changed. The entire fuselage bay surrounding the camera was painted matt black and sealed off with black tape to prevent the entry of ambient light which may have caused glare on the Perspex window, compromising the quality of the camera images.

To improve the ground handling, a more durable, semi-scale undercarriage was manufactured. This features a bungee shock absorber-type mechanism as per the full scale J3 Cub. For the main wheels, 6 in. radius, low-pressurized soft tires are used. The tail wheel and its steering mechanism were also replaced with a heavier duty design. The final weight of the aircraft was nearly double its design weight, increasing the stall speed and thus the takeoff and landing distance. The aircraft wings were modified to incorporate flaps. Multiple settings allow additional lift at takeoff and additional lift and drag upon landing. A larger engine than standard was also selected to reduce the takeoff distance. The engine-mounting box was designed to incorporate engine isolator mounts to reduce the effects of vibration on the airframe and payload. The final specifications of the aircraft are listed in Table 116.2.

The modular nature of the payload installation in the J3 Cub allows for different payload types to be carried in the future. Its ability to fly for several hours and operate from short, unimproved areas makes it eminently suitable for continuing research of this type.

116.5.2 Woody Weed Surveillance Field Experiments

The main objectives of this experiment were to produce accurate, geo-referenced 3D maps of the terrain of the operational area and to detect and classify the different species of vegetation present in the map. As illustrated in Figs. 116.2 and 116.11, the fixed-wing UAV platform was equipped with a sensor payload box consisting of an IMU, a GPS receiver, and a downward-pointed color camera. Fused IMU and GPS data allowed for the estimation of the UAV's position and orientation at any given time. This information was later used to geo-reference of the detected woody weeds. The same fixed-wing UAV platform configuration was later is used in mapping of cacti infestations over inaccessible semiarid rangelands.

The fixed-wing UAV operated on an approximately 24 km² of test area. In order to survey differences in coverage and spatial resolution, flight plans were prepared in such a way that the fixed-wing UAV operated at two different altitudes: 100 m above ground level (AGL) and 500 m AGL. Based on the camera resolution of 1,024 × 768 pixels and the use of a 12.5 mm camera lens with a field of view of approximately 28 × 22°, this provided an expected spatial resolution of approximately 3.7 cm/pixel and a ground footprint of 38 m at 100 m altitude and, a spatial resolution of approximately 18.6 cm/pixel and a ground footprint of 190 m at 500 m altitude. In this configuration, a flight time of 1 h at a speed of approximately 90 km/h was appropriate. Based on the calculated footprints, a flight pattern of successive swaths along the flight area with approximately 20 % lateral overlap was performed in each flight. In a single flight, the system could cover an area of 4,000 × 600 m at 100 m altitude and an area of 6,000 × 1,500 m at 500 m (MLA 2010).

Once the fixed-wing UAV had completed its mission, the acquired imagery, logged IMU, and GPS data were downloaded at the test site. SIFT features were extracted from overlapping frames and an EKF estimated the UAV pose at the time of each image frame capture. The pose data was used for the calculation of 3D coordinates of the extracted image features. A non-linear least squares bundle adjustment phase was then used to optimize both the trajectory and 3D feature point estimates using all of the raw IMU, GPS, and extracted vision feature data. The 3D feature points and corresponding vision frames were finally used to build a surface model of the terrain on which the collected imagery was used to texture the surface (Bryson et al. 2011b).

In order to detect woody weed crowns, the colour and texture, and the shadows were used. This is a three-phase process involving image segmentation, object detection, and classification. The image segmentation phase divides the image into three different classes based on the color and texture information. Extracted color and texture features are grouped into a single feature vector consisting of 3 color channels and 30 texture channels. Using SVM as the classifier, the feature vectors are then labelled to identify their classes as object, shadow, and background (Hung et al. 2011, 2012). The detected objects are further classified as mesquite, parkinsonia, and prickly acacia and native trees (Fig. 116.12) (Bryson and Sukkarieh 2011b).

Fig. 116.12 A stitched image mosaic of a woody weed infestation. Colored dots indicate classified tree crowns of woody weed and native vegetation. (Blue, parkinsonia; cyan, mesquite; red, mimosa bush; yellow, native tree)

116.6 Cacti and Sleeper Weeds

Wheel cactus (*Opuntia robusta*), which is native to northern Mexico, was introduced to Australia as a hedge and garden plant. It is well adapted to the semiarid environment of southern Australia. As with other weeds, high density of wheel cacti has adverse impact on the native flora and fauna (Patrick et al. 2010). Trial flights for surveillance of the wheel cactus infestations were performed near Oraparinna, in the Flinders Ranges of South Australia (Fig. 116.13). In conjunction with the flight trails, a ground-based survey of cacti in the flight area was also performed. Coordinates of cacti in the test area were recorded into a database as the ground truth. This data was later used for the validation of the detection and mapping algorithms (Bryson and Sukkarieh 2011a).

The operation region has hilly terrain with steep cliffs causing prolonged strong turbulent airflow at low altitudes. Undulated terrain also limits the line-of-sight operations for low-flying UAV. Hence, the fixed-wing 1:3 scale J3 UAV platform was used at an altitude approximately 100 m above the highest point of the terrain.

Unlike previously mentioned aquatic weed and woody weed surveillance and management missions, in the cacti detection mission UAV helicopter was not used for the dispensing of herbicides. The mission was limited to classification and mapping wheel cactus infestations. The main objective of this mission was to demonstrate that UAV platforms with low-cost vision sensor payloads can be used for identification and mapping of cacti in remote locations.

The success of the detection and classification was limited. Although cacti were successfully detected, the classification results also contain a fairly large number of false detections. This can be attributed to the shape of the cacti. As shown in Fig. 116.13, the wheel-like structure of cacti has a narrow horizontal cross section compared to its side view. This makes it difficult to see from the downward-pointed

Fig. 116.13 Wheel cacti (*Opuntia robusta*) on a hilly terrain near Oraparinna, in the Flinders Ranges of South Australia

camera on the fixed-wing UAV platform. Hence, it is envisaged that increasing the spatial resolution of aerial imagery would help improve the classification results.

Wheel cacti are more easily distinguishable from the horizontal perspective. The round, wheel-like appearance of the cacti can be utilized in the future, if aerial imagery can be obtained from a more horizontal perspective using a gimbaled camera on low-flying helicopter UAV platform as shown in [Fig. 116.5b](#). However, strong turbulent airflow due to the undulated terrain is a limiting factor for small-scale helicopter operations (Bryson and Sukkarieh [2011a](#)).

116.7 Conclusion

This chapter presented an Unmanned Aircraft System (UAS) developed as a cost-effective tool for the surveillance and management of weeds. The UAS incorporates a G18 helicopter and a 1:3 scale J3 Cub fixed-wing UAV platform, onboard autopilot, navigation and vision payloads, ground control station (GCS), post-mission image processing and machine learning systems, and operational personnel.

There is a significant scope for this UAS to be actively used in weed surveillance. The UAV platforms provide a means of traversing large distances, accessing difficult

ground and aquatic operation areas. Weed detection, classification, and mapping techniques using aerial imagery continue to improve the efficiency of the weed management life cycle. However, the future holds many new regulatory, operational, and scientific challenges. These form part of the ongoing operational and scientific research in the area.

In addition to specific weeds mentioned in this chapter, there are also another group of weeds called *sleeper weeds* which are invasive plants that become established in a relatively small region and have not spread widely (Brinkley and Bomford 2002). Their limited spread may be due to limited pollinators, or the exotic natural enemies introduced along with the weed or unsuitable environmental and climate conditions (Scott et al. 2009). Early identification, eradication or containment of sleeper weeds before they start spreading rapidly and destroying the native biodiversity is both important environmentally and economically (Cunningham et al. 2004). Successful trials performed on aquatic weed, woody weed, and cacti infestations suggest that, a UAS can have potential to be used in the assessment and identification of risk categories of sleeper weeds.

The UAS has been operated over weed a variety of weed-infested land and aquatic habitats in different regions of Australia. Successful results of these experiments are encouraging and suggest that robotic aircrafts in a properly designed UAS can play an important role in environmental robotics science.

Acknowledgments This work is supported in part by the Australian Centre for Field Robotics (ACFR) funded by the New South Wales State Government and Land & Water Australia (LWA) as a part of the “Defeating the Weed Menace” (DWM) program; by Meat and Livestock Australia (MLA) under project code B.NBP.0474; “UAV Surveillance Systems for the Management of Woody Weeds,” the Australian Weeds Research Council (AWRC) under project code AWRC08-04; the ARC Centre of Excellence program and Linkage Project LP0989291, funded by the Australian Research Council (ARC); and the New South Wales State Government. Authors express their appreciation to Judy Lambert, DWM program Coordinator; Andrew Petroeschovsky, National Aquatic Weeds Coordinator, NSW Department of Primary Industries, Grafton Agricultural Research & Advisory Station; Luke Joseph, Farm & Dam Control Pty Ltd; and SunWater for their invaluable advice. This project would not be possible without the dedicated work of Mitch Bryson, Calvin Hung, Alistair Reid, Nick Lawrence and Zhe Xu, and the support of ACFR’s Aerospace Group members, particularly without the state-of-the-art engineering support from the team of Jeremy Randle, Steve Keep, and Muhammad Esa Attia.

Abstract

Cyber-physical systems (CPS) are tightly coupled systems of hardware and software providing large-scale, closed-loop control or management of high-level, complex dynamical systems. Effective cyber-physical systems require data for operation. Unmanned aircraft systems (UAS), including small UAS (SUAS), can acquire unique data about physical processes, allowing a CPS to efficiently accomplish real-time monitoring, management, or control and actuation tasks. In this chapter, several examples of SUAS sensing-enabled CPS scenarios are presented, enabling adaptive management and effective control of complex physical systems such as water distribution based on measurement of soil moisture and crop evapotranspiration, radio tag-based tracking of fish, alternative energy harvesting, mapping of invasive plant species, and airborne plume (pollution) tracking. This chapter serves as a motivator for potential wide-spreading UAS applications where UAS are used as mobile sensors and/or mobile actuators in large-scale, closed-loop CPS.

117.1 Introduction

As unmanned aircraft systems offer enhanced functionality and utility and improved levels of safety, applications for these versatile platforms will rapidly become abundant in the coming years. Civilian applications for UAS are an emerging field, one that has great potential and the possibility of explosive growth, as aerial vehicles are fully utilized for such applications. The U.S. Congress is aware of these possibilities and has given the Federal Aviation Administration (FAA) a deadline of 2015 for the creation of rules allowing the inclusion and integration of UAS into the greater U.S. National Airspace System (NAS). This integration will not be determined by policy alone; the challenges and opportunities of addressing ethics and the public perception of UAS (Oh 2012) will forever be a part of aviation and robotics as levels of integration and technology progress. The FAA's UAS access rules for the NAS may eventually be in the familiar form of "file and fly," and domestic UAS operations will be commonplace. With the proper certification and standards, government and commercial operations will include regular UAS use, including integration into large-scale operations such as cyber-physical systems.

The possibilities of civilian UAS use in areas ranging from science exploration to high-valued precision agriculture are abundant. Applications in law enforcement, search and rescue operations, intelligence gathering, and fire-fighting applications have been championed as the future of UAS, but such applications are only the beginning: remote sensing and many other technical activities will benefit greatly from the utilization of UAS. In fact, real remote sensing with small SUAS is not only feasible but has significant advantages. Much like the personal computing revolution of the past 40 years, advancements in SUAS will bring remote sensing down to the personal level, allowing for unprecedented levels of knowledge and empowering change for the greater good at smaller scales of operation than ever before.

Fig. 117.1 UAS-sized sensors for water management: thermal and shortwave infrared imagers (Infrared Cameras Incorporated [2012](#); Goodrich ISR Systems [2012](#))

Fig. 117.2 A 10 cm-resolution mosaic of thermal imagery collected by the AggieAir™ small unmanned aerial vehicle system (Coopmans et al. [2012](#))

The rise of SUAS has auspiciously coincided with significant advances in sensors. Currently there are sensors capable of scientific data collection that is perfectly suited to fly in small, low-cost unmanned aerial vehicles (UAVs). As in Fig. 117.1, shortwave infrared (SWIR), thermal infrared (TIR), as well as near-visible infrared (NIR) and visible light cameras can be used to improve agricultural, civil, and scientific data collection in new and exciting ways. Thermal imagery (Fig. 117.2) can be utilized for vegetation monitoring (Berni et al. [2009](#)), and multispectral imagery can be utilized effectively in crop monitoring (Hunt et al. [2010](#)) as well as many wetlands applications (Jensen et al. [2011](#)).

Cyber-physical systems are the future of large-scale sensing and actuation. A key factor in CPS success is data that is detailed enough temporal and spatial resolution for effective operation, and the use of SUAS as mobile sensing platforms will deliver data more frequently and with higher quality than ever before. This chapter attempts to illustrate some perspective UAS-enabled CPS applications given the

current and proximal capabilities of SUAS and to inspire further research toward the goal of CPS. This chapter is organized as follows: Sect. 117.2, cyber-physical systems, introduces the concepts of a CPS and how an SUAS can be utilized within it. The following section, personal remote sensing, focuses on the underlying concepts of remote sensing at the personal level and the challenges associated with it. Sections 117.4–117.8 describe examples of CPS enabled by SUAS. Finally, concluding remarks and discussion on the future of UAS are presented in Sect. 117.9.

117.2 Cyber-Physical Systems (CPS)

Control and management of the real world are challenging, complex tasks. Processes interact at many spatial and temporal scales but when dealt with properly can be controlled just as a simple traditional process. With appropriate choices of sensors and actuators, closed-loop control can be implemented around any controllable process, limited only by the desired outcomes of the controlled system and the complexity of the controller.

A cyber-physical controller (Fig. 117.3) is a general structure that includes a real-world process (the “plant” in controls terminology), estimations of the dynamics of a process under control (an “observer”), and a controller. This allows closed-loop feedback to be instantiated for control of processes that might be outside of traditional definitions of control, such as the moisture in a farm field or the population of fish at an important aquatic site.

Models of physical processes can be used to help predict the behavior of a system in a particular scenario or the reaction of a process to a given input. Cyber-physical control is enabled by modeling (usually digitally) a target process and utilizing that model to make decisions and exert control over the process by way of an actuator or a set of actuators. Since cognitive computer modeling and control of complex processes require higher computational resources for higher accuracy, a computational cloud may be employed, distributing modeling tasks spatially and increasing reliability. Using advanced techniques such as fractional calculus (Jiao et al. 2012), sophisticated models of physical processes can be constructed with proper boundary conditions and, when refined by quality data, can be reliably and robustly controlled in real time.

Control loops cannot be closed without feedback data. Due to the nature of cyber-physical control, the process under control can be multivariate, and therefore, cyber-physical controllers (CPCs) potentially have very broad requirements for sensing. Since in any closed-loop system better sensing may equate to better control, providing CPCs with the most useful “best” data is of primary importance.

This is one requirement UAS can effectively fulfill in CPS: they can generate data with high spatial and temporal resolutions about complex processes, allowing for CPC loops to operate on new and heretofore hard-to-control plants.

UAS can also act as actuators in closed-loop scenarios. Chemicals, such as herbicides, can be applied with high precision to areas determined to be in need,

Fig. 117.3 The big picture of closed-loop cyber-physical system control

or a fire-fighting agent can be precisely dropped in advance of a fire's predicted path. A heterogeneous configuration of fixed- and rotary-wing aircraft in teaming scenarios can be beneficial as well; fixed-wing flying sensors can determine areas of interest, and rotary-wing craft can take more specific, detailed data or drop payloads such as ground sensor pods or radio relays for extending network communication. Ground or even underwater vehicles can act as part of this team, with robotic systems of many different kinds working together to become a cohesive cyber-physical system.

Networked systems, or “systems of systems,” will pervade the physical world in the coming years. These networks are themselves CPSs and must be engineered with the goal of long-term functionality and integration. This means that CPSs of many scales will eventually be integrated, and as in Fig. 117.4, these systems will work together for even more functionality and resilience.

117.3 Personal Remote Sensing (PRS)

Remote sensing is simply detection at a distance. Humans have a given set of perceptions granted by a suite of sensors (eyes, ears, nerves, etc.), but with science, through engineering, it is possible to significantly extend these perceptions. While information can come from many sources, the best way to collect specific information is by the use of a sensor – a device specifically constructed for the purpose of data collection. Multiple sensors may work in concert providing many sources of useful information at once; depending on the information demanded,

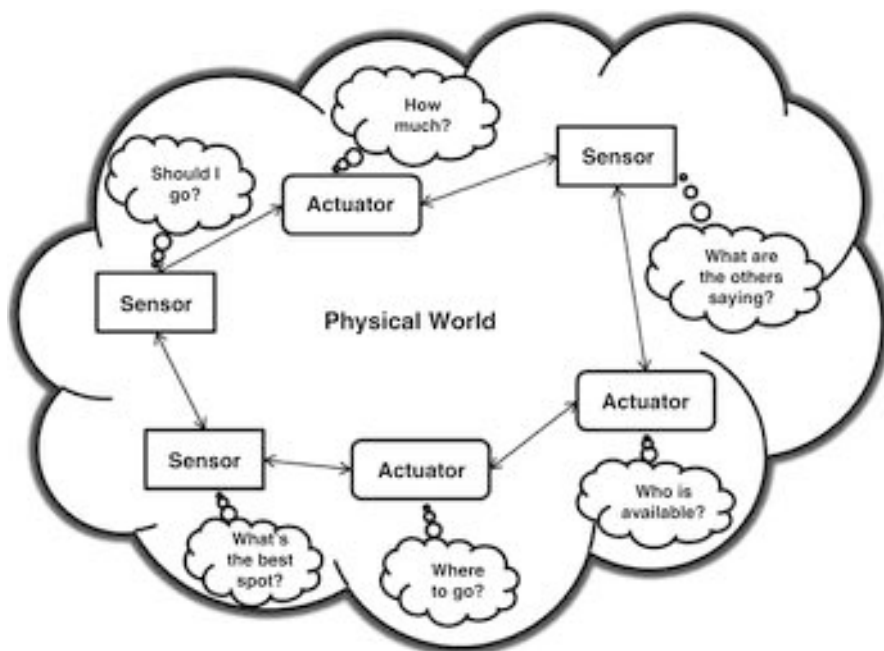

Fig. 117.4 Systems of systems: how many CPS interact to perform complex tasks

these sensors can change modes via communication to gather better data as time passes and requirements or environments change. Remote sensing allows us to gather data at a physical distance, including data for which there is no other way, or no safe way, to collect in person. In difficult-to-access or inhospitable environments, remote sensing is the only feasible method for accurate and reliable data collection.

Remote sensing, depicted in Fig. 117.5, usually connotes large-scale instruments requiring large-scale support operations (such as the Hubble telescope) and financial resources far beyond even the most serious everyday user's budget. Humanity has been attempting to extend the senses to gain advantages or additional knowledge for as long as tools have existed. Devices such as binoculars allow eyes to see further, and the hearing aid extends the range of an ear. These are examples of personal remote sensing: the detection of data useful to a small number of people – perhaps only a single person – on short timescales and within small budgets.

However, to be convenient, sensing requires aspects of autonomy: traditional systems require a large amount of user interaction for useful function. Flying, driving, or otherwise controlling a remote sensing system can be time consuming and in some cases demands high levels of skill or training for consistent quality data. An autonomous system can be preprogrammed to patrol for changes in a scene or “follow” a data trail, such as an airborne pollutant, to collect data automatically. In the case of the use of normalized difference vegetation index (NDVI) in agriculture, a farmer could use a UAS for remotely sensing the plant

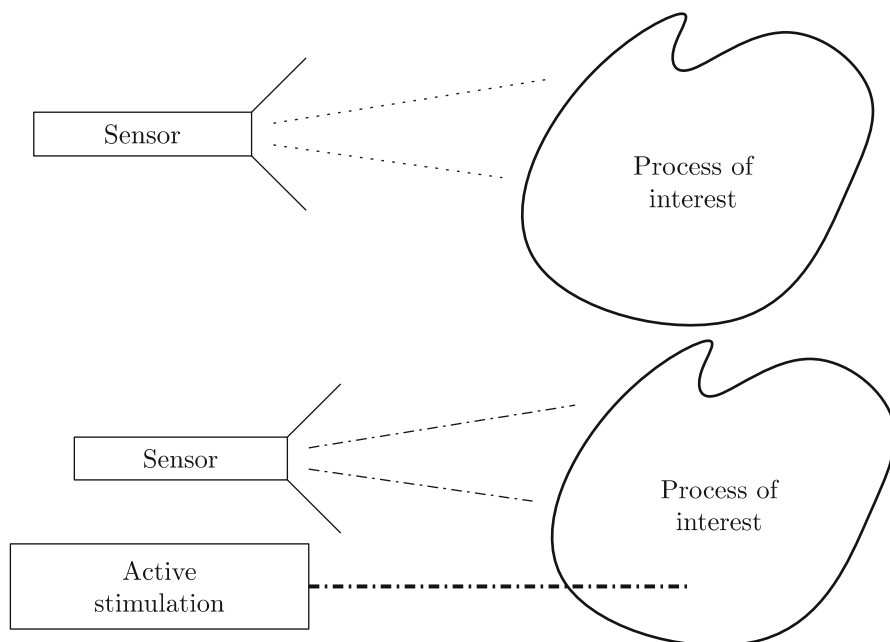

Fig. 117.5 Passive remote sensing vs. active remote sensing, which requires some kind of stimulation to reveal the desired data

growth and vigor, vegetation cover, and biomass in her fields and for determining where water, fertilizer, etc., are needed most. Such a PRS could reduce the costs of the inputs to agricultural production through greater efficiency in application and increase sustainability, yields, and profits.

The key driver for success with PRS systems is cost. Personal remote sensing can only be personal if individuals and small groups can afford to own and operate systems capable of delivering the data they need. Progression of technology (Microelectromechanical (MEMS) devices, embedded processing power, battery power density, etc.) coupled with acceptance of PRS systems by industry, regulators, and legislators, will allow PRS to become commonplace. Low-cost small UAS platforms, constructed for a little as 500 USD, have been demonstrated to be usable for remote sensing (Di and Chen 2011).

Personal remote sensing systems are poised to provide the next generation of useful data about our world. While large-scale remote sensing (like large-scale computing) will always have applications, such as weather prediction, PRS allows individuals or small groups to collect valuable data about situations or processes that concern them specifically. Personal remote sensing is an upcoming and perhaps disruptive technology which will show efficacy when combined with UASs and other autonomous systems. With PRS, new ways of interaction and feedback can be used – with scientific accuracy – to make better, more efficient decisions about what concerns us most.

Fig. 117.6 The MASnet platform with control station and CSOIS MASmote robotic platforms

Although sensing is fundamental, once a decision about managing the world around has been made, action must be taken. Even a nonaction can be considered an active response if properly considered, and therefore, sensing is naturally coupled with actuation. Sensing and actuation cycles can be coupled in a multitude of configurations, and the use of robotic mobile platforms in addition to traditional static sensors can lead to new scenarios which have never before been conceived or implemented.

The Mobile Actuator and Sensor Network (MASnet) research platform in the Center for Self-Organizing and Intelligent Systems (CSOIS) at Utah State University combines wireless sensor networks with mobility (Bourgeois et al. 2006). In other words, the robots can serve both as actuators and sensors. Although each robot has limited sensing, computation, and communication ability, they can coordinate with each other as a team to achieve challenging cooperative control tasks such as formation keeping and environmental monitoring.

The MASnet platform is comprised of MASmotes, an overhead USB camera, and a base station PC, shown in Fig. 117.6. MASmotes are actually two-wheel differentially steered robots that can carry sensors and actuators with MicaZ from Crossbow serving as the processor. Thus, MASmotes support inter-mote communication, sensor data collecting, and pulse-width-modulated (PWM) signal generation. The overhead camera, called pseudo-GPS, is used to determine each robot's position and orientation. Images are processed on the base PC, which also serves for programming board communication and control algorithm computation. The base station communicates with a gateway mote mounted on a programming board by serial link, then the gateway mote then communicates with the MASmotes over a 2.4 GHz wireless mesh network. The base station can send commands and pseudo-GPS information to each MASmote, and all the MASmotes communicate with each other over the 2.4 GHz wireless mesh network.

Using such a hardware platform allows for various scenarios to be studied and proven beyond theory, including acquisition of data with mobile platforms such as UAS, which can be used as mobile actuators to complete the sensing

and actuation cycle. Once this basic framework has been established and proven, many applications for CPS can be implemented in a laboratory environment and experimentally verified before being taken to a much larger scale in the outside world.

Current sources of remote sensed aerial imagery (e.g., manned aircraft and satellites) are either expensive, have low spatial and/or temporal resolution, or have long turnover times. These shortcomings make it difficult to use remote sensing effectively for many applications, yet the market for these services is growing tremendously as costs fall. There are many potential applications for low-cost, effective remote sensing platforms including emergency response and disaster management, land management, resource monitoring, and civil engineering. For example, in emergency response, lives and money can be saved with the ability to send out small UAS to autonomously fly grid patterns over areas of interest for search and rescue operations or disaster zones. Additionally, in many watershed science applications, it is important to have up-to-date, aerial images of a river multiple times throughout the year at different flow levels. However, due to the price of aerial imagery from conventional sources, researchers performing work on rivers are currently limited in their ability to obtain multiple maps over their area of interest within the time frames required. In addition, since a river system can be constantly changing, if the processing turnaround time is too long, the imagery used by field crews will not be up-to-date and will be almost impossible to use. Satellite imagery can be especially difficult to work with because the time when a satellite passes overhead and local weather conditions cannot be controlled.

The AggieAirTM UAS was developed by the Center for Self-Organizing and Intelligent Systems (CSOIS), and the Utah Water Research Laboratory (UWRL) at Utah State University was designed to be the perfect SUAS remote sensing platform in response to a market demand requiring high-quality aerial imagery for agricultural, riparian, wetland, and civil engineering applications.

The AggieAir UAS platform (Fig. 117.7) is an autonomous, multispectral remote sensing platform. AggieAir makes aerial imagery more accessible and convenient by allowing the user to choose when and where the imagery is acquired by giving the user full control of the platform and through the AggieAir platform's independence of a runway. The aircraft launches using a bungee and glides to the ground for a skid landing (Fig. 117.8).

In order to assure mission success for a PRS SUAS, namely, the acquisition of data, extensive testing must take place. Payload handling and fault detection is a very important part of the AggieAir system. Since consumer-level cameras and other sensors are not constructed to a relatively high-quality level, allowances must be made in payload control software architecture. Figure 117.9 shows this software in detail and provides justification for many critical choices in payload design for scientific data collection (Coopmans et al. 2012). The performance of this system can be verified through extensive testing; especially useful is a hardware-in-the-loop simulation testing capability, providing simulated flight data into the payload system for confirmation of performance and reliability over any specific mission.

Fig. 117.7 AggieAir SUAS system diagram (Haiyang Chao 2009)

Fig. 117.8 AggieAir bungee launch and skid landing

During flight, images are captured every 4 s along with data describing the GPS position and aircraft orientation of the UAS at time of exposure of each image. After the UAS has completed a data collection mission and successfully landed, camera imagery and flight information are downloaded from the payload system. The images and their corresponding position and orientation information can be quickly, approximately, georeferenced to generate a map within 30 min after flight (Jensen 2009). However, due to the errors in position and orientation estimation by the aircraft sensors, the images are not perfectly georeferenced. Figure 117.10a shows a set of images that were taken over a river and directly georeferenced. Notice that they appear approximately where they should, but do not align well with each other.

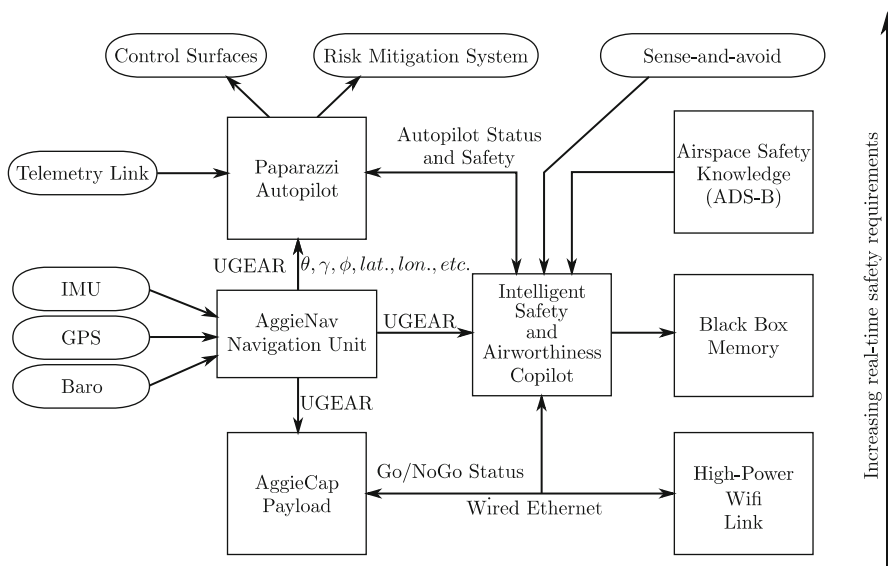

Fig. 117.9 The AggieCap software architecture

While directly georeferenced images might be sufficient for some applications, others need more accurate results. For this EnsoMOSAIC UAV is used. EnsoMosaic UAV, developed by Mosaic Mill of Finland, is an image processing software that reads aerial images captured with compact digital cameras and stitches them into seamless orthorectified image mosaics (MosaicMill EnsoMOSAIC 2012). Figure 117.10b shows an orthorectified mosaic made from the imagery displayed in Fig. 117.10a (generated by post-processing) was prepared and available only 72 h after the data collection flight.

117.4 CPS Enabled by SUAS: UAS-Based Real-Time Irrigation Control (WaterWatch)

Aerial remote sensing can be used to better regulate and control water use by optimally distributing irrigation supplies on the basis of predicted demand.

As seen in Fig. 117.11, a water domain is depicted as a closed-loop control system. Starting with weather and climate, the water becomes available. Combined with water rights, an optimal irrigation policy can be established (Tricaud and Chen 2011; Chao et al. 2008) that will allow the gates and flumes which control water flow to direct the water to its best use. While some water is lost to evaporation and leakage, most will reach the geo-domain of interest, allowing use of the water.

Fig. 117.10 Data collected from AggieAir before (a) and after post-processing (b)

During an example use of the water (a farmer's field), traditional ground sensor pods will determine the moisture level in the application areas, as well as UAS-borne sensors flying above the field. Aerial imagery collected in the visible, near-infrared, and thermal bands can be combined to determine the water content of the vegetation and the surface soils in the scene (Bajwa and Vories 2006), and data fusion can combine the ground and aerial sensor data into the controller, thereby closing the water loop on the particular field in question.

Use of multispectral sensors can provide deep insight into moisture content as seen in Fig. 117.12. Thermal infrared, shortwave infrared, and near-visible infrared, as well as visible light sensors, are needed to complete the picture and provide detailed moisture maps, allowing more data about the distribution of water and enabling greater control or management.

Fig. 117.11 Water distribution and use as a closed-loop control problem

117.5 CPS Enabled by SUAS: Algal Bloom Tracking for Alternative Energy

According to the NSF, “The United States faces a critical challenge to transform our current fossil fuel based energy economy to a stable and sustainable energy economy” (NSF 2012).

Sustainable Energy Pathways, SEP, is a new research program by the NSF, to encourage and “support interdisciplinary efforts by teams of researchers to address the challenges of developing efficient pathways towards a sustainable energy future. *The overarching theme of the solicitation is “sustainability” in all of its facets*” (NSF 2011).

In one example of sustainability, algae grow in wastewater lagoons (such as Logan, Utah City, sewage lagoons, shown in Fig. 117.13) and feed on nutrients from detergents, etc. These algae can be processed and transformed into energy: both biofuels and methane can be produced from algae, allowing small communities to transform local waste into power. Once the algae have been harvested, it is consumed in a bioreactor such as microbial fuel cells as detailed in Dye et al. (2010).

The algae harvesting cycle:

1. Algae grow in a controlled environment (lagoon) fed by wastewater.
2. Algae “bloom,” or rapidly increase, its biomass.
3. When sufficient biomass is available, the algae are harvested, providing raw materials for energy production.
4. The algae lagoon begins growing another batch of algae.

Fig. 117.12 Multispectral data collected from an agricultural scene: (a) Visible and NIR data before flood. (b) Visible and NIR data after flood

To maximize biomass in Step 3 above, feedback is needed to determine when to harvest the algae to maximize production and minimize production times. This feedback can be provided by a UAS in a PRS configuration, flying at an appropriate frequency to estimate and predict the peak algae biomass.

One perspective configuration for using a PRS UAS as a CPS to establish a SEP is seen above in Fig. 117.14. Stations like this one allow production of algae-based power by drawing on wastewater from a local community, keeping the energy pathway short and allowing the highest efficiency. When coupled with other sustainable energy sources such as solar power, the efficiency and autonomy is much higher, allowing for better localization of energy resources.

While algae grow in the phosphorus-rich wastewater of the lagoon, the algae's natural predator, *Daphnia*, presents a threat to the water treatment and energy production processes. When *Daphnia* are present in the water, the algae are only able to decrease the phosphorus by 1/40th the amount if they were alone

Fig. 117.13 A view of the Logan Lagoons from Google Earth (2012)

(Chea et al. 2010). This presents a compelling problem: harvest the algae *before* the *Daphnia* do, when the algae are at peak saturation.

UASs are used to survey the algae and detect the optimum harvesting time for the algae crop. Once this is determined, the algae are harvested by some automated means, and the reactor uses the algae as fuel to produce power. The solar grid shown is mainly for operation of the algae farm; however, if there is a power surplus, it can be directed out as product energy.

As seen in Fig. 117.13, the Logan Lagoons support 8 local districts and at 460 acres and are ideally sized for small UAS data collection. Relative to traditional static (i.e., non-mobile) pod sensors embedded in the ponds themselves, UASs cost less.

117.6 CPS Enabled by SUAS: Invasive Species Management

Accurately assessing changes in wetland vegetation over time is important for both natural resource management and ecological research. A fundamental question in ecology is what drives the distribution of plant species; addressing this question implies that we are able to accurately determine where certain species occur and how their occurrence changes over time. At the same time, natural resource managers need to be able to determine where desirable native plant species occur and how

Fig. 117.14 Algae land: A UAS-enabled CPS for SEP. A water treatment lagoon as a UAS-enabled CPS to create biofuel from wastewater

management activities drive changes in vegetation. One of the biggest challenges for natural resource managers is whether they can accurately track changes in invasive plant species, either their expansion or their retraction, in response to control efforts. Many currently available remote sensing strategies do not operate at fine enough resolutions in space or time to be useful for these ecological and management purposes. Satellite imagery lacks sufficient resolution in both space and time to provide decision-relevant information to wetlands managers. Imagery obtained from the use of conventional aircraft platforms is too expensive for many wetlands management applications. In contrast, high-resolution imagery can be obtained from the application of unmanned aerial vehicles at very low cost in several different spectral bands.

Utah's wetlands are among the most valuable habitats in the state, yet the expansion of invasive species presents an ongoing threat to their productivity in terms of their value for habitat to birds, fish, and wildlife.

Research has been conducted at the Bear River Migratory Bird Refuge (BRMBR) which is located on the northeast shore of the Great Salt Lake, Utah, at the terminus of the Bear River. The Refuge is managed by the U.S. Fish and Wildlife Service as part of the National Wildlife Refuge System; comprises over 115 square miles of marsh, open water, uplands, and alkali mudflats; and is one of the largest wetland complexes along the Great Salt Lake. With this location and size, the Refuge provides critical wetlands wildlife habitat and resting grounds for migratory

Fig. 117.15 Processed and classified UAS imagery for a 4-square-mile area at the BRMBR, Utah

birds along the Pacific Flyway. It is one of the most important habitat areas for migratory birds in North America.

In the work done by researchers at the Utah Water Research Laboratory (UWRL), aerial imagery in the red, green, blue, and near-infrared spectra was obtained for approximately 50 square miles of the BRMBR and used to produce a high-resolution base map of the entire area wherein *Phragmites* is a problem. These data were used in combination with on-ground field inspections to identify specific areas or patches, totaling approximately 12 square miles, where AggieAir UASs were used to conduct aerial sampling at three other points in time. The imagery that was acquired was used to identify the distribution of *Phragmites* within that 12-square-mile area and to measure the spread of *Phragmites* throughout the year. Each of these four high-elevation UAS flights (i.e., one 50-square-mile flight and three flights of 12 square miles each) produced mosaicked and ortho rectified images that have a resolution of approximately 25 cm (see Fig. 117.15a, b).

Recognition of wetland vegetation using remote sensing is very difficult (Yamagata and Yasuoka 1993). A machine learning strategy which uses remotely sensed reflectance data to classify the wetland vegetation into different categories was used to identify *Phragmites* at high accuracy. The approach is based on a multiclass relevance vector machine (MCRVM) that has been successfully used for multiclass land cover classification and crop identification with good results

(Zaman and McKee 2012). The machine has been shown to have good generalization capability. A MCRVM model was trained with the remotely sensed vegetation reflectance data acquired over the BRMBR and the data obtained from on-ground sampling. The MCRVM model was capable of classifying previously unseen data into different categories, including *Phragmites* and other vegetation types growing in the BRMBR. An example of the results of this classification application is shown in Fig. 117.15c, where the location of *Phragmites* (in bright red) has been determined with an accuracy of approximately 95 % (Zaman et al. 2011). After the classification results are obtained, GIS and ERDAS Imagine software is used to estimate the area occupied by different species, or mixes of species, in the wetland.

117.7 CPS Enabled by SUAS: Tagged Fish Tracking and Wildlife Management

In order to preserve our native fish species, managing, monitoring, and studying fish habitat is very important. Extensive fish habitat studies are conducted to minimize environmental impact before building a dam, while restoring natural habitat in a river, or to ensure economic strength of a fisheries market.

An important part of these habitat studies is tracking where these fish are migrating, moving, and living. This is commonly done by tagging a fish with a radio transmitter as seen in Fig. 117.16 and using it to locate the fish after some period of time to see to where it has moved (Hillyard et al. 2009; Gray and Haynes 1979). Locating a tagged fish is done using a receiver and a directional antenna. As the antenna is pointed in the direction of the fish, the beacon sent from the transmitter becomes stronger, and the operator navigates toward the fish. While this method has proved effective, it is time consuming and costly.

An alternative method to track radio-tagged fish is to use the AggieAir SUAS, for which a fish-tracking payload has been developed. With this payload, AggieAir can be used to fly over a body of water and receive the beacon transmitted by a tagged fish, measuring the signal strength and logging other data including position, orientation, and speed of the SUAS. For fish-tracking applications in rivers, one SUAS could be sent along the river to collect data. After the flight, the data can be post-processed into a map that shows the estimated locations of all tagged fish and the variance of the estimations. While this simple solution could work well for a one-dimensional feature like a river, it may not work as well for two-dimensional features such as lakes. A better solution for tracking fish or other animals in a two-dimensional scenario would be using multiple SUASs in formation. Multiple SUASs could better estimate where a tagged fish is and update their flight plans to get better approximations.

In a general radio tracking problem, Frew et al. (2005) proposed a radio localization technique cast as a distributed estimation problem. Consensus within a group of SUASs was reached with a decentralized method; however, the algorithms used are computationally complex and only considered communication with one neighboring SUAS. Korner (Korner et al. 2010) introduced a method using particle

Fig. 117.16 Implantable radiotransponder tags, allowing remote detection of fish of various sizes (From Lotek corporation (2012))

filters to track multiple targets with radio tags, but only one UAS was used. While these methods work well, a simple, decentralized method is needed to work in practice.

117.8 Other Ideas for UAS Sensing-Enabled CPSs

Since the markets for UAS-based remote sensing, personal remote sensing, and civilian unmanned systems in general are under developed, many more ideas, which are ultimately limited by our imagination, can be realized with the AggieAir personal remote sensing platform. Some of these stimulating ideas are presented briefly in this section.

(a) *Optimal Animal Grazing and Herding*

In his book *The Omnivore's Dilemma* (Pollan 2006), Micheal Pollan presents some thought-provoking dilemmas found in our food industry. Further along this line of thinking (relating to scarcity of resources), how will we survive if chemical fertilizer production is no longer possible? One chemical fertilizer-free solution is to revert to more ancient ways of food production, by using the manure produced by animal production to fertilize farmland in a more optimal way.

Figure 117.17 shows a CPS where grazing animals are moved from plot to plot during farming. Simultaneously, UASs are used as mobile sensors to sense water and nitrogen content of the soil. The goal is to make the grassland uniformly grow in a self-sustainable manner, which is only possible if UASs are

Fig. 117.17 Movement of animals during grazing can optimize nutrients in a field

employed as remote sensors in such a large area. Many research questions arise: How many animals per acre? How often are animals' locations changed? How often is aerial data collected? Most importantly, what is the optimal location for the animals at a given time? Perhaps the health of the animals can also be considered in the CPS, allowing for more healthy livestock as well as better land use.

(b) *Multi-UASs for Wind Field Mapping, Pollution, and Plume Characterization*

A UAS could serve as a new measurement platform for the surface wind field because UASs could be easily commanded to any 3D point in the Atmospheric Boundary Layer, which is a difficult mission for meteorological stations. Common microsensors such as temperature, humidity, pressure, and wind speed are now very easily mounted on UASs. Recently, it has become possible to employ multiple small UASs to form a team to measure the horizontal or vertical profile simultaneously. Such a configuration of UASs working in coordination on a common data collection assignment is called a "coven." This capability can offer significant advantages for detection of wind gradients.

The prevailing wind is also called longitudinal wind, which is the wind prediction estimated from larger-scale synoptic data. It is the prevailing direction at the predicted height without considering the surface frictions and complex terrains (see Fig. 117.18). The technique suggested is to send the UAS to measure the wind speed and estimate the noise level at the same time.

The formation shape (Fig. 117.19) could also be changed based on different resolution requirements. For example, a closer formation is needed for areas with turbulence while a formation of larger separation is chosen for prevailing wind dominant areas. The UAS distance could also be determined by the resolution requirements.

(c) *Wildfire and Disaster Emergency Response*

Wildfires are common in much of the Western USA. Many brave men and women give their lives to fight these fires and many millions of dollars are spent controlling the spread of fire and protecting the lives and property of the public.

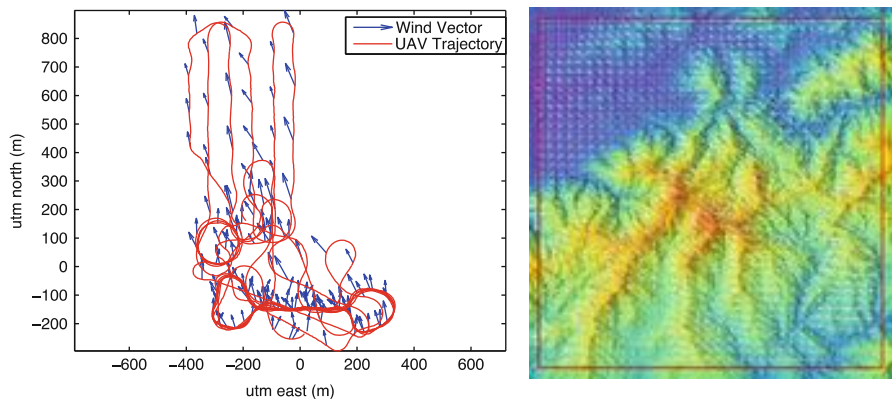

Fig. 117.18 Measured and estimated wind data from UAS flight (Chao and Chen 2012)

Fig. 117.19 A coven of UASs in a cube formation for better characterization of wind field

Figure 117.20 shows a CPS setup to control a wildfire. The UASs pictured on the left includes wind measurement sensors, as well as thermal mapping sensors. While the UASs provide real-time data about the fire, a base station computes the most probable path of the fire and automatically dispatches a larger UAS (to the right of Fig. 117.20) with fire retardant (water, etc.) to preemptively lessen the fire’s destructive power by dropping payload in the most useful location.

Fig. 117.20 Several UASs work together to control a wildfire with sensors and retardant

The prediction of the fire's path can also be used to warn the surrounding populace about the impending arrival of the fire automatically, allowing the residents the most possible time to evacuate before the fire arrives.

(d) *Multi-UAS and Nuclear Radiation Level Characterization and Tracking*

Multiple UASs can work together in a nuclear disaster scenario to profile and help predict the distribution of radiation after an unintended release of radioactive materials. This will help the surrounding populace react to the leak by avoiding the worst of the radiation and allow rescue efforts to be prioritized by suggesting safe zones, while helping manage the radiation exposure of the rescue crews.

The UASs involved can be equipped with total radiation dose (TRD) sensors, allowing a UAS to cognitively determine if it has been exposed to too much radiation and whether it must be decommissioned at a predetermined safe disposal site. In this way, aircraft are used to their fullest potential and any humans involved in a nuclear disaster response scenario are optimally kept from harm's way. Figure 117.21 shows AggieAir small UASs performing cognitive cooperative tasks such as formation flight for sensing.

117.9 Conclusions and UAS-Enabled CPS Outlook

The future of UASs is undoubtedly bright. While the current public perception of UASs is one of espionage and warfare, they will become more accepted into domestic use as their potential value becomes apparent and as the airspace rules change to include them. While current regulations of UASs are restrictive and

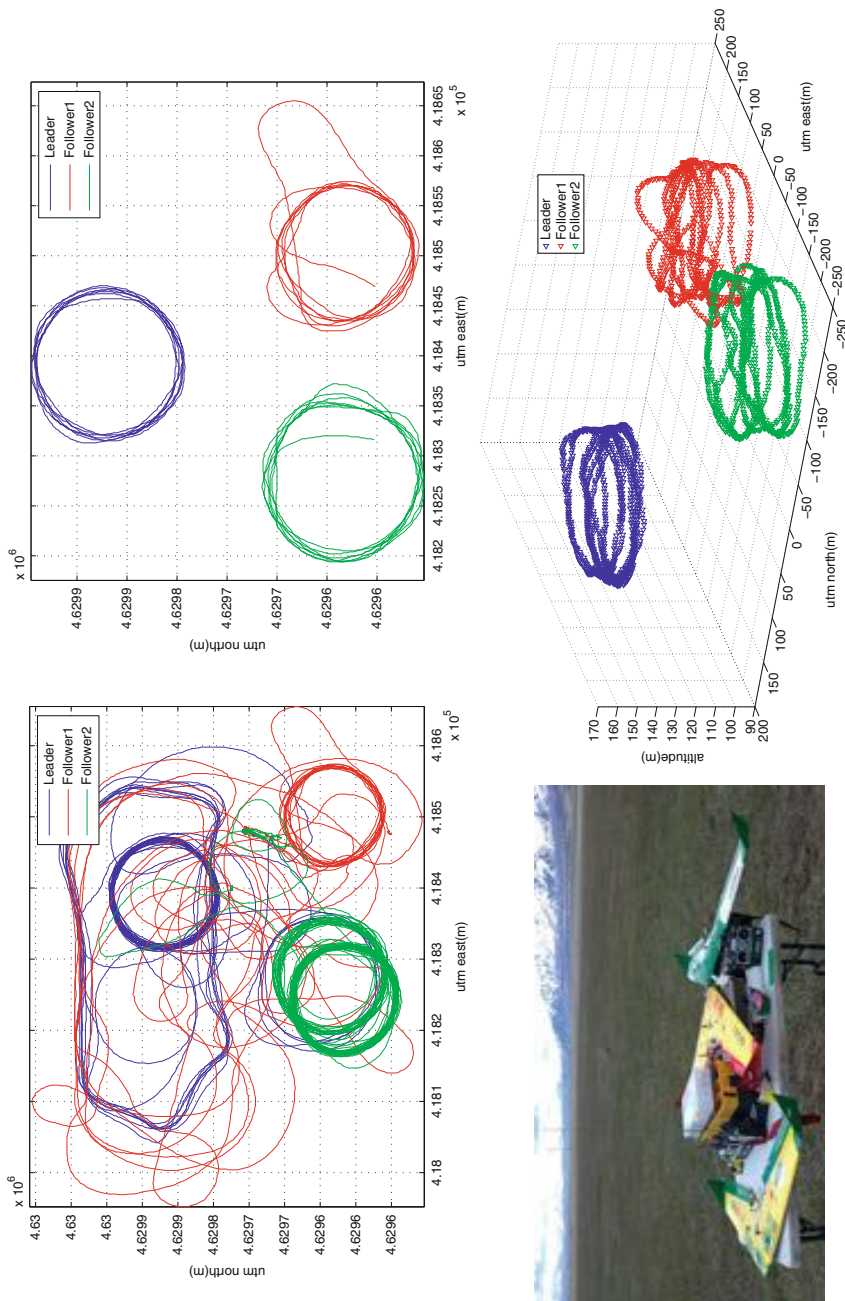

Fig. 117.21 Three UAS formation flight under cognitive autopilots

limited in the USA, soon UASs will become available for regular use as standards for certification and airworthiness are developed.

UAS applications such as search and rescue and precision agriculture are now well known, and more applications appear nearly every day. Small UASs in particular are expected to play a major role in domestic UAS operations. Versatile, inexpensive, and easily maintainable, these smaller systems can be utilized effectively in many applications where fast responses are needed with precision information. Further applications of these systems will lead to their utilization as part of larger cyber-physical systems as sensors or even actuators, providing integration and control on larger scales and higher complexities.

Cyber-physical systems are the future of solving real-world problems such as water management and alternative energy production. By using SUASs as sensors, better data can be collected and used to make informed control decisions, transforming difficult, complex, or abstract problems into closed-loop systems that can be analyzed and controlled.

In the next 15 years, the development of unmanned technology will enable UASs to be mobile actuators, actively exerting control in optimal locations for precision in both sensing and actuation and cognitive control systems for large-scale complex systems that were previously uncontrollable or impractical to control. Management of crisis situations such as food and water shortages, energy production, floods, and nuclear disasters can be assisted by SUASs. Difficult problems can be solved with cyber-physical systems. This chapter serves as a motivator to position small, inexpensive UASs as flying sensors and actuators within the closed loops of cyber-physical control.

the warfighters themselves, making the case for the use of ethical autonomy in unmanned systems, which is deemed necessary since warfare will continue and autonomous robots will ultimately be deployed in its conduct. In this way, one may hope that battlefield atrocities will not become progressively worse given the progression of standoff weapons and increasing use of technology.

► [Moral Predators: The Duty to Employ Uninhabited Aerial Vehicles](#) by Strawser focuses on the supposed objections to the use of UAVs in principle, defending the view that society has a duty to protect an agent engaged in a justified act from harm to the greatest extent possible so long as that protection does not interfere with the agent's ability to act justly. Since UAVs do afford such protection, an argument is made that a nation is obligated to employ UAV weapon systems if it can be shown that their use does not significantly reduce a warfighter's operational capability.

► [Killer Robots: Ethical Issues in the Design of Unmanned Systems for Military Applications](#) by Sparrow argues that designers of unmanned systems used for military applications must consider ethical, operational requirements and limits of such systems. This chapter identifies and discusses a number of issues and offers some analysis of the implications of each issue and how it might be addressed.

The concluding chapter in this section, ► [Ethical Issues of UAVs for National Academy of Sciences](#) contains a transcript of testimony presented by Lucas to a select ad hoc committee convened by the National Academy of Sciences (USA) in response to a request from the U.S. Defense Advanced Research Projects Agency (DARPA) to evaluate the "Ethical and Societal Implications of Advances in Militarily Significant Technologies that are Rapidly Changing and Increasingly Globally Accessible." This testimony was delivered at the inaugural meeting of the committee on 31 August 2011 at the NAS Beckman Center, on the campus of the University of California – Irvine.

Although collectively this section presents diverse but justifiable points of view, we are far from reaching closure on these issues, which will often be revisited as the technology progresses.

Abstract

This introduction provides an overview of ethical and legal challenges arising from the military and security uses of robotics and “unmanned” or “uninhabited” (and sometimes “remotely piloted”) vehicles in a number of relevant conflict environments. The discussion focuses primarily upon the use of autonomous unmanned platforms in combat and low-intensity international conflict but also offers guidance for the increased domestic uses of both remotely controlled and fully autonomous unmanned aerial, maritime, and ground systems for immigration control, border surveillance, drug interdiction, and domestic law enforcement. An outline of the emerging debate concerning “robot morality” and computational models of moral cognition and an examination of the implications of this debate for the future reliability, safety, and effectiveness of autonomous systems (whether weaponized or unarmed) that might come to be deployed in both domestic and international conflict situations are also included.

e-mail: grlucas@nps.edu

The legal and ethical controversy surrounding the use of armed UAVs in military operation began in earnest with the publication of an article entitled “Killer Robots,” by Australian philosopher, Robert Sparrow (2007), arguing that the development of autonomous lethal UAVs in particular would constitute a violation of international law of armed conflict, inasmuch as no predictable or meaningful notion of accountability for “war crimes” could be connected with their use. Subsequently, the Hon. Philip Alston, UN Special Rapporteur for Extrajudicial Executions, publicly denounced the use of UAVs by the USA in particular to carry out “targeted killings” of enemy insurgents within the sovereign borders of nations with which it was not formally at war. These developments and the social and political factors leading to an ever-increasing reliance of conventional military forces on the use of unmanned systems of all varieties was outlined dramatically in a widely read work, *Wired for War*, by Brookings Institution scholar Peter W. Singer (2009).

The case for and against the use of remotely piloted “drones” and the risks associated with proposals to equip subsequent systems with the ability for independent, non-supervised operations (“autonomy”) was thoroughly outlined in a lengthy report funded by the U.S. Office of Naval Research (Lin et al. 2008), while a comprehensive review of the existing legal regime in domestic and international law, coupled with proposals for its clarification and improvement, was undertaken by an interdisciplinary and interinstitutional consortium of legal scholars, engineers, scientists, and philosophers (Marchant et al. 2011). Meanwhile, two of the world’s leading authorities on robotics and computer science cited in Singer’s book subsequently began a series of debates in public appearances and in print, on the one hand defending efforts to develop lethal autonomous systems (e.g., Arkin 2010), while on the other hand roundly condemning such operations, not only as illegal under current international law but as profoundly reckless, dangerous, and irresponsible (e.g., Sharkey 2010).

Finally, a former U.S. Air Force officer and ethics instructor published a widely read article proposing what he termed “the Principle of Unnecessary Risk” (PUR), according to which responsible governments owed their war fighters and security forces every advantage and precaution that could be provided them in the pursuit of their otherwise legal and morally justifiable operations in behalf of national defense and security or law enforcement (Strawser 2010). This meant, according to the author, that the current use of remotely piloted systems, at very least, was not only legally sound but morally obligatory on the part of responsible governments, *provided* that the military and security operations in which they were employed were, in all other respects, firmly within the bounds of law and morality.

The use of “manned” or “remotely piloted” UAVs in pursuit of a nation’s enemies across sovereign national borders, or by nonmilitary personnel carrying out targeted assassinations, continues to provoke legal and moral controversy, while industrial and engineering efforts to develop systems that would operate largely without human oversight or supervision present enormous new legal and moral challenges, particularly for the engineers and defense industries in the logistical procurement and supply chain involved in the design, development, manufacture, and eventual deployment of such systems. A select and representative sample of the authors

and contrasting positions outlined above is presented in this section, while a more detailed survey and analysis of the larger debate, focused particularly upon those issues surrounding engineering design and eventual military use, together with a complete list of references, is provided below.

119.1 Remotely Piloted Systems

A view prevalent among defense industry engineers and U.S. Department of Defense (DoD) policymakers is that, in their present nonautonomous status, unmanned or remotely piloted systems raise no genuinely new legal or moral questions. They merely place the operator at a safe distance from the mission, which is otherwise unchanged. Inasmuch as the distance between a weapons platform and its operator is not itself a relevant factor in determining the justification of a military mission, moral concerns specifically addressed to the development and deployment of these new systems are misplaced. As with most exotic new technologies, the novelty of the technology itself blinds us to the fact that the moral issues involved in its use are entirely familiar and conventional and not appreciably different from those associated with the development of previous and current weapons technology.

There is some measure of truth in this claim, at least as applied to “remotely piloted” systems. A morally and legally justified military mission does not suddenly lose its justification, simply because the pilot is removed from the cockpit. The moral issues *are* nevertheless “technology driven,” at least in the sense that UAVs make feasible missions whose objectives would otherwise prove exceptionally risky, dangerous, and difficult (if not impossible) to undertake from a logistical standpoint. Hence, the criticisms of drone warfare in the literature reflect the legitimate concerns raised by this *dramatic expansion of mission feasibility*, to include an increase in the capacity to undertake or inflict:

1. Assassination or “targeted killing,” especially across or within the sovereign borders of nations with which the attacker is not formally at war
2. Collateral damage to innocents and their property
3. Thereby magnifying the probability for errors in targeting judgment (i.e., mistakes) that would not otherwise be made (since many of the missions in question could not otherwise be undertaken)
4. Perhaps most troublingly, increasing the opportunities and incidents of use of deadly force in a military context by nonmilitary personnel (such as civilian intelligence operatives or private security contractors)

The last emerging aspect of drone warfare is disconcerting on many levels but especially when it involves the summary execution, without any form of “due process,” of a nation’s own citizens allegedly engaged in criminal enterprises abroad.

While it is quite true that such anomalous and morally murky activities often occurred during the conduct of espionage and covert actions, it is equally true that drone technology substantially magnifies the prospects for engaging in such missions. This is one striking feature of unconventional or “irregular” warfare

(Lucas 2009b, 2010). First, adversaries and insurgent interest groups deal with the radical asymmetries in our favor in conventional settings, by disrupting social systems and attacking the weak links in logistical supply chains through the use (for example) of suicide bombers and IEDs that throw conventional military forces seriously off balance. Subsequently, a new technology, initially owned only by the besieged conventional forces, becomes the optimal response. Drone attacks by a technologically advanced nation are systemic in precisely the same sense as non-state actor's (or insurgent's) IEDs and suicide bombers, i.e., disrupting the adversary's command structure, relentlessly hunting him out where he lives and hides, and so demoralizing him in return and hopefully breaking his ability and will to fight. Subsequent legal and ethical questions that might arise stem from this relentless tactical arms race – this perennial “give and take” between political adversaries, or between security forces representing the rule of law, and international criminals intent on circumventing that rule.

119.2 Autonomous UAVs

In what way, if at all, does rendering the robotic or unmanned systems technology autonomous, self-governed, and self-directed (requiring little or no human oversight, once enabled and launched) significantly alter or transform this debate?

Paradoxically, if one is concerned (as in #4 above) about nonmilitary personnel operating military assets and undertaking inherently military operations, then the advent of machine autonomy would indeed transform that debate, since it would no longer be the case that nonuniformed personnel were engaging in military operations. Rather, these missions would henceforth be undertaken solely by machines (presumably with military authorization and oversight). This, in effect, turns “topsy-turvy” the “accountability dilemma” first raised by Robert Sparrow (2007, 2009, 2011) and Noel Sharkey (2007a, 2008b, 2010), in that defenders of these practices could now plausibly claim (albeit again rather disingenuously) that no “nonmilitary personnel” are engaged in questionable actions like extrajudicial killing of adversaries or of allegedly treasonous U.S. citizens. Only machines (and not persons) are undertaking the activities in question. In short, one can make the moral and legal anxieties raised by the policies and practices considered in the other essays in this volume simply disappear, merely by redefining the activities in question as involving “machine behavior exclusively,” and hence immune from the charges leveled against the remotely piloted missions.

This rather odd line of argument merely rings a change on a more familiar denial of responsibility by engineers involved in the research, development, manufacture, and ultimately deployment of any new weapons technology during wartime. That argument consists in the observation that a nation's defense industries, scientists, and privately contracted personnel are, to a large extent, servants or handmaidens of the policy decisions of the ruling government. It is the government and its political leadership and not its defense industries, scientists, or contractors that determine whether and how to prosecute its military conflicts and, accordingly,

whether to use military or nonmilitary means and personnel to do so. Indeed, the senior-level managers and directors of private military contractor and defense contracting firms are often eager to emphasize the point that their efforts support the defense of the State and that their industries and organizations exist solely to support the requirements of the State in carrying out this inherently governmental responsibility.

Such a neat division of labor, conveniently absolving defense contractors of their individual or organizational responsibilities, is hardly as definitive as it might appear, of course, inasmuch as leading military and political decision-makers (or trusted colleagues and associates) often leave government service to work in defense industries or for private military contractors, and vice versa. The boundaries between what or who is military or nonmilitary, public or private, are extremely porous. Even beyond these potential conflicts of interest, however, the public-private division of authority does not specifically excuse defense industries or their employees, in particular, for performing merely as mindless (let alone narrowly self-interested) technocrats. CEOs, as well as essential scientists, engineers, and employees of such industries, are also citizens of the State, who should be concerned to avoid increasing either the risk or the incidence of war through their efforts (even if they might justifiably claim that war's most destructive effects are lessened through their inventions). Their dual responsibilities as citizens, as well as subject-matter experts in military technology, might be said to run parallel to those of military personnel themselves to offer faithful advice, grounded in their professional experience, on the prospects and problems inherent in political policies regarding preparation for or engagement in military conflict (Cook 2004; Lucas 2009a). Thus, as P.W. Singer (2009, 2010), in particular, has forcibly maintained, scientists, engineers, and captains of industry engaged in the development and manufacture of military robots and unmanned systems generally must take upon themselves much more explicitly the responsibility for ensuring their wise and lawful use. This criticism has profound implications for the vocation of defense engineering that are treated in this chapter's conclusion.

119.3 Autonomous UAVs and Force Multiplication

From yet another vantage point, it is a well-recognized problem in robotics and unmanned systems research that the most substantial dividends from automating certain features of the battlefield would come from what is termed "force multiplication." On the one hand, at present, it is already the case that a single Predator or Reaper, remotely piloted by anywhere from one to five human operators, considerably magnifies the ability of military forces engaged in justified missions to accomplish those missions with greater success, precision, and reduction of risk of harm to innocents than their "manned" counterparts. This is an important dimension of what Bradley J. Strawser (2010) defines as "the Principle of Unnecessary Risk" (PUR): when otherwise engaged in legal and morally justifiable military or security missions, military and security personnel are owed as much safety and minimized

risk of harm as available military technology can afford them. The ability to operate several of these platforms simultaneously, under the supervision of a single operator, however, would considerably magnify mission capability without a corresponding increase in scarce and expensive (and nonexpendable) human personnel. Thus, the pursuit of “force multiplication” through some kind of systems engineering modification or technological enhancement of existing military weapons systems is simply an additional logical implication of PUR.

In principle, this objective of “force multiplication” with respect to military robotics in particular can be achieved, in turn, in either of two ways:

1. Either by improving the human-automation interface (e.g., cleaning up the current messy and cluttered Predator/Reaper control stations and replacing them with vastly simplified and more effective governance hardware)
2. Or else by endowing each unmanned platform with enhanced autonomy and independence of operation

The first of these alternative strategies is relatively straightforward and achievable through the application of thoroughly conventional engineering ingenuity (Cummings 2010a,b). One might, in principle, easily replace the four to five computer terminals (and their corresponding keyboards and “mice”) – all of which are presently required to operate a Predator drone – with a single joystick or smartphone “controller.” Importantly, *this path of engineering modification in the pursuit of force multiplication would not invoke any new ethical or legal challenges* beyond those already considered in the ongoing debate about the morality and legality of remotely piloted ISR and lethal missions that are wholly under human supervision and control. That is, *if* it is otherwise deemed ethical as well as legally permissible within the framework of international humanitarian law for a team of operators, for example, to conduct a remote strike against a Taliban or al-Qaeda stronghold, then it remains so even if one replaces the four or five remotely located operators with a single operator employing more efficient command and control technology. Again, this conclusion is consistent with Strawser’s PUR.

Far more esoteric and appealing to engineers and many policy analysts, however, is the “force multiplier” dividend attained by dispensing altogether with the human operator, whether “in” or merely “on” the loop (exercising merely supervisory or “executive” oversight). The appeal is many faceted, from the straightforward projected cost savings anticipated by acquisitions and supply officers to the improvements in “latency” (i.e., signal and reaction time), targeting, and overall mission effectiveness imagined by unmanned systems operators and commanders in the field. Computer scientists and artificial intelligence (AI) researchers are eager to take on such an interesting and engaging challenge.

But to concerned critics, such as Sparrow, Sharkey, Singer, or the eminent computer scientist and “father” of American robotics, George Bekey (2005), this *relentless drive toward machine autonomy* is the source of the most problematic moral and legal conundrums. The seemingly unreflective eagerness of scientists, engineers, and military and political leaders to move ahead with the development of autonomous weapons systems, notwithstanding these objections and concerns of critics, constitutes an attitude toward public welfare and the substantial risk of

unintended consequences that is characterized by these critics as ranging from what, in domestic tort and criminal law, are termed *reckless endangerment* to outright *criminal negligence*.

To make matters even worse, much of this dispute between proponents and critics of enhanced machine autonomy is mired in a nearly hopeless kind of conceptual confusion and linguistic equivocation. Proponents of increased machine autonomy often complicate the issues unnecessarily by invoking spurious concepts like machine “morality” and proposing “ethical governors” for lethally armed autonomous robots (e.g., Arkin et al. 2012). They misleadingly describe autonomous combat weapon systems that would be empowered to make “moral decisions and judgments” and also (in principle at least) experience the machine equivalent of “guilt” from sorties gone wrong and “learn” from those experiences. Consequentially, proponents argue, lethally armed, autonomous military robots will be “more ethical” and even “more humane” than their human counterparts. This use of moral terminology appears unnecessarily provocative and highly misleading, when what is actually being proposed is legal compliance, attained through machine and software program design and not capabilities more akin to human moral judgment.

Critics for their part worry needlessly about “killer robots” running amok (Asaro 2008; Krishnan 2009), as well as the inappropriateness of machines “making decisions to kill humans” (Larkin 2011; Billitteri 2010), or the lack of meaningful accountability for resulting “war crimes” that might consequently be committed (Sparrow 2007; Asaro 2008; Lucas 2011). Such critics appear to envision cyborgs (like “the Terminator”), or the infamous intelligent computer “HAL” (from Arthur C. Clarke’s science fiction novel, 2001: *A Space Odyssey*) in command on the bridge of a nuclear submarine, or “R2D2” and “C3PO,” fully weaponized and roaming the mountains of southern Afghanistan but unable to distinguish (without human supervision) between an enemy insurgent and a local shepherd.

Both extremes are, frankly, preposterous. Enhanced machine autonomy, even when married with lethal force, represents something far different from what either critics or proponents describe or imagine and presents its own unique ethical and legal challenges for engineering and industry, often quite different from those currently under discussion. For one thing, nothing so fanciful nor technologically infeasible as the outlandish scenarios outlined above is required, envisioned, or desired. Machines need not be “ethical,” and it is highly misleading to speak in this fashion. Likewise, machines cannot commit “war crimes,” inasmuch as they lack intentionality or self-motivation, and are utterly devoid of the interests (or emotions) required as ingredients for criminal culpability. Ethics, and accountability under international law, remain firmly and solely in the domain of human experience.

Likewise, the “autonomy” requisite for moral decision-making is something quite distinct from “machine autonomy.” The latter merely involves unmanned systems performing in complex environments without the need for continuous human oversight. In the latter, purely mechanical sense of “autonomy,” a Cruise missile and an iRobot “Roomba” vacuum cleaner are both “autonomous,” in that they perform their assigned missions, including encountering and responding to obstacles, problems, and unforeseen circumstances with minimal human oversight.

But the missile does not unilaterally change its mission en route or reprogram its targeting objectives – let alone does it raise “moral objections” about the appropriateness of the targets selected for it. Likewise, one would probably not wish to equip their Roomba with the additional capacity to “decide” whether or not it is necessary or appropriate to shoot an intruder their home.

In general, one neither needs nor desires autonomous machines to make those kinds of moral judgments. “Single -state, mission oriented” robot sentries in highly scripted environment, such as an “area-denial” scenario, constitute perhaps the sole exception to this general rule (Lucas 2011): e.g., sentry robots in a border or demilitarized” zone or protecting the so-called “no-go” zone around a Naval flotilla, in which ample warning is given, and all attempts made to dissuade violation of the boundaries or prohibited zone.

Paradoxically, the rhetoric of ethics and law have not proven very useful analytical tools in the analysis of machine autonomy, largely because both concepts are so widely misunderstood, misused, and misinterpreted by the participants in this debate. Critics of autonomous lethal platforms worry that these might be indiscriminate and uncontrollable, and in any case, unaccountable for their inevitable “war crimes,” and so illegal from the outset. But this concern, likewise, rests upon a conceptual equivocation: “R2D2” and “C3PO” in the imaginary Afghan scenario above could not ever commit “war crimes.” Unlike these fictional Hollywood portrayals, real autonomous systems have no intentionality or self-awareness. They do not care about their own survival. They have no “interests.” Importantly, they cannot “get scared,” or “get angry,” nor could they possibly try to “get even” (human emotions and intentions which are most often the source of war crimes). Rather, unmanned autonomous platforms would do precisely and only what they were programmed or commanded to do, *unless they happen to malfunction*. The anthropomorphic, romantic nonsense attached to robotics in the popular minds by Hollywood science fiction fantasies seriously compromises the ethical analysis of the use of genuine, real-world military robots within the confines of international law.

119.4 Ethics and Engineering

Robots that, by definition, cannot commit *war crimes* per se but only malfunction or make mistakes require a radically different metric for assessment than the moral metric that is too loosely and inaccurately applied. Moral evaluation of behavior pertains solely to human agents. For robots, as tools, by contrast, one must talk about *safety, reliability, and risk*. It would be madness, for example, to deploy a weapons system that was unsafe or unreliable, that killed the wrong people, or that killed innocent people, instead of destroying the legitimate enemy targets they were designed to attack. Accordingly, in international law as in domestic law, the expectation that would be laid down regarding accountability for wrongful death and destruction would be “due care” and the absence of reckless endangerment or criminal negligence (Lucas 2011). Deploying a patently unreliable system is surely

reckless (and therefore morally culpable) and in extreme circumstances might be found explicitly to be “criminally negligent.” The attitude that Singer, Sharkey, and others discern among engineers and defense industries, all too ready to pursue autonomy without adequate investigation of these problems, would constitute one glaring example of “criminal negligence.”

By contrast, deploying an autonomous platform that has proven to be safe and reliable under rigorous testing in stringent conditions would, on the whole, constitute an acceptable, even a morally responsible, action. If such a system malfunctioned (even as humans and their manned systems sometimes make mistakes, hit the wrong targets, or inadvertently kill the wrong people), then the procedure in the machine case would parallel that of the human case in similar circumstances. An inquiry would be held, and an investigation into circumstances conducted. If no intentional wrongdoing or culpable error by operators was discerned, then well-intentioned governments and their militaries would presumably issue an apology and do their best to make restitution for the harm inflicted.

In these respects, the dilemma of military robotics differs little from that of human combatants, who must be similarly trained to follow the applicable rules of engagement (ROEs) for a given conflict that in turn represent the translations by military lawyers of international humanitarian law and law of armed conflict into actionable mission parameters in given conflicts. Failure to comply due to misjudgments, accidents, and mistakes (that are not attributed to criminal negligence or recklessness, in the human case) is then acknowledged by the respective militaries and their governments: apologies are issued, and compensation for damages (ineffectual though that may be) is offered, in analogy with similar kinds of product liability situations in domestic law.

This process is grounded, however, in the prior expectation of what Michael Walzer (1977/2010) first termed “double intention” (in contrast to the more lenient moral criterion of double effect). Walzer’s principle of “double intention” would, in this instance, hold manufacturers and designers strictly accountable for exercising *due care* (as well as simply for not deliberately *intending* to do harm) in testing and assuring the reliability and safety of their commercial and industrial products (for robots and drones, when all is said and done, are nothing more than that). One would certainly seek to define the engineering design specifications for these products to require that they perform (in morally and legally relevant respects) as well or better than human combatants under similar circumstances. This specification would ensure that autonomous unmanned systems were fully compliant with the constraints of the law of armed conflict and applicable rules of engagement for a given conflict. If they can, and if they do achieve this benchmark engineering specification, then their use is morally justifiable. If they can’t, *or if designers and manufacturers have not taken due care to ensure that they can*, they one has no business building or deploying them. Just like Aegis and Patriot missiles and other semiautonomous systems, *due care* in the development and manufacture of new autonomous systems requires reliable target recognition threat-level escalation, sufficient to lead to a proportionate, discriminate, and therefore appropriate response in the use of deadly force.

The criterion that robots comply as or more effectively with applicable constraints of LOAC on their use of force and doing of harm than human combatants under similar circumstances constitutes the “Arkin Test” for robot “morality” (although this phrasing remains somewhat misleading, as the criterion pertains straightforwardly to compliance with international law, not with the exhibiting of moral judgment; Lucas 2010, 2011). In this sense, the test for “morality” (i.e., for the limited ability to comply with legal restrictions on the use of force) is similar to the “Turing Test” for machine intelligence: the criterion is satisfied whenever machine behavior is indistinguishable from (or better than) human behavior in any given context.

Satisfying this engineering criterion for safety and reliability is quite enough of a technological challenge, without muddying the waters with science fiction or specious metaphysical concerns. Engineers, in any case, are not close to being able to design machines that are fully capable of such activities. The systems they do propose to build and deploy at present have “autonomy” only in a very limited and highly scripted sense. Platforms such as “Sea Scouts,” Israeli-designed “Harpies,” and Korean “border sentry” robots, for example, are all designed to reliably target adversarial threats in extremely limited and very well-defined scenarios. In addition, these weapons systems usually focus on disarming a perceived threat or (as in the case of “Harpies”) dismantling the target’s weapons and command/control technology. Such systems are designed to employ force only in very limited situations that leave little room for ambiguity or error. The mistakes that might nonetheless be made are regrettable but usually not criminally negligent or culpable (as when a child strays into the DMZ or a boater foolishly transgresses the well-defined and well-publicized “no-go” zone around a military aircraft carrier). Naval engineer John Canning has long argued that this targeting of an adversary’s weapon systems (rather than the adversaries themselves) is the proper objective of lethally armed, fully autonomous, unmanned systems (Canning 2008; Canning et al. 2004). Otherwise, such systems should at most be armed with nonlethal weapons or programmed to undertake evasive action rather than use force in self-defense.

119.5 Conclusion

Machines equipped with lethal force need to be designed to operate according to precise engineering specifications, including the specifications that their actions comply accurately and unerringly with relevant international law pertaining to distinction, proportionality, and the avoidance of needless suffering (the so-called cardinal principles of international humanitarian law), as well as to the operant constraints of “standing” and specific rules of engagement (ROEs). Such constraints are identical to those currently imposed upon human combatants in the field (often with less than perfect success). It is needlessly provocative to cite the potential for robots to behave “more ethically” or for autonomous, lethally armed platforms to be “more humane” than human combatants. They are an entirely different class of

entity. Just as with rifles, missiles, and jet aircraft, one demands that they be reliable and safe to operate (meaning they don't malfunction and inadvertently destroy the operator or creator or wantonly destroy property or innocent human life). Ever greater degrees of machine autonomy may be desirable in order to increase the efficiency and "force multiplier" effects of using unmanned systems in a military's overall force mix. But they cannot, nor would a scientifically literate policymaker wish to have them, "behave ethically." Invoking this speculative criterion, in lieu demanding merely reliable operation of UAVs in strict compliance with the law international law of armed conflict, simply confuses the proper objectives of robotics research.

Singer (2009, 2010) is highly critical of what might be characterized as "ethical illiteracy" among engineers, whom he describes as uncomfortable with these questions and all too willing to proceed with their scientific and technological work while leaving the moral concerns to others outside their field. This criticism is not entirely fair: this introductory chapter on ethics and UAVs includes references to the extensive contributions to moral debate and the framing of moral issues in military robotics made by a number of scientists and engineers in the field (e.g., Arkin, Canning, Sharkey). Their work is every bit as significant, and perhaps more credible in their fields, than that undertaken by moral philosophers or experts in international relations. Moreover, much of the engineering contributions to the ethics of unmanned and future autonomous systems is appropriately published in well-regarded scientific and professional journals, such as the *Proceedings of the IEEE*.

Singer may be more accurate in complaining that far too many practitioners in the field are simply unaware of, or unconcerned with, such matters. Far too many members of the engineering profession simply have not stayed current with the ongoing and published research undertaken by their colleagues. Arkin, for example, has developed methods and a plan for operationalizing what he labels the "ethical governance" (i.e., legal compliance) for autonomous machine behavior. Other research teams have pursued alternative, less complex methods of achieving this goal and hence for satisfying the "Arkin Test" (e.g., McGhee et al. 2011; Tessier et al. 2010). Satisfying this test in *some* fashion, however, is not optional but constitutes instead a *strict operational and design specification* for future unmanned systems armed with lethal force. Together, these efforts define a program of research involving alternative testable and falsifiable operational parameters, designed to address this essential design specification for future autonomous systems. It therefore constitutes a serious lapse of professional ethics and must henceforth be recognized as professionally inexcusable, for practitioners in the field of military robotics engineering to remain unaware, unconcerned, and uninvolved in this scientific research. Deliberate and willful neglect of this essential dimension of the overall robotics engineering project constitutes what is known as "culpable ignorance." Practitioners guilty of it could henceforth find themselves morally culpable and very possibly criminally liable as well, simply for otherwise pursuing their current lines of research in the absence of this important dimension.

Abstract

This article seeks to provide a background of some of the principal legal issues and initiate a much-needed legal and ethical dialogue related to the use of lethal autonomous robotic technologies in the military context. Following a brief introduction, Sect. 120.2 of this article provides a brief history and illustrations of autonomous robots in the military, including the pending development of LARs. Section 120.3 sets forth a number of important ethical and policy considerations regarding the use of robots in military endeavors. Section 120.4 reviews the current patchwork of guidelines and policies that apply to the use of military robots. Section 120.5 considers the role that international treaties and agreements might play in the governance of LARs, while Sect. 120.6 investigates the potential role of soft law governance mechanisms such as codes of conduct.

120.1 Introduction

Military technology is a field driven by change – the constant pursuit to be better, faster, and stronger. Certain technological achievements like guns and planes have happened in the purview of the public and have revolutionized the world of war as we know it. Yet many technological changes have occurred under the radar, in military labs and private test fields, with the majority of citizens unaware of the leaps and bounds of progress. Robotics is one such modern military technology advancement that has largely escaped public attention to date. Combining the most

advanced electronic, computer, surveillance, and weapons technologies, the robots of today have extraordinary capabilities and are quickly changing the landscape of battle and dynamics of war. One of the most important achievements has been the creation of robots with autonomous decision-making capability [1]. In particular, the development of autonomous robots capable of exerting lethal force, known as lethal autonomous robots (“LARs”) has significant implications for the military and society.

A variety of never before anticipated complex legal, ethical, and political issues have been created, issues in need of prompt attention and action. There have recently been growing calls for the potential risks and impacts of LARs to be considered and addressed in an anticipatory and preemptive manner. For example, in October 2010, a United Nations human rights investigator recommended in a report to the United Nations that “[t]he international community urgently needs to address the legal, political, ethical and moral implications of the development of lethal robotic technologies” [2]. In September 2010, a workshop of experts on unmanned military systems held in Berlin issued a statement (supported by a majority but not all of the participants) calling upon “the international community to commence a discussion about the pressing dangers that these systems pose to peace and international security and to civilians...” [3]. While there is much room for debate about what substantive policies and restrictions (if any) should apply to LARs, there is broad agreement that now is the time to discuss those issues. The recent controversy over unmanned aerial vehicles (“UAVs”) that are nevertheless human-controlled (often referred to as “drones”) demonstrates the importance of anticipating and trying to address in a proactive manner the concerns about the next generation of such weapons, autonomous lethal robotics [4].

120.2 Background on Autonomous Military Robotics

In the United States there has been a long tradition of applying innovative technology in the battlefield that has often translated into military success [5]. The Department of Defense (“DOD”) naturally extended this approach to robotics. Primary motivators for the use of intelligent robotic or unmanned systems in the battlefield include:

- Force multiplication* – with robots, fewer soldiers are needed for a given mission, and an individual soldier can now do the job of what took many before.
- Expanding the battlespace* – robots allow combat to be conducted over larger areas than was previously possible.
- Extending the warfighter’s reach* – robotics enable an individual soldier to act deeper into the battlespace, for example, seeing farther or striking farther.
- Casualty reduction* – robots permit removing soldiers from the most dangerous and life-threatening missions.

The initial generation of military robots generally operate under direct human control, such as the “drone” unmanned aerial vehicles being used by the U.S.

Fig. 120.1 Phalanx Close-In Weapons System (U.S. Navy Photograph)

military for unmanned air attacks in Pakistan, Afghanistan, and other theaters [6]. However, as robotics technology continues to advance, a number of factors are pushing many robotic military systems toward increased autonomy. One factor is that as robotic systems perform a larger and more central role in military operations, there is a need to have them to continue to function (just as a human soldier would) if communication channels are disrupted. In addition, as the complexity and speed of these systems increase, it will be increasingly limiting and problematic for performance levels to have to interject relatively slow human decision-making into the process. As one commentator recently put it, “[m]ilitary systems (including weapons) now on the horizon will be too fast, too small, too numerous and will create an environment too complex for humans to direct” [7].

Based on these trends, many experts believe that autonomous, and in particular lethal autonomous, robots are an inevitable and relatively imminent development [8]. Indeed, several military robotic automation systems already operate at the level where the human is still in charge and responsible for the deployment of lethal force, but not in a directly supervisory manner. Examples include (i) the Phalanx system for Aegis-class cruisers in the Navy “capable of autonomously performing its own search, detect, evaluation, track, engage and kill assessment functions” [9] (Fig. 120.1); (ii) the MK-60 encapsulated torpedo (CAPTOR) sea mine system, one of the Navy’s primary antisubmarine weapons capable of autonomously firing a torpedo and cruise missiles (Fig. 120.2); (iii) the Patriot anti-aircraft missile batteries; (iv) “fire and forget” missile systems generally; and (v) antipersonnel mines or alternatively other more discriminating classes of mines (e.g., antitank) [10]. These devices can each be considered to be robotic by some definitions, as they all are capable of sensing their environment and actuating, in these cases, through the application of lethal force.

In 2001, Congress issued a mandate that stated that by 2010 one-third of all U.S. deep strike aircraft should be unmanned and by 2015 one-third of all ground vehicles should be likewise unmanned [11]. More recently, the U.S. Department of Defense (“DOD”) issued in December 2007 an Unmanned Systems Roadmap spanning

Fig. 120.2 Tomahawk cruise missile on display (U.S. Navy Photograph)

25 years, reaching until 2032, that likewise anticipated and projected a major shift toward greater reliance on unmanned vehicles in U.S. military operations [12].

As early as the end of World War I, the precursors of autonomous unmanned weapons appeared in a project on unpiloted aircraft conducted by the U.S. Navy and the Sperry Gyroscope Company [13]. Multiple unmanned robotic systems are already being developed or are in use that employ lethal force such as the ARV (armed robotic vehicle), a component of the Future Combat System (“FCS”); Predator UAVs (unmanned aerial vehicles) equipped with hellfire missiles, which have already been used in combat but under direct human supervision; and the development of an armed platform for use in the Korean Demilitarized Zone to name a few [14].

The TALON SWORDS platform (Fig. 120.3) developed by Foster-Miller/QinetiQ has already been put to test in Iraq and Afghanistan and is capable of carrying lethal weaponry (M240 or M249 machine guns or a Barrett .50 caliber rifle). Three of these platforms have already served for over a year in Iraq and as of April 2008 and were still in the field at the time, contrary to some unfounded rumors [15]. A newer version, referred to as MAARS (Modular Advanced Armed Robotic System), is ready to replace the earlier SWORDS platforms in the field. The newer robot can carry a 40 mm grenade launcher or an M240B machine gun in addition to various nonlethal weapons. The President of QinetiQ stated the purpose of the robot is to “enhance the warfighter’s capability and lethality, extend his situational awareness and provide all these capabilities across the spectrum of combat” [16].

It is interesting to note that soldiers have already surrendered to unmanned aerial vehicles (“UAVs”) even when the aircraft has been unarmed. The first documented instance of this occurred during the 1991 Gulf War. An RQ-2A Pioneer UAV, used

Fig. 120.3 Foster-Miller
TALON SWORDS robot
(Department of Defense

for battle damage assessment for shelling originating from the USS Wisconsin, was flying toward Faylaka Island, when several Iraqis hoisted makeshift white flags to surrender, thus avoiding another shelling from the battleship [17]. Anecdotally, most UAV units during this conflict experienced variations of attempts to surrender to the Pioneer. A logical assumption is that this trend will only increase as UAVs' direct response ability and firepower increases.

The development of autonomous lethal robotics raises questions regarding if and how these systems can conform as well or better than our soldiers with respect to adherence to the existing laws of war. This is no simple task however. In the fog of war it is hard enough for a human to be able to effectively discriminate whether or not a target is legitimate. Fortunately for a variety of reasons, it may be anticipated, despite the current state of the art, that in the future autonomous robots may be able to perform better than humans under these conditions, for the following reasons [18]:

- The ability to act conservatively: i.e., they do not need to protect themselves in cases of low certainty of target identification. Autonomous armed robotic vehicles do not need to have self-preservation as a foremost drive, if at all.

They can be used in a self-sacrificing manner if needed and appropriate without reservation by a commanding officer.

- The eventual development and use of a broad range of robotic sensors better equipped for battlefield observations than humans' currently possess.
- They can be designed without emotions that cloud their judgment or result in anger and frustration with ongoing battlefield events. In addition, "Fear and hysteria are always latent in combat, often real, and they press us toward fearful measures . . ." [19]. Autonomous agents need not suffer similarly.
- Avoidance of the human psychological problem of "scenario fulfillment" is possible, a factor believed partly contributing to the downing of an Iranian airliner by the USS Vincennes in 1988 [20]. This phenomenon leads to distortion or neglect of contradictory information in stressful situations, where humans use new incoming information in ways that only fit their preexisting belief patterns, a form of premature cognitive closure. Robots can be developed so that they are not vulnerable to such patterns of behavior.
- Robots can integrate more information from more sources far faster before responding with lethal force than a human possibly could in real time. This data can arise from multiple remote sensors and intelligence (including human) sources, as part of the Army's network-centric warfare concept and the concurrent development of the Global Information Grid [21]. "Military systems (including weapons) now on the horizon will be too fast, too small, too numerous and will create environments too complex for humans to direct" [22].
- When working in a team of combined human soldiers and autonomous systems as an organic asset, they have the potential capability of independently and objectively monitoring ethical behavior in the battlefield by all parties and reporting infractions that might be observed. This presence alone might possibly lead to a reduction in human ethical infractions.

The trend is clear: warfare will continue and autonomous robots will ultimately be deployed in the conduct of warfare. The ethical and policy implications of this imminent development are discussed next, followed by a discussion of governance options.

120.3 Ethical and Policy Aspects

There are numerous ethical, policy, and legal issues relating to creation and deployment of lethal autonomous robots. Although an exhaustive list of these issues will not be offered here, a number of the key ones will be outlined. Rather than defending a particular point of view on the technology, the primary aim is to promote awareness of these issues and to encourage lawyers, policymakers, and other relevant stakeholders to consider what may be appropriate legal and regulatory responses to LARs as they are being developed.

120.3.1 Responsibility and Risks

Australian philosopher Robert Sparrow has been a prominent voice in debates about the ethics of lethal autonomous robots. For instance, he examines the complexities associated with assigning ethical and legal responsibility to someone, or something, if an autonomous robot commits a war crime [23]. He considers several possible solutions to this puzzle, including “the programmer,” “the commanding officer,” and “the machine” itself but concludes that each option has its profound share of difficulties [24]. Remaining neutral on whether Sparrow is correct, assigning responsibility to a LAR’s behavior (or misbehavior) is an important matter that warrants further investigation. Along related lines, Peter Asaro doubts whether a robot can be punished in a meaningful way since it is unlikely to possess any form of moral agency, observing that traditional notions from criminal law such as “rehabilitation” and “deterrence” do not seem applicable here [25].

One of the principal justifications for relying on autonomous robots is that they would have access to a greater amount of information than any human soldier. Yet this advantage raises key questions, including whether a robot should ever be permitted to refuse an order and, if so, under what conditions. Refusing an order on the battlefield is of course a serious matter, but should a robot be given more latitude to do so than a human soldier?

Battlefield units containing human soldiers and LARs will raise additional ethical issues relating to risk and responsibility. According to Sparrow, “human beings will start to be placed in harm’s way as a result of the operations of robots” [26]. But will soldiers genuinely be aware of the kinds of risks they are being exposed to when working with robotic counterparts? If not, Sparrow fears that soldiers might place too much trust in a machine, assuming, for example, it has completed its assigned tasks [27]. And even if soldiers are fully aware of the risks associated with reliance on robotics, how much additional risk exposure is justifiable?

120.3.2 Legal Status of Civilians

In any treatment of LARs, the question of potential liability to civilians must be considered. Civilians initially responsible for empowering or placement of LARs may not necessarily be absolved of legal responsibility should the LAR perform unintended consequences. For example, it is entirely possible that a failure to recognize and obey an attempt for surrender could invoke a violation of the Law of Armed Conflict (“LOAC”). If a civilian software writer failed to initially write code that recognized the right to surrender through a flag of truce or other means, then a “reach back” to civilian liability for the breach might be possible. Likewise, if the civilian software writer failed in attempts to program identifiable legally protected structures such as places of worship, hospitals, or civilian schools, the code writer may be subject to potential liability in those scenarios as well.

The use of smaller yet lethal robots is gaining acceptance in battlefield operations. It is entirely possible that a small three foot or less autonomous robot might be thrown or “launched” into an open building or window with lethal gunfiring capabilities much like a whirling dervish [28]. Should this whirling dervish either not be programmed to accept or fail to recognize internationally established symbols of surrender such as a white flag, would the robot’s responsible forces, probably including civilian software code writers, escape legal liability for these omissions?

Similarly, well-intentioned and seemingly complete software programming might go astray in other ways. Under law of war concepts, and specifically the Hague Convention (Hague VIII), it is forbidden to lay unanchored automatic contact mines unless they will become harmless at 1 h or less after the mines are no longer under the control of the person (nation) who laid them [29]. If one examines unmanned vehicles, particularly unmanned underwater sea vehicles launched from a manned “mother ship,” in the event that the mother ship become lost or disabled, the unmanned “robotic” ship vehicle must, consistent with international navigational regulations and protocols, be able on its own to comply with the navigational regulations and responsibilities. No matter the degree of robotic autonomy, a legal responsibility is likely to exist for the actions of the untethered “loose” unmanned vehicle.

Consider the situation described by P.W. Singer in “Wired for War” in which a robot programmed to perform sentry work failed to identify a threatening action [30]. In that scenario in which a bar patron suffers from the hiccups, a robot trained to act as a sentry with accompanying lethal force could reasonably fail to identify the well-intentioned furtive handgun gesture of the bartender so that the patron might be scared so as to lose the hiccups. If the robot sentry failed to identify this mimicked handgun gesture and mistakenly shot the bartender “thinking” a lethal threat existed, it is conceivable that the software writer of the code might be responsible for the mistaken actions.

The above examples illustrate how seemingly complete autonomous robotic systems may still pose legal liability issues upon the civilians initially responsible for their use within battlespace operations. Amidst these scenarios, the civilian software code writer’s work and ultimate responsibilities may enjoy a much longer and unanticipated legal life.

120.3.3 Complexity and Unpredictability

Unfortunately, a full awareness of the risks from autonomous robots may be impossible. Wallach and Allen discuss how predicting the relevant dangers can be fraught with uncertainty [31]. For example, a semiautonomous antiaircraft gun accidentally killed several South African soldiers [32]. Roger Clarke pointed out years ago that, “[c]omplex systems are prone to component failures and malfunctions, and to intermodule inconsistencies and misunderstandings” [33]. Blay Whitby echoes the notion by arguing that computer programs often do not behave as predictably

as software programmers would hope [34]. Experts from computing, robotics, and other relevant communities need to continue weighing in on the matter so the reliability of LARs can be more thoroughly assessed.

Perhaps robot ethics has not received the attention it needs, given a common misconception that robots will do only what we have programmed them to do. Unfortunately, such a belief is sorely outdated, harking back to a time when computers were simpler and their programs could be written and understood by a single person. Now, programs with millions of lines of code are written by teams of programmers, none of whom knows the entire program; hence, no individual can predict the effect of a given command with absolute certainty, since portions of large programs may interact in unexpected, untested ways. Even straightforward, simple rules such as Asimov's Laws of Robotics can create unexpected dilemmas [35]. Furthermore, increasing complexity may lead to *emergent behaviors*, i.e., behaviors not programmed but arising out of sheer complexity [36].

Related major research efforts also are being devoted to enabling robots to learn from experience. Learning may enable the robot to respond to novel situations, an apparent blessing given the impracticality and impossibility of predicting all eventualities on the designer's part. But this capability raises the question of whether it can be predicted with reasonable certainty *what* the robot will learn. Arguably, if a robot's behavior could be adequately predicted, the robot would just be programmed to behave in certain ways in the first place instead of requiring learning. Thus, unpredictability in the behavior of complex robots is a major source of worry, especially if robots are to operate in unstructured environments, rather than the carefully structured domain of a factory or test laboratory.

120.3.4 Just War Theory

An overarching concern is whether the use of LARs is consistent with time-honored principles, rules, and codes that guide military operations, including just war theory, the Law of Armed Conflict ("LOAC"), and the Rules of Engagement. Scholars are already starting to analyze whether LARs will be capable of fulfilling the requirements of just war theory. Noel Sharkey, for example, doubts that robots will be capable of upholding the principle of discrimination, which involves being able to distinguish between combatants and non-legitimate targets such as civilians and surrendering soldiers [37]. While discussing military robots and the principle of proportionality, Sparrow argues that "decisions about what constitutes a level of force *proportionate to the threat* posed by enemy forces are extremely complex and context dependent and it is seemingly unlikely that machines will be able to make these decisions reliably for the foreseeable future" [38]. However, at this point, it remains an open question whether the differences between LARs and existing military technology are significant enough to bar the former's use.

Further, Asaro examines whether military robots may actually encourage wars by altering pre-conflict proportionality calculations and last resort efforts [39]. A fundamental impediment to war is the loss of human life, especially the lives of

fellow citizens; casualties are a significant reason why wars are not more common. Sending an army of machines to war – rather than friends and relatives – may not exact the same physical and emotional toll on a population [40]. Assuming the existence of a just cause, one could celebrate this new calculus, which more readily permits legitimate self-defense. However, this reduced cost may, in turn, reduce the rigor with which nonviolent alternatives are pursued and thus encourage unnecessary – and therefore unjust – wars. While this possible moral hazard obviously does not require us to maximize war costs, it does require efforts to inform and monitor national security decision-makers.

Finally, Singer suggests that these LARs weapons could undermine counterinsurgency efforts, where indigenous respect and trust is crucial to creating a reasonable chance of success [41]. Unmanned weapons may be perceived as indicative of flawed characters and/or tepid commitments and are incapable of developing necessary personal relationships with local citizens. And even if remote controlled or autonomous are more discriminate than soldiers, they are commonly perceived as less so.

120.3.5 Civilian Applications

Technology developed for military purposes frequently has civilian applications and vice versa. For instance, Singer notes how the REMUS, the Remote Environmental Monitoring Unit, was originally used by oceanographers, but later an altered version of it was deployed in Iraq [42]. Further, many federal and state agencies have sought permission to use military technology such as UAVs [43]. Consequently, once LARs are developed for military use, what might the implications be down the road for their use in civilian contexts [44]?

120.3.6 Broader Ethical and Social Considerations

Any decisions and policies regarding military development and use of LARs will impact, and be impacted by, broader technological and social considerations [45]. The failure to acknowledge these considerations upfront, and include them in the analysis, can lead to dysfunctional results and unnecessary failure of legal and policy initiatives. Accordingly, we will highlight some relevant considerations and their potential implications.

Consider first what a LAR actually is: one of many potential functions platformed on a generic technology base, which itself may be highly variable. Thus, a “lethal” function, such as a repeating kinetic weapon mounted on a robotic system, is one that is intentionally programmed to identify, verify, and eliminate a human target. At other times, the same basic robotic system might be fitted for cargo carrying capacity, for surveillance, or for many other functions, either in a military or a civil capacity. “Autonomous” means that the platform is capable of making the necessary decisions on its own, without intervention from a human. This, again, may involve

the lethality function, or it may not: one might, for example, tell a cargo robot to find the best way to a particular destination, and simply let it go [46].

Similarly, “robot” may sound obvious, but it is not. Tracked machines, such as the Talon or PackBot, or UAVs, such as the Predator or Raven, are fairly obvious robotic technologies, but what about “smart” land mines that are inert until they sense the proper triggering conditions and are capable of jumping, or exploding, or doing whatever else they are built to do [47]? What about bombs that, once deployed, glide above the battlefield until finding an enemy target, which are then attacked while sparing cars, busses, and homes [48]? And what about a grid of surveillance/attack cybersects (insect size robots or cyborgs consisting of biological insects with robotic functions integrated into them)? Each cybersect taken alone may be too insignificant dumb to be considered a robot, but the cybersect grid as a whole may actually be quite intelligent [49]. Going one step further, what should we call a weapons platform that is wirelessly connected directly into a remote human brain (in recent experiments, a monkey at Duke University with a chip implanted in its brain that wirelessly connected it to a robot in Japan kept the Japanese robot running by thought so that the robot was in essence an extension of its own physicality) [50]? Even now, the Aegis computer fire control system deployed on Navy vessels comes with four settings: “semiautomatic,” where humans retain control over the firing decision; “automatic special,” where humans set the priorities but Aegis determines how to carry the priorities out; “automatic,” where humans are kept in the loop but the system works without their input; and “casualty,” where the system does what it thinks necessary to save the ship [51].

This brief digression raises serious questions about what a LAR actually is. Certainly, it has a technology component, but in some ways this is almost trivial compared to its social, political, ethical, and cultural dimensions. In fact, one might well argue that in many important ways, a LAR is more of a cultural construct than a technology, with its meaningful dimension being intent rather than the technology system [52]. This is an important point, for it suggests that any legal or regulatory approach that focuses on technology may be misplaced; conversely, it means that the underlying technologies which come together in a LAR will continue to evolve independent or irrespective of any direct controls on LARs – including the functionality of the physical hardware, the sophistication of the software, and the integrated technological capability we call “autonomy.”

It is because the technologies are separate from the use that the discussion of LARs is frequently confused: LARs are often discussed as if they were a “military technology,” when in fact they are a set of technologies that can be integrated in ways that are effective and desirable given current military conditions. Let us begin by identifying two levels at which technologies function: Level I, or the shop floor level, and Level II, or the institutional and social system level [53]. Thus, for example, if one gives a vaccine to a child to prevent her from getting a particular disease, one is dealing with a Level I technology system: the desired goal, no disease, is inherent in use of the technology. On the other hand, if one starts a vaccine program in a developing country in order to encourage economic growth because of

better health, it is a Level II system: use of vaccines may contribute to such a goal, but there are many intervening systems, pressures, policies, and institutions.

To return to LARs, then, one might begin by asking why deploy such a technology in any form? Here, one has serious coupling between Level I and Level II issues. The immediate Level I response is that deployment of LARs would save soldiers' lives on the side that deployed them; many explosive devices in Iraq and Afghanistan that might otherwise have killed and maimed soldiers have been identified, and eliminated, by robots. But this is in some ways only begging a serious Level II question. In World War I, for example, generals thought little of killing 100,000 men at a go by sending them into the teeth of concentrated machine gunfire. Consequently, simply avoiding casualties is an inadequate explanation. That world, however, has changed, especially for the U.S. military, which faces a particularly stark dilemma. It is charged by its citizens with being able to project force anywhere around the world, under virtually any conditions. But, for a number of reasons, American civilians have become increasingly averse to any casualties. So the U.S. military finds itself in the dilemma of being required to project its power without American soldiers dying. Additionally, the long-term demographics are not good: Americans, like other developed countries, are looking at an aging demographic, with the immediate implication that there are less young people to fill boots on the ground [54].

The institutional and social context of military operations for the United States is increasingly one where better military productivity becomes paramount, with productivity measured as mission accomplishment per soldier lost. And robots can potentially contribute significantly to achieving such productivity. It's not just about saving soldier's lives, a Level I technology. It's also about building the capability to continue to project power with fewer casualties, and to do so because culture and society are changing to make fatalities, whether soldier or civilian, less acceptable, which are Level II trends.

In sum, LARS raise a broad range of complex ethical and social issues, which have only begun to address here. Suffice it to say, though, that any attempt to regulate or govern such technology systems must address these issues in addition to the more concrete technological and legal issues. The various models available to attempt this task are discussed in the following sections.

120.4 Existing Governance Mechanisms for Military Robots

At present, there are no laws or treaties specifically pertaining to restrictions or governance of military robots, unmanned platforms, or other technologies currently under consideration within the purview of this article. Instead, aspects of these new military technologies are covered piecemeal (if at all) by a patchwork of legislation pertaining to projection of force under international law, treaties or conventions pertaining to specific technologies and practices, international humanitarian law, and interpretations of existing principles of the Law of Armed Conflict (LOAC) [55].

There are, for example, multiple conventions in international law which purport to deal with specific technologies and practices, such as agreements pertaining to biological weapons [56], chemical weapons [57], certain types of ammunition [58], the hostile use of environmental modification [59], land mines [60], incendiary weapons [61], blinding laser weapons [62], and numerous others [63]. The United States is not a party to all of these conventions, and to the extent their requirements do not rise to the level of customary international law, the United States is not specifically bound by them. On the other hand, the United States has taken considerable interest in the articulation of standards which purport to regulate conduct generally on the battlefield, including how weapons are used. Thus, while no international agreements specifically regulate the use of LARs today, it is possible that such agreements might be negotiated and implemented in the future, as discussed later in this article.

In the interim, it bears mention that there are a variety of other potential existing constraints found in military doctrines, professional ethical codes, and public “watchdog” activities (as well as in international law) that might pertain to the present governance dilemma regarding military robotics. These constraints, generally, were created to address a variety of issues which are not wholly consistent with or applicable to the challenges created by the development and use of robots for military and security purposes. Yet, their existence does provide an architecture upon which to build a system of governance regarding the military use of robots on the battlefield.

As we contemplate employing this existing architecture toward the governance of military robotics, it bears noting that governance systems that are successful in obtaining compliance with a particular policy, rule, or directive share a number of important characteristics. Successful systems of “good governance” involve *clearly defined and articulated* expectations: that is, they identify the precise problems to be solved, changes to be made, or goals to be sought through governance in straightforward terms. The solutions proposed to these problems, moreover, are *realistic*: that is, they do not attempt to articulate ideal norms of what *ought* to be but rather provide feasible norms describing what *can*, in fact, be accomplished, under existing political, cultural, and legal constraints. Successful systems of governance, moreover, are *holistic and inclusive*, in the sense that all stakeholders are identified and involved in some fashion in making the rules. Finally, they issue rules or principles that are *subject to assessment*: that is, the results are capable of measurement and evaluation of effectiveness, in a manner that allows for subsequent amendment and improvement of the requirements when appropriate [64].

If these principles of good governance are not adhered to, expectations and pronouncements often go unheeded. In light of these canons of best practice for good governance, we argue that the goal of technological innovation governance should be to insure that all technological innovation is accomplished within the framework of a culture that respects the long-term effects of such work, while considering, insofar as possible, the likely ramifications of the proposed innovation and development. Appropriate governance should also insure that future end users or consumers of the specified technological innovations are aware of those

ramifications, ideally in the design phase, but at very least well before development or application of the innovations in question. All this should be accomplished, moreover, without placing too heavy of a legislative hand on, nor otherwise discouraging, the creative and competitive energies that generate much-needed innovation.

Measured against the foregoing standards, contemporary governance architecture regarding the innovation and use of military robots would appear wholly inadequate to the task. And yet, there is considerable professional, national, and international infrastructure upon which to hang a regime of articulated goals and proscriptions.

At the professional level, for example, there are multiple codes for ethical guidance regarding both best practices and limits on acceptable professional practice for a wide range of academic and professional disciplines. These are ethical codes that might conceivably find themselves applied in innovation in the field of robotics, especially for participants from professions such as engineering, computer science, biology, medicine, law, and psychology. As a general rule, these ethical codes or guidelines for professional practice are grounded in the traditional responsibilities of their individual professions and do not contemplate the challenges which can be said to presently exist for innovation generally or within the field of robotics specifically. Professions, for example, are often regulated at the state level based upon varying degrees of oversight by private organizations and societies. Those codes speak primarily to issues of the professional's relationship and responsibilities toward clients and customers, as well as toward likely competitors, and likewise address important moral and legal issues such as privacy, intellectual property, and education but often lack any concrete obligations relating to broader social responsibilities for technology development [65].

Some of these internal ethical codes also appear to contemplate the future contexts in which professionals will have to operate. For example, a "Pledge of Ethical Conduct" printed in the commencement program for the College of Engineering at the University of California, Berkley, in May 1998, reads:

I promise to work for a BETTER WORLD where science and technology are used in socially responsible ways. I will not use my EDUCATION for any purpose intended to harm human beings or the environment. Throughout my career, I will consider the ETHICAL implications of my work before I take ACTION. While the demands placed upon me may be great, I sign this declaration because I recognize that INDIVIDUAL RESPONSIBILITY is the first step on the path to PEACE [66].

To date, the most relevant initiative relating to the ethics of military technologies such as robotics is a "Code of Ethics" for robots being proposed by the Republic of South Korea (although the terms of the Code have yet to be fleshed out) [67]. The main focus of the charter appears to deal with social problems, such as human control over robots and humans becoming addicted to robot interaction (e.g., using robots as sex toys) [68]. The document will purportedly deal with legal issues, such as the protection of data acquired by robots and establishing clear identification and traceability of the machines [69].

These internal professional codes and norms are complemented by a host of nongovernmental organizations ("NGOs") which contribute to the transparency

of innovation programs, especially those performed on behalf of the State. The goals and agendas of these organizations are as varied as their names, but their methodologies generally help to educate the end user or consumer about what is being developed and what the future may portend. Such NGOs often succeed in establishing a record of evidence and impact regarding a particular thread of innovation and placing this evidence before the public and state funders (legislatures, policymakers, and appropriate government agencies) and providing news media with the expertise to report on the likely ramifications of proposed technological innovations [70]. An NGO specifically focused on promoting arms control for military robots has recently been formed, called the International Committee for Robot Arms Control ("ICRAC") [71].

At the national level in the United States, existing governance can be described as *decentralized* and, in one sense, *reactionary*. It reflects the *push* and *pull* of multiple constituencies and philosophies regarding the efficacy of support for technological innovation. U.S. federal law and regulation reflect the belief that innovation is best encouraged, on the one hand, by vigorous and unrestrained marketplace competition [72] while recognizing, on the other hand, the need for the government to organize federal funding, encourage innovation, and regulate the more egregious results of commercialization [73]. Within the United States, for example, there appears to be no urgency regarding the coordination of governance of emerging technologies such as robotics within the federal government generally, nor is there any evidence of a prevailing belief that the present governance architecture requires any type of thorough overhaul to respond to the challenges of the twenty-first century. Indeed the President's Council of Advisors on Science and Technology, in its report of April 2008 on nanotechnology, concluded:

[T]here are *no ethical concerns that are unique to nanotechnology today*. That is not to say that nanotechnology does not warrant careful *ethical* evaluation. As with all new science and technology development, all stakeholders have a shared responsibility to carefully evaluate the ethical, legal, and societal implications raised by novel science and technology developments. However, the[re is] . . . no apparent need at this time to reinvent fundamental ethical principles or fields, or to develop novel approaches to assessing societal impacts with respect to nanotechnology [74].

Turning to military uses of robotics, specifically, development and use of robots for military purposes continues to be constrained, as mentioned above, by various restrictions regarding the projection of force found in international law, as translated variously into national laws and regulations. There are, as cited above, multiple conventions which purport to deal with specific technologies and practices. Even though the United States is not a party to all of these conventions nor necessarily bound by all of them, it is nonetheless the case that the United States has taken considerable interest in the articulation of standards which purport to regulate conduct generally on the battlefield, including how weapons are used.

There are five principles which run through the language of the various humanitarian law treaties [75] (the rules) which the United States acknowledges and generally honors regarding the conduct of warfare. These are (i) a general prohibition on the employment of weapons of a nature to cause superfluous

injury or unnecessary suffering, (ii) military necessity, (iii) proportionality, (iv) discrimination, and (iv) command responsibility. These principles, as discussed below, impose ethical and arguably legal restraints on at least some uses of lethal autonomous robots.

First, some weapons, it is argued, are patently inhumane, no matter how they are used or what the intent of the user is. This principle has been recognized since at least 1907 [76], although consensus over what weapons fall within this category tends to change over time. The concept here is that some weapons are *A design-dependent*: that is, their effects are reasonably foreseeable even as they leave the laboratory. In 1996, the International Committee of the Red Cross at Montreux articulated a test to determine if a particular weapon would be the type which would foreseeably cause superfluous injury or unnecessary suffering [77]. The so-called “SIrUS” criteria would ban weapons when their use would result in:

- A specific disease, specific abnormal physiological state, specific and permanent disability, or specific disfigurement
- Field mortality of more than 25 % or a hospital mortality of more than 5 %
- Grade 3 wounds as measured by the Red Cross wound classification scale
- Effects for which there is no well-recognized and proven treatment [78]

The operative term here is *specific*; the criteria speak to technology specifically designed to accomplish more than render an adversary *hors de combat*. This test for determining weapons exclusion is a medical test and does not take into consideration the issue of military necessity. For this reason, these SIrUS criteria have been roundly criticized and rejected by the United States specifically and by the international community generally, notwithstanding support for the general principle against the use of inhumane weapons [79].

The second principle, *military necessity*, requires a different analysis. This principle “...justifies measures of regulated force not forbidden by international law which are indispensable for securing the prompt submission of the enemy, with the least possible expenditures of economic and human resources” [80]. *Military necessity* recognizes the benefit to friend and foe alike of a speedy end to hostilities. Protracted warfare, it assumes, creates more rather than less suffering for all sides. In order to determine the necessity for the use of a particular technology, then, one needs to know what the definition of victory is and how to measure the submission of the enemy in order to determine whether the technology will be *necessary* in this regard.

The third principle, *proportionality*, is of considerable concern to the developer and user of new technologies. A use of a particular technology is not *proportional* if the loss of life and damage to property incidental to attacks is excessive in relation to the concrete and direct military advantage expected to be gained [81]. In order to make this determination, it can be argued, one must consider the military necessity of a particular use and evaluate the benefits of that use in furtherance of a specific objective against the collateral damage that may be caused.

Discrimination, the fourth principle, goes to the heart of moral judgment. Indiscriminant attacks (uses) are prohibited under the rules. Indiscriminant uses occur whenever such uses are not directed against a specific military objective

or otherwise employ a method or means of combat, the effects of which cannot be directed at a specified military target (e.g., indiscriminant bombing of cities). Indiscriminate usage also encompasses any method or means of combat, the effects of which cannot be limited as required, or that are otherwise of a nature to strike military and civilian targets without distinction.

A final principle is *command responsibility*, that principle which exposes a multiple of superiors to various forms of liability for failure to act in the face of foreseeable illegal activities. This is a time-honored principle, grounded on the contract between soldiers and their superiors, which requires soldiers to act and superiors to determine when and how to act. It has a long history reflective of the need for control on the battlefield [82].

A 1997 Protocol to the Geneva Convention requires that each state party “determine whether the employment of any new weapon, means or method of warfare that it studies, develops, acquires or adopts would, in some or all circumstance, be prohibited by international law” [83]. The legal framework for this review is the international law applicable to the State, including international humanitarian law (“IHL”). In particular this consists of the treaty and customary prohibitions and restrictions on specific weapons, as well as the general IHL rules applicable to all weapons, means, and methods of warfare. General rules include the principles described above, such as protecting civilians from the indiscriminate effects of weapons and combatants from unnecessary suffering. The assessment of a weapon in light of the relevant rules will require an examination of all relevant empirical information pertinent to the weapon, such as its technical description and actual performance, and its effects on health and the environment. This is the rationale for the involvement of experts of various disciplines in the review process [84].

Once again, the United States is not a signatory to this Protocol and, thus, technically not bound by its requirements. Nonetheless, to the extent that it sets out reasonable requirements and methodologies for use by states fielding new and emerging technologies, however, this treaty could well set the standard in international law for what may be considered appropriate conduct. A final constraint worth noting is the emerging trend in international law to hold those responsible for fielding weapons which allegedly contravene the principles enunciated above through the use of litigation based on the concept of *universal jurisdiction* [85]. While litigation to date has revolved primarily around allegations of practices such as genocide, torture, rendition, and illegal interrogation, there is no reason to believe that future prosecutions may be justified where decisions regarding illegal innovation, adaptation, and use of weapons systems are made.

These various principles and requirements of international humanitarian law and ethical rules of military conduct would clearly impose some limitations on the development and use of lethal autonomous robots. However, given the ambiguous meaning and uncertain legal binding status of these principles, they are unlikely to adequately constrain and shape the development and use of LARs on their own. Additional oversight mechanisms may therefore be warranted, which are further explored in the subsequent section.

120.5 Legally Binding International Agreements

A more formal and traditional approach for oversight of a new weapons category such as LARs would be some form of binding international arms control agreement [86]. Under existing international law, there is no specific prohibition on lethal autonomous robots. In September 2009, robotics expert Noel Sharkey, physicist Jurgen Altmann, bioethicist Robert Sparrow, and philosopher Peter Asaro founded the International Committee for Robot Arms Control (“ICRAC”) to campaign for limiting lethal autonomous robots through an international agreement modeled on existing arms control agreements such as those restricting nuclear and biological weapons [87]. ICRAC called for military robots to be barred from space and that all robotic systems should be prohibited from carrying nuclear weapons [88]. The ICRAC is a small group at this time and as of yet its campaign does not yet seem to have gained the momentum necessary to spark a new international legal regime. However, there is precedent for a nongovernmental organization, the International Committee to Ban Landmines, successfully leading the charge toward banning a weapons system [89].

While ICRAC’s work has raised the issue of limiting lethal autonomous robots through an international arms control agreement, the wisdom of such a course of action is far from clear. Do explicit international legal restrictions on lethal autonomous robots make sense? Are they feasible – both from a political and a technological perspective? Does the ICRAC’s specific proposal make sense? The goal of this section is to make some preliminary points about what the options may be for international legal restrictions on lethal autonomous robots, if a policy choice is made to attempt to restrict them.

International law contains a significant number and diversity of precedents for restricting specific weapons. Existing legally binding arms control agreements and other instruments include a wide variety of different types of restrictions on targeted weapons, including prohibitions and limitations (restrictions that fall short of prohibition) on (i) acquisition, (ii) research and development, (iii) testing, (iv) deployment, (v) transfer or proliferation, and (vi) use.

These various types of prohibitions and limitations form a kind of menu from which the drafters of an international legal instrument addressing lethal autonomous robots – or other emerging warfighting technologies – could choose in accordance with their goals and the parameters of political support for such restrictions. A similar menu could be created of the various types of monitoring, verification, dispute resolution, and enforcement mechanisms that implement the prohibitions and limitations contained in existing international legal arms control instruments.

These prohibitions and limitations (as well as any accompanying monitoring/verification, dispute resolution, and enforcement provisions) can be contained in any of a number of different types of international legal instruments. They are typically contained in legally binding multilateral agreements, including in multilateral agreements primarily focused on arms control and also in the Rome Statute of the International Criminal Court. However, there are also examples of prohibitions and limitations contained in legally binding bilateral agreements, as well as examples of

prohibitions and limitations contained in legally binding resolutions of the United Nations Security Council or in customary international law (which consists of rules of law derived from the consistent conduct of States acting out of the belief that the law required them to act that way). As with the content of the restrictions and their implementing provisions, the choice of type of instrument depends on the drafters' goals and the parameters of political support for the desired restrictions and implementing provisions.

New international legal arms control instruments are typically freestanding. However, there is also at least one existing multilateral legal framework agreement with respect to which it is worth exploring whether that agreement could usefully be amended to itself provide a vehicle for some or all desired restrictions on lethal autonomous robots. This is the 1980 Convention on Prohibitions or Restrictions on the Use of Certain Conventional Weapons Which May Be Deemed to Be Excessively Injurious or to Have Indiscriminate Effects (the CCW) [90], which has been ratified by over 100 state parties [91].

The operative provisions of the CCW are contained within its protocols. The five protocols currently in force contain rules for the protection of military personnel and, particularly, civilians and civilian objects from injury or attack under various conditions by means of fragments that cannot readily be detected in the human body by x-rays (Protocol I), land mines and booby traps (amended Protocol II), incendiary weapons (Protocol III), blinding lasers (Protocol IV), and explosive remnants of war (Protocol V) [92]. It is worth noting that the case that lethal autonomous robots should be restricted by the CCW could be made most effectively if it were argued that such robots are contrary to the "principle," cited in the CCW preamble, "that prohibits the employment in armed conflicts of weapons, projectiles and material and methods of warfare of a nature to cause superfluous injury or unnecessary suffering" [93].

120.5.1 Menu of Types of Restrictions Contained in Current International Legal Arms Control Instruments

Some international legal arms control instruments prohibit a full range of activities involving the targeted weapons. For example, state parties to the Convention on the Prohibition of the Use, Stockpiling, Production and Transfer of Anti-Personnel Mines and on Their Destruction, typically referred to as the "Mine Ban Treaty," commit to not developing, producing, acquiring, retaining, stockpiling, or transferring antipersonnel land mines [94]. The following menu contains additional examples of existing international legal instruments which adopt the specified types of restrictions on a narrower basis:

120.5.1.1 Prohibitions and Limitations on Acquisition

Several international legal arms control instruments completely prohibit the acquisition of targeted weapons. For example, the Biological Weapons Convention ("BWC") prohibits all state parties from acquiring, producing, developing,

stockpiling, or retaining – and requires all state parties to within 9 months destroy or divert to peaceful purposes – (1) biological agents and toxins “of types and in quantities that have no justification for prophylactic, protective or other peaceful purposes” and (2) weapons, equipment, and delivery vehicles “designed to use such agents or toxins for hostile weapons or in armed conflict” [95]. The Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on Their Destruction (“CWC”) prohibits all state parties from producing or acquiring, as well as developing, stockpiling, or retaining, chemical weapons [96].

In contrast, the Treaty on the Non-Proliferation of Nuclear Weapons (“NPT”) creates two classes of states with regard to nuclear weapons [97]. Nuclear-weapon state parties are those which had manufactured and exploded a nuclear weapon or other nuclear explosive device prior to January 1, 1967 (China, France, Russia, the United Kingdom, and the United States) [98]. The NPT does not require nuclear-weapon state parties to give up their nuclear weapons but does require those parties to “pursue negotiations in good faith on effective measures relating to cessation of the nuclear arms race at an early date and to nuclear disarmament” [99]. Non-nuclear-weapon state parties to the NPT are prohibited from receiving, manufacturing, or otherwise acquiring nuclear weapons [100].

The Inter-American Convention on Transparency in Conventional Weapons Acquisitions [101] provides a very different model, with a focus on transparency rather than prohibition of acquisitions. The convention does not prohibit any acquisitions but does require its state parties to annually report on their imports of certain specified heavy weapons, as well as submit notifications within 90 days of their incorporation of certain specified heavy weapons into their armed forces inventory, whether those weapons were imported or produced domestically [102].

120.5.1.2 Prohibitions and Limitations on Research and Development

Few, if any, international legal arms control instruments prohibit all research that could be useful for targeted weapons. Limitations on development differ from instrument to instrument. The CWC flatly prohibits the development of all chemical weapon munitions and devices [103]. In contrast, the BWC contains a more nuanced prohibition, banning the development, production, acquisition, and retention of (1) microbial or other biological agents or toxins “of types and in quantities that have no justification for prophylactic, protective or other peaceful purposes” and (2) weapons, equipment, or means of delivery “designed to use such agents or toxins for hostile purposes or in armed conflict” [104]. It is important to note that restrictions based on quantities or intended use rather than the underlying nature of the technology can be exceptionally difficult to verify, at least without highly intrusive inspections.

120.5.1.3 Prohibitions and Limitations on Testing

Prohibitions and limitations on testing of targeted weapons are most prominent in the nuclear-weapon context. For example, the Comprehensive Test Ban Treaty (“CTBT”), which has not yet entered into force, prohibits “any nuclear weapon test

explosion or any other nuclear explosion” [105]. The CTBT’s entry into force awaits ratification by nine key countries, including the United States [106]. In contrast, the 1963 Treaty Banning Nuclear Weapon Tests in the Atmosphere, in Outer Space and Under Water (also known as the “Limited Test Ban Treaty”) – which unlike the CTBT is in force – specifically prohibits nuclear weapon tests “or any other nuclear explosion” only in the atmosphere, in outer space, and underwater [107]. The Limited Test Ban Treaty also prohibits nuclear explosions in all other environments, including underground, if they cause “radioactive debris to be present outside the territorial limits of the State under whose jurisdiction or control” the explosions were conducted [108].

120.5.1.4 Prohibitions and Limitations on Deployment

Some international legal arms control instruments focus on limiting deployment of the targeted weapons, such as with overall or regional numerical caps. For example, the Strategic Offensive Reductions Treaty, entered into by the United States and Russia in 2002, requires the two countries to reduce their operationally deployed strategic nuclear forces to between 1,700 and 2,200 warheads by December 31, 2012 [109]. The Conventional Armed Forces in Europe Treaty, ratified by the United States in 1992, contains bloc and regional limits on deployment of certain weapons [110].

120.5.1.5 Prohibitions and Limitations on Transfer/Proliferation

Many international legal arms control instruments include prohibitions or limitations on transfer or other proliferation of the targeted weapons. For example, the NPT prohibits parties that possess nuclear weapons from transferring the weapons to any recipient as well as from assisting, encouraging, or inducing any non-nuclear-weapon state to manufacture or otherwise acquire such weapons in any way [111].

The CWC bans the direct or indirect transfer of chemical weapons [112]. The CWC also bans assisting, encouraging, or inducing anyone to engage in CWC-prohibited activity [113]. Similarly, the BWC bans the transfer to any recipient, directly or indirectly, and assisting any state, group of states, or international organizations to manufacture or otherwise acquire (1) biological agents and toxins “of types and in quantities that have no justification for prophylactic, protective or other peaceful purposes” and (2) weapons, equipment, and delivery vehicles “designed to use such agents or toxins for hostile weapons or in armed conflict” [114]. In contrast, the Inter-American Convention on Transparency in Conventional Weapons Acquisitions does not prohibit exports but does require its state parties to annually report on their exports of certain specified heavy weapons [115].

120.5.1.6 Prohibitions and Limitations on Use

Several international legal arms control instruments include prohibitions or limitations on use of the targeted weapons. The International Court of Justice, in its 1996 advisory opinion on the Legality of the Threat or Use of Nuclear Weapons, ruled that “the threat or use of nuclear weapons would generally be contrary to the rules

of international law applicable in armed conflict, and in particular the principles and rules of humanitarian law; However, in view of the current state of international law, and of the elements of fact at its disposal, the Court cannot conclude definitively whether the threat or use of nuclear weapons would be lawful or unlawful in an extreme circumstance of self-defence, in which the very survival of a State would be at stake” [116]. The Rome Statute of the International Criminal Court prohibits (1) employing poison or poisoned weapons, (2) employing poisonous gases, and (3) employing bullets which flatten or expand easily in the human body [117]. This list is potentially expandable. While the CWC bans chemical weapons use or military preparation for use [118], the BWC does not ban the use of biological and toxin weapons but reaffirms the 1925 Geneva Protocol, which prohibits such use [119].

Protocol IV of the CCW prohibits the use of lasers specifically designed to cause permanent blindness [120]. It further obliges state parties to make every effort to avoid causing permanent blindness through the use of other lasers [121]. While prohibiting the use of blinding lasers, the convention does not rule out their development or stockpiling [122]. However, it does outlaw any trade in such arms [123].

120.5.2 Cautionary Note Regarding the Utility of International Legal Arms Control Instruments

It is worth noting that even the broadest and most aggressively implemented international legal arms control instruments suffer from certain inherent weaknesses. For example, existing international legal arms control instruments only apply to states. Their impact on non-state actors is at best indirect (e.g., the CWC and BWC require state parties to prohibit activities on their territory that are prohibited directly for them). Yet non-state actors, particularly transnational terrorist groups, may present a significant threat of utilizing lethal autonomous robots. In addition, these international legal arms control instruments typically require state consent – states can choose not to ratify these agreements and can withdraw from them if they do join [124].

120.6 Soft Law/Governance Approaches

There have been a number of proposed strategies for managing the risks and regulating the uses of emerging military technologies [125]. Those strategies vary in formality and scope. Proposed measures range from formal, binding agreements such as treaties to informal initiatives such as codes of conduct [126]. Oversight of lethal autonomous robots likely falls toward the latter end of this spectrum at least initially, in that some form of coordinated international oversight is warranted, but formal, “hard law” treaties may not be practicable, at least in the short term.

In a growing number of areas of international oversight, ranging from environmental to commercial to social to military issues, traditional “hard law”

treaties and agreements are being supplemented or in some cases displaced by new “soft law” approaches [127]. “Soft law” approaches seek to create and implement substantive principles or norms without creating enforceable legal requirements. The traditional model of binding international regulation that relies on formal treaties negotiated by government officials has a number of limitations, including the excessive resources and time needed to negotiate a formal international agreement, problems in enforcement of and compliance with such agreements, and the lack of flexibility and responsiveness in adapting such instruments to changing circumstances [128].

Many new models of international oversight or harmonization have been developed to circumvent such problems. These new models tend to be more flexible and reflexive, capable of being launched relatively quickly and adapted easily to changing technological, political, and security landscapes. These new soft law approaches have their own limitations, including perhaps most importantly that they are not as binding and often specific as traditional legal agreements. Yet, their growing popularity is due to advantages such as the relative ease by which they can be adopted and updated and the broader roles they create for stakeholders to participate in their substantive formulation [129].

Some of the key soft law/governance approaches that have been applied in other areas of emerging technologies that could conceivably be adapted to military use of robotics are briefly described below.

120.6.1 Codes of Conduct

Codes of conduct are nonbinding and often somewhat general guidelines defining responsible, ethical behavior and which are intended to promote a culture of responsibility. They can be developed and implemented by a variety of different entities, including governmental agencies, industry groups, individual companies, professional or scientific societies, nongovernmental organizations, or collaborative partnerships involving two or more of these entities.

One of the first, and possibly most successful, codes of conduct was at the outset of the field of genetic engineering. The Asilomar guidelines on recombinant DNA research were adopted in the 1970s in response to safety concerns about some early genetic engineering experiments [130]. These guidelines were initially developed by scientists based on discussions at a 1975 conference held at Asilomar, California, were subsequently adopted into more binding guidelines (at least for funding recipients) by the National Institutes of Health in 1976, and were widely complied with by scientists around the world [131]. More recently, codes of conduct have emerged at the forefront of discussions to restrict the use of genetic engineering to create new biological weapons [132]. Although there are concerns that unenforceable codes of conduct will not provide strong enough assurances against the creation of new genetically engineered biological weapons, they may play an important bridging role in providing some initial protection and governance until more formal legal instruments can be negotiated and implemented [133].

In the same way, codes of conduct may play a similar transitional role in establishing agreed-upon principles for the military use of robots.

Codes of conduct are being created for other emerging technologies with potential military applications. The areas of synthetic biology and nanotechnology are two examples. In synthetic biology three different groups have recently proposed competing codes of conduct to manage security implications [134]. The groups are the U.S. Government, the International Association Synthetic Biology (IASB), and the International Gene Synthesis Consortium (IGSC) [135]. This proliferation of competing codes flags a key question about who has the authority and influence to promulgate effective codes of conduct that relevant parties will comply with.

A number of codes of conduct have also been created in the field of nanotechnology. The first code was developed by the Foresight Institute in the form of “guidelines,” with a primary objective of discouraging the creation and deployment of autonomous replication nanosystems [136]. The Foresight Institute guidelines have since been updated six times [137], demonstrating the flexibility and adaptivity that is possible with codes of conduct which can be relatively easily updated (at least compared with a treaty or other more formal instrument). The current Foresight guidelines are extremely thorough and address issues and implications of nanotechnology in professional, industry, military, health, policy, and other contexts [138]. The guidelines are based on the premise that professional ethics and soft law measures can be at least as effective as hard law in promoting safe practices [139]. The drafters of the Foresight guidelines also recognize the value in promoting the least restrictive legal alternative while developing good practices in areas of emerging technology [140].

The European Union recently adopted a code of conduct for nanotechnology researchers [141]. The code promotes a responsible and open approach to research conducted within a safe, ethical, and effective framework [142]. Regular monitoring and revision of the code will occur in order to keep the code current with advances in nanoscience and nanotechnology [143].

Another nanotechnology code of conduct originating in Europe, but with international applicability, is the Responsible NanoCode [144]. The Responsible Nanocode is an example of a code of conduct developed as a result of significant collaboration and designed to reach a wide target audience. The creators are United Kingdom’s Royal Society, a nanotechnology industry trade group and a public interest organization [145]. The code is for companies that handle nanomaterials, and the specific objective of the code is to “establish a consensus of good practice in the research, production, retail and disposal of products using nanotechnologies” [146]. The code was developed to be universally applicable; it was devised “to be adopted by organisations in any part of the world, under any regulatory regime” [147].

Much of the discourse concerning codes of conduct tend to refer to codes of conduct as a single concept with a singular meaning or interpretation. But codes of conduct can exist on a continuum with respect to their objectives, specificity, audience, and expectations of compliance. The goal of all codes is to affect behavior, but different types of codes seek to shape behavior in different ways [148].

There are actually three primary types of codes: codes of ethics, codes of conduct, and codes of practice [149]. Codes of ethics entail professionalism; codes of conduct espouse guidelines of appropriate behavior; codes of practice embody practices to be enforced [150]. Many commonly referred to codes of conduct may, in reality, be a combination of two or even all three types of codes.

The principal benefit of codes of conduct may not be the codes themselves but rather the educational and cooperation-building effects of working on developing a code [151]. So, notwithstanding the ultimate utility and efficacy (or lack thereof) of a code, the production of the code itself may have expressive value. The discussion and collaboration required to develop a code raises awareness of relevant issues and prompts dialogue between relevant parties [152]. It is important that individuals, institutions, and countries are aware of their ethical obligations [153]. Once a code is created, it can help achieve that end by being a valuable educational tool [154]. It is critical that countries are aware of other countries' intentions and limits when it comes to the use of autonomous robots, and so it is reasonable to expect that the exercise of attempting to develop a code of conduct addressing these issues could have both utility and educational benefits.

Even though their tangible outcomes may be hard to identify, measure, and quantify, codes of conduct possess unique features which make them attractive informal measures. The multiple codes of conduct that exist in the synthetic biology and nanotechnology industries highlight some of the salient benefits and drawbacks of codes of conduct. In terms of benefits, they can be created rather quickly – compared to the time it would take to develop formal legal regulations – they can be drafted by interested parties who are knowledgeable in the area, and they can be customized to address unique properties of a technology. On the other hand, there can be difficulties in application. Because anyone can craft a code of conduct, when multiple codes are introduced into an area, whose code takes precedent? There is no hierarchical relationship among codes of conduct that would provide a clear sense of priority. The strengths of codes of conduct and other soft law mechanisms – being voluntary, cooperative, flexible measures – come at a price: they have no rank order; they are all on the same playing field.

Despite sounding like a straightforward concept, it is not a simple process to create a code of conduct. Drafting a comprehensive, appropriate, and effective code requires a thorough consideration of a myriad of issues, attention to detail, as well as a proper balancing of the policy interests of interested parties [155]. While a code of conduct will not likely be sufficient to ensure the appropriate and ethical use of autonomous military robots, the process of creating and disseminating such a code is undeniably a step forward and can be an important piece or at least starting point of eventual treaty or agreement in this area [156].

120.6.2 Transgovernmental Dialogue

“Transgovernmental dialogue” refers to a growing number of informal and flexible arrangements under which governmental officials from different countries meet

on a regular basis to discuss and coordinate policies. These opportunities for discussion provide a forum to share information and “best practices,” to seek to harmonize policies and oversight mechanisms, to coordinate enforcement practices, and to help anticipate, prevent, and resolve international disputes [157]. Through these practices, transgovernmental dialogue can greatly enhance cooperation and influence policy outcomes. It achieves that end through collaborative mechanisms and countries’ shared desire to address a common problem or goal. These types of dialogues are beneficial to the nations involved and are becoming increasingly common in areas requiring international coordination, with national security issues being a prime example [158]. They offer “a structure that is less threatening to democratic governance than private transnational action and less costly than interstate negotiations, yet they can lay a firm foundation for harmonized national regulation and even, if appropriate, for international regulation” [159].

An example of a transgovernmental dialogue in the national security context is the Australia Group, which is an informal forum of officials from 41 nations with a common interest in preventing proliferation of materials that could be used for chemical or biological weapons [160]. Arising out of the experiences of the Iraq/Iran war of the late 1980s, the Australia Group was chiefly concerned with the use of chemical and biological weapons deployed in that conflict, but the Group has subsequently developed a list of dual use [161] items that each country agrees to control through national export regulations. Achieving the goals set forth by the Australia Group depends completely on the voluntary good-faith commitment of the individual countries to the Group’s goals because member countries do not have any legally binding obligations [162]. The group meets annually to discuss ways to prevent proliferation of chemical and biological agents through national export licensing policies and other measures.

Another example of an existing transgovernmental institution is the *International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH)*, which brings together pharmaceutical regulators from the United States, Europe, and Japan, along with pharmaceutical industry representatives from the same three jurisdictions, to coordinate pharmaceutical regulatory policy issues with a view to harmonization [163]. In addition to increasing harmonization, another goal of the ICH is to reduce the need for duplication of testing products, an accomplishment which is intended to reduce delays in the development and distribution of new medicines around the world [164].

A third example is the Organization for Economic Co-operation and Development (OECD), an organization of 30 industrialized countries that has created 2 committees (the Working Party on Manufactured Nanomaterials (WPMN) and the Working Party on Nanotechnology (WPN)) to undertake a variety of informal harmonization activities [165]. The objective of the WPN is to promote international cooperation that fosters the research, development, and responsible commercialization of nanotechnology [166]. The WPN facilitates communication between governments which promotes discussion, awareness, and ideally a coordination of policy responses [167]. Meanwhile, the WPMN is international effort to analyze the environmental health and safety risks posed by nanotechnology [168].

Another example from the nanotechnology realm is the International Dialogue on Responsible Research and Development of Nanotechnology, a forum that has brought together regulators from almost 50 nations every 2 years (2004, 2006, 2008) to discuss nanotechnology regulation [169]. The initial meeting of this forum was sponsored by an NGO (the Meridian Institute), but the national governments volunteered to sponsor subsequent meetings (Japan in 2006 and the EU in 2008).

These various examples of transnational dialogue are effective in starting a discussion among policymakers from different nations and are relatively easy and quick to implement. The only major requirement is a sponsoring organization or nation to convene at least the initial meeting. While not usually creating any binding international policies themselves, such dialogue initiatives can be an important first step to more concrete policy measures in the future and may serve a useful function in that regard to start the dialogue among government policymakers on international policies for military robots.

120.6.3 Information-Sharing and Confidence-Building Measures

Various types of information-sharing and other confidence-building measures have been used to enhance stability, trust, and security for a variety of problems, including in the military and national security contexts. Information-sharing and confidence-building measures (“CBMs”) can be adopted unilaterally or can be coordinated or negotiated among several parties. The concept of CBMs arose in the sphere of international relations, and such measures are frequently used in international conflicts as the initial steps for reducing hostilities between enemies. In this international context, CBMs usually involve some mix of communication, constraint, transparency, or verification measures. Information-sharing mechanisms are one type of CBM. An example of legally implemented information-sharing mechanism is the Biosafety Clearinghouse adopted under the Cartagena Protocol to the UN Convention on Biodiversity, which creates a web-based portal that provides a forum for nations to share information on scientific, risk, regulatory, legal, and ethical determinations from each nation [170].

One could envision a variety of potential CBDs for military robotics, consisting of either unilateral or multilateral initiatives. For example, individual or groups of nations could commit to a limited moratorium on the deployment of such systems. Nations could share information on technical issues with regard to lethal autonomous robots, including issues relating to potential compliance and verification of any future international agreement concerning LARs. Nations could even take relatively minor but helpful steps by convening an international conference to discuss the issue of LARs.

120.6.4 Framework Convention

A final potential soft law mechanism, which is really more of a hybrid between soft law and the more formal international agreements discussed in the previous section,

is a framework agreement or convention. A framework convention, at its most basic level, creates a process and an institutional basis for gradually developing a more substantive international agreement. It consists of an initial agreement to create the framework agreement, often with little or no substantive “teeth” originally, but which sets in place an annual meeting of representatives of the participating nations, perhaps a small secretariat to manage the process, and provisions for negotiating and adopting more substantive protocols that member nations can then consider ratifying on an individual basis. For example, the Vienna Convention for the Protection of the Ozone Layer began as a rather weak agreement but was gradually strengthened by various additions and protocols over time such as the Montreal Protocol and its amendments. Other prominent examples of such framework agreements include the Framework Convention on Climate Change and the Framework Convention on Tobacco.

While the lack of substantive content at the outset may seem a weakness of such agreements, it has the benefit of thereby being nonthreatening to uncertain or recalcitrant states who may otherwise be reluctant to sign onto any international agreement because of major scientific or technological uncertainties or differences in perspective or distrust of other participating states. Once the nations agree to participate in the framework agreement, the process that is created can be the vehicle for greater convergence of positions and building of trust going forward, opening the door for more substantive commitments on an incremental basis. Thus, a framework agreement provides several potential benefits to states, including to:

- Acknowledge that a problem may exist, legitimating it as an international concern.
- Draw the attention of relevant experts, interest groups, and the public to the problem.
- Commit themselves to take, or at least consider, more substantive action if the problem proves to be sufficiently serious.
- Demonstrate that they are taking the issue seriously [171].

In addition to these benefits, the framework agreement can sometimes involve more concrete steps, such as the establishment of technical or scientific committees that can provide important for a for understanding and cooperating on such issues, and also potentially the inclusion of reporting and other information-sharing mechanisms that can improve transparency on an issue. All of these mechanisms and benefits would potentially be timely and useful for addressing LARs.

120.7 Conclusion

Many years ago, David Collingridge recognized a fundamental tension in the governance of new technologies – prior to the development and deployment of the technology, not enough is known about the potential risks of that technology to warrant or guide any restrictions or limitations, whereas once the technology has been developed and deployed, it is often too late to undertake meaningful regulations because the commercial momentum behind the technology is now too strong and entrenched to sway [172]. Lethal autonomous robotics offers an opportunity to

break this cycle. Enough concern and information exists now to consider appropriate governance models in a timely and proactive manner. Yet, the time to take action is short before the current window of opportunity to design a relevant governance or oversight system for LARs closes.

The need to take action on LARs is therefore urgent and timely. This article has not tried to prescribe a specific action or form of oversight but rather has sought to identify the range of possible governance mechanisms that can be brought to bear on this problem. This can range from ethical principles implemented through modifications or refinements of national policies, law of war and rules of engagement, international treaties or agreements, or a variety of other “soft law” governance mechanisms. Of course, any governance approach need not be restricted to any one of these modes of oversight but could involve a combination of two or more approaches. The critical point is that discussions on these options, at both national and international levels, must advance promptly if we are to successfully manage the technological convergence of rapidly advancing robotics technology with military needs, incentives, and temptations.

Abstract

Robots in warfare are an inevitable stage in the evolution of weapon development designed to separate fighters from their foes. Weapon technology has evolved to enable killing from ever-increasing distances throughout the history of warfare. From stones to pole weapons to bows and arrow cannon to aerial bombing to cruise missiles, killing has become ever easier. Battlefield robots may not change the character of war, but they will change the way that wars are fought. The focus of this chapter accordingly is on ethical concerns about the application of armed robots in areas with mixed combatant and civilian populations. It is unclear whether international humanitarian law (the Laws of War) will eventually need to be amended to accommodate emerging technologies. But for now one must scrutinize the mapping between the applications of the new technology and the current laws to ensure that those laws are preserved and followed.

121.1 Introduction

In 2010, the ultimate distance weapons in the sights of military organizations throughout the world are armed robots. To be clear, the robots discussed here are mobile platforms that can carry multiple weapon systems, bombs, cameras, sensors, or other payloads. They can be recalled, refueled, and re-weaponized. Operationally, they can be sent into the theatre on a fishing expedition without a preset goal. It is this type of flexibility that separates them from other robots such as cruise missiles and torpedoes. Of course there are some exceptional systems such as loitering munitions that fall between the cracks. For example, the Israeli Harpy and Harop made by IAI are a cross between a missile and an unmanned aerial vehicle (UAV). They are launched like a missile but hover over an area and select their own targets (hostile radar signatures) as they arise and then impact them like a missile. Thus they have some mission flexibility but not reusability.

Many thousands of robots have been used during both the Iraq and Afghanistan conflicts (up from 150 in 2004) for tasks such as bomb disposal and cave clearance on the ground and for surveillance from the air. The undisputed success of UAVs (now more commonly known remotely piloted aircraft (RPA) or drones) for gathering intelligence in the Iraq/Afghanistan conflicts has made them a showcase for military powers everywhere. There is an almost insatiable military demand for UAVs. Troops do not like to move without them. This same demand is reflected in more than 40 other countries that are either developing or purchasing military robots. These include Russia, China, Israel, Pakistan, Korea, India, and Iran.

The main ethical concerns expressed here are about the planned use of the armed autonomous “decision-making” robots that have appeared in all of the U.S. military’s road maps since 2004. However, before examining the issues surrounding autonomous lethal force in detail, it will be useful to look at some of the ethical problems that have arisen for man-in-the-loop or remotely piloted drones. There are lessons to be learned that will highlight some of the dangers of fully autonomous armed robots.

121.2 Armed “Man-in-the-Loop” Systems

The USA leads the field with its armed drones. The Predator MQ-1 was first armed by the CIA in 2001 with its now standard two hellfire missiles. Nowadays “pilots” of the 432nd Air Expeditionary Wing fly official military missions over Iraq and Afghanistan from Creech Air Force Base in the Nevada desert, thousands of miles away from the action. The Royal Air Force 39th Squadron also participates at Creech. Each plane has a two person crew: a remote pilot and a sensor operator who sit at what looks like game consoles making decisions about the application of lethal force. The planes are flown around the clock in shifts, and it is easy for pilots to take a break from “battle” at any time or even go home for dinner with their families.

In October 2007, the Predator fleet was joined by the larger and more powerful MQ-9 Reaper with its larger payload capacity of 1,700 kg – up to 14 hellfire missiles or a mixture of missiles and bombs. The number of Reapers flying in operations

doubled after their first year, and General Atomics have reported difficulties in keeping up with the demand. By March 2009, the number of armed flying drones in the field was reported to be 195 Predators and 28 Reapers. The number has grown dramatically since.

Anticipated increases can be seen in the training figures for Predator crews. In 2005, 32-person crews consisting of a pilot and sensor operator were being trained per year, whereas in 2008, 160 crews were trained, and in late 2008, an additional \$412m was added to the budget for training more non-pilot operators. In 2009, the number of remote pilot operators trained outnumbered the number of conventional pilots. Figures for the size of the current fleet of Predators and Reapers were not publicly available at the time of writing, but in May 2009 the Obama administration budgeted \$5.5 billion to add to the fleet in 2010. The military demand for the armed UAVs is highlighted by the more than a million mission hours flown by the MQ-1 by 2010 (up from 250,000 in June 2007).

121.3 Moral Disengagement

Flying a UAV from thousands of miles away from the battlefield clearly alleviates one of the two fundamental obstacles that warfighters must face – fear of being killed. As Daddis (2004) pointed out, fear is one of the greatest obstacles to a soldier's effectiveness in battle. It is obvious that the greater the distance from the enemy, the less fear will play in the action. Many battles throughout history have been lost by men bolting in panic as fear swept through the ranks (Holmes 2003).

Certainly the remote pilots of attack planes like the Reaper and the Predator have no need to worry about their personal safety. Sitting in cubicles thousands of miles away from the action, they can give a mission their full attention without worrying about being shot at. They are in highly secure home ground where no pilot has ever been safer. The second fundamental obstacle is *resistance to killing*. Grossman (1995) argues that “not firing” is not cowardice but really a compulsion of ordinary men not to kill. In his book, *Acts of War*, Holmes (ibid.) argues that the *hit rates* in a number of historical battles show that many soldiers were not prepared to fire directly at the enemy. This is also borne out by the analyses and findings of Marshall (1947) from his interviews of soldiers after WWII.

Similarly, Royakkers and van Est (2010) discuss the emotional and moral disengagement of UAV pilots, or “cubicle warriors” as he calls them, from the consequences of their actions in the field. The crux is that the type of control system used encourages a “PlayStation” mentality that makes an operator more careless about decisions to kill. Royakkers and van Est suggest that new recruits may have been playing video games for many years and may not see a huge contrast with that of being a cubicle warrior. He provides examples from Peter Singers book *Wired for War* in which a young pilot is reported to have said, “It’s like a video game. It can get a little bloodthirsty. But it’s fucking cool” (Singer 2009, 308–309). And in a further example, a young pilot says, “The truth is, it wasn’t all I thought it was cracked up to be. I mean, I thought killing somebody would be this life-changing experience. And then I did it, and I was like ‘All right, whatever.’ . . . Killing people

is like squashing an ant. I mean, you kill somebody and it's like 'All right, let's go get some pizza.'" (Singer 2009, 391–392).

In contrast to this view, there are reports of remote pilots suffering from different types of stress than onboard pilots. After an attack the operator gets to see the aftermath of using high-resolution cameras. This is more than a conventional fighter pilot ever sees, and, at least on the surface, it would seem that remote operators would be less morally disengaged than the crew of a high-altitude bomber.

However, for an article appearing in the *Air Force Times* (Lindlaw 2008), five remote pilots interviewed said that they had not been particularly troubled by their missions although they can sometimes make for a strange existence. Col. Chris Chambliss, a commander of the 432nd Wing at Creech, said that only on four or five occasions had sensor operators gone to see the Chaplain or their supervisors and that this was a very small proportion of the total number of remote operators.

All of this is anecdotal evidence and proper scientific research needs to be conducted to find out what kind of stresses, if any, the operators are facing. It is well known that making good decisions is more difficult under stressful conditions. Longitudinal studies would be required as the operators may start out being stressed by graphic scenes but then become inured with sufficient exposure. This is bit like the process trainee surgeons and nurses go through. They are known to often faint when they start out but quickly habituate to horrific medical events.

Killing distance does not have to be physical distance. It can be psychological as well. Grossman (ibid.) cites Clausewitz and du Picq for expounding at length that the vast majority of deaths in battle occurred when the victors chased the losing side in retreat. Du Picq suggests that Alexander the Great lost fewer than 700 men over all his battles because his army was never pursued by a victorious enemy. Although UAV operators have high-resolution images on large screens, the cameras are looking down from above and it can be very hard to make out the faces of their victims. Is this so different from attacking retreating troops?

One type of stress that keeps getting mentioned in the press as if to counter the game mentality notion is that of remote pilots not getting a chance to wind down together and bond in their mutual operations. They return home to their families after their shifts have finished and even go to parents evening at school. The problem is that they have no debriefing about their day on the battlefield and can't talk to their families about it. This is a very different issue from whether or not they are morally engaged or disengaged from the killer strikes.

121.4 Targeted Killings

Up until now the discussion has centered on conventional forces using armed drones to support troops on the ground in the war zones of Afghanistan and Iraq. But there is a second armed UAV "Air Force" controlled by the CIA out of Langley in Virginia. The first ever U.S. kill with a drone was in Yemen in 2002 when a CIA-operated MQ-1 killed a known al-Qaeda leader and five other men traveling in the same vehicle. This was controversial at the time but was considered, by DoD lawyers, to be a legitimate defensive preemptive strike against al-Qaeda. Since then, the use of

Table 121.1 UAV Strikes Carried out by CIA

| Numbers killed | | | | |
|-------------------|-------------------|---------------|--------------|----------------|

| 2009 | 53 | 709 | 413 | 10 |
| 2010 ^a | 86 | 719 | 426 | 10 |

^aThrough October 10, 2010

drones for targeted killings or “decapitation strikes” in states that are not at war with the USA has been rising at an accelerating pace. It is what the Asia Times has called “the most public ‘secret’ war of modern times” (Turse 2010).

According to estimates published on the New America Foundation website (NAF 2010), the attacks in Pakistan have risen from 9 between 2004 and 2007 up to 85 in 2010 by mid-October. The estimates are shown in Table 121.1. The number of civilian deaths has been very difficult to estimate and has ranged from as few as 20 to more than a 1,000. There are many different counts and no objective way to decide between them. The New America Foundation gives a figure of 1 in 3 civilian to insurgent ratio, while the Brookings Institute study in 2009 indicated that only 1 in 10 of those killed was an insurgent.

The legality of targeted killing is at best questionable. The word decapitation is often used to mean cutting off the leaders of an organization or nation fighting a war from the body of their warfighters. The aim of the current spate of aerial decapitation strikes was initially to target al-Qaeda and Taliban leaders without risk to U.S. military personnel. The idea is to eventually leave only replacements from the shallowest end of the talent pool that will be ineffective and easy to defeat. With less risk, the targeted leaders do not have to be at the highest level. This explains the increasing number of death-delivering attacks in Pakistan using Predators and Reapers.

These individually targeted killings come despite the banning in the USA of all politically motivated killing of individuals since the famous Church commission report on the CIA political assassinations in 1975. In 1976, President Ford issued a presidential executive order that “no person employed by or acting on behalf of the United States Government shall engage in, or conspire to engage in, assassination.” This is not codified in the U.S. law but is an executive order that the president can change at will and without public notice. President Reagan issued Executive Order 12333, which expanded the ban to include persons acting on *behalf* of the U.S. government and all subsequent presidents have supported it. However, EO 12333 does not limit lawful self-defense options against legitimate threats to the national security of U.S. citizens. During wartime, a combatant is considered to be a legitimate target at all times. If a selected individual is sought out and killed, it is not termed an assassination. According to a memorandum on EO 12333, which is said to be consistent with United Nations (UN) Charter 51, “a decision by the President to employ clandestine, low-visibility, or overt military force would not constitute assassination if U.S. military forces were employed against the combatant forces of

another nation, a guerrilla force, or a terrorist or other organization whose actions pose a threat to the security of the United States” (NAF 2010).

But the real legal question is does the CIA have a right to assassinate *alleged* insurgent combatants without due process. Seymour Hersh (2002), whose writings were one of the main motivations for the Church commission, complained that “the targeting and killing of individual al-Qaeda members without juridical process has come to be seen within the Bush Administration as justifiable military action in a new kind of war, involving international terrorist organizations and unstable states.” The insurgents have been redefined as combatants, but without receiving the rights of prisoners of war and without being given the chance to surrender or to face trial. This move, in combination with Article 51, provides legal cover for the right to assassinate insurgent combatants.

The legality of the targeted killings has also been challenged at the UN General Assembly meeting in October 2009 by Philip Alston, UN special rapporteur on extrajudicial killings. He made a request for U.S. legal justification about how the CIA is accountable for the targets that they are killing. The USA turned down the request by refusing to comment on what they said were covert operations and a matter of national security.

A rebuttal by Harold Koh (2010), Legal Adviser, U.S. Department of State, stated, “U.S. targeting practices including lethal operations conducted by UAVs comply with all applicable law including the laws of war.” However, there are no independent means of determining how the targeting decisions are being made. It remains unclear as to what type and level of evidence is being used to sentence non-state actors to death by hellfire without right to appeal or right to surrender. It is also unclear as to what other methods were exhausted or attempted to bring the targets to justice. The whole process sits behind an unjustified cloak of national secrecy.

The CIA use of drones was also questioned at a senate hearing in a prepared statement by U.S. law professor Kenneth Anderson (2010). Anderson said that Koh “nowhere mentions the CIA by name in his defense of drone operations. It is, of course, what is plainly intended when speaking of self-defense separate from armed conflict. One understands the hesitation of senior lawyers to name the CIA’s use of drones as lawful when the official position of the U.S. government, despite everything, is still not to confirm or deny the CIA’s operations.”

However, the director of the CIA, Leon Panetta (2008), has been very open about the CIA use of drones. He told the Pacific Council on International Policy in 2008 that “it’s the only game in town in terms of confronting and trying to disrupt the al-Qaeda leadership.” Revealing the CIA’s intentions on the expansion of targeted drone kills, Panetta went on to say of al-Qaeda that “If they’re going to go to Somalia, if they’re going to go to Yemen, if they’re going to go to other countries in the Middle East, we’ve got to be there and be ready to confront them there as well. We can’t let them escape. We can’t let them find hiding places.”

This expansion of targeted killing is just what was concerning the UN special rapporteur on extrajudicial killings. A subsequent report by Alston (2010) to the UN General Assembly discusses drone strikes as violating international and human

rights law because both require transparency about the procedures and safeguards in place to ensure that killings are lawful and justified: “a lack of disclosure gives States a virtual and impermissible license to kill.” Some of Alston’s arguments also revolve around the notion of “the right to self-defense” and whether the drone strikes are legal under Article 51. He also examines some of the complex legal issues surrounding proportionality on the different conditions that pertain when the military action is called “self-defense.”

Panetta and many others have made the case that armed UAVs are more accurate and will kill less civilians than a B-52 bomber in attacking the tribal regions in Pakistan. But as a former CIA operative told me, there is no way that Pakistan or other state actors not at war with the USA could “turn a blind eye” to the bomber strikes as they do now for drones. It can be argued that it is their perceived precision and accuracy that allow them to penetrate areas and kill people in ways that would not previously have been available without major political and legal obstacles.

Attacking with a remotely piloted vehicle is no different under the Laws of War than attacking with a manned helicopter gunship or even with a rifle. The worry is that the nature of an unmanned vehicle with no risk to military personnel, an ability to hover over an area for very many hours, and its perceived accuracy may lead to considerable expansion of potential targets.

I qualified “accuracy” with the word “perceived” here both because the attacks are often on buildings where the targets cannot be verified, and, if the Brookings or New America Foundation figures discussed above are anything to go by, the accuracy is not as high as some might imagine. One of the oft-cited targeting methods of the CIA is to locate the locations of people through their cell phones; switch on your phone and you are dead. But a recent copyright lawsuit between two companies sheds doubt on the accuracy of this targeting method (Stein 2010). A small company called Intelligent Integration Systems alleges that one of its client companies, Netezza, reverse engineered their software, Geospatial, on a tight deadline for the CIA. The court heard that the illegal version of the software could produce locations that were out by as much as 40 ft and that the CIA had knowingly accepted the software.

But even if targeting was 100 % accurate, how can we be sure that alleged insurgents are “guilty as charged.” Information about target identity and their role and position is heavily dependent on the reliability of the intelligence on which it is based. There are lessons that should have been learned from the Vietnam War investigations of Operation Phoenix in which thousands were assassinated. It turned out that many of those on the assassination list had been put there by South Vietnamese officials for personal reasons such as erasing gambling debts or resolving family quarrels.

Philip Alston (*ibid.*) reports that during a mission to Afghanistan, he found out how hard it was for forces on the ground to obtain accurate information. “Testimony from witnesses and victims’ family members showed that international forces were often too uninformed of local practices, or too credulous in interpreting information, to be able to arrive at a reliable understanding of a situation.” He suggests that

“States must, therefore, ensure that they have in place the procedural safeguards necessary to ensure that intelligence on which targeting decisions are made is accurate and verifiable.”

121.5 From *in the Loop* to *on the Loop* to *Out of the Loop*

Since 2004 all of the road maps and plans of the U.S. forces have made clear the desire and intention to develop and use autonomous battlefield robots. Fulfillment of these plans to take the human out of the loop is well underway. The end goal is that robots will operate autonomously to locate their own targets and destroy them without human intervention (Sharkey 2008a). The Committee on Autonomous Vehicles in Support of Naval Operations National Research Council (2005) wrote that “The Navy and Marine Corps should aggressively exploit the considerable war-fighting benefits offered by autonomous vehicles (AVs) by acquiring operational experience with current systems and using lessons learned from that experience to develop future AV technologies, operational requirements, and systems concepts.” We can only hope that the “lessons learned” will include ethical and moral lessons. The ethical problems will only be amplified and added to by the use of autonomous robots.

Before delving into these problems, it is important to clarify what is meant by “robot autonomy” here. This is often confused with science fiction notions of robots with minds of their own with the potential to turn on humanity. The reality is very different. The autonomous robots being discussed for military applications are closer in operation to your washing machine than to a science fiction *Terminator*. The way the term “autonomy” is used in robotics should not be confused with how the term is used in philosophy, politics, individual freedom, or in common parlance. It is more related to the term automatic. An automatic robot carries out a preprogrammed sequence of operations or moves in a structured environment. A good example is a robot arm painting a car. An autonomous robot is similar except that it operates in open or unstructured environments. To do this, the robot is controlled by a program, takes inputs from its sensors, and adjusts the speed and direction of its motors and actuators as specified. If the goal of a robot is to avoid objects and the sensors detect an object, the program would adjust the motors so that the robot moves to avoid it. For example, if the left hand sensors detect the object, the robot would move right, and if the right hand sensors detect the object, the robot would move left.

This leads us to another often-misunderstood topic, the robot decision process. This should not be confused with human decision making except by analogy. A computer decision process can be as simple as, IF object on left, THEN turn right OR IF object on right, THEN turn left, ELSE continue. Alternatively, the activity on a sensor may activate a different subprogram to help with the decision. For example, to get smoother passage through a field laden with objects, a subprogram could be called into calculate if a turn to the left would result in having to negotiate more obstacles than a turn to the right.

Programs can become very complex through the management of several sub-programs and making decisions about which subprogram should be initiated in particular circumstances. But the bottom line for decision making by machine, whether it is using mathematical decision spaces or AI reasoning programs, is the humble IF/THEN statement.

The other important thing to say about autonomy is that a system does not have to be exclusively autonomous or exclusively remote operated. The U.S. Army, Navy, and Air Force have all at some point discussed the classification of robot control on a continuum from totally human operated to fully autonomous. Each has separate development programs and each has its own operational definitions of the different levels of robot autonomy. The Army has ten levels, while the Air Force has four. The Navy goes for a characterization in terms of mission complexity but points to three different classes of autonomous robot vehicle: (i) *scripted* in which the robot carries out a preplanned script of the “point, fire, and forget” variety; (ii) *supervised* in which some or all of the functions of planning, sensing, monitoring, and networking are carried out with the help of human operators to make decisions; (iii) *intelligent* in which attributes of human intelligence are used in software to make decisions, perceive and interpret the meaning of sensed information, diagnose problems, and collaborate with other systems.

The first of the Navy classifications, *scripted*, is the closest to “automatic” and includes cruise missiles, torpedoes, and automated weapons such as the Phalanx CIWS. The *supervised* category refers to both the current “man-in-the-loop” systems such as the Predator and Reaper control and the newly proposed “man-on-the-loop” systems. And the *intelligent* category refers to fully autonomous operation although frankly I am not sure exactly what they mean by “attributes of human intelligence in software.” Perhaps there is a little slippage into wishful thinking here.

There are a number of reasons that make an autonomous robot militarily desirable including the following: (i) remote-operated systems are more expensive to manufacture and require many support personnel to run them; (ii) it is possible to jam either the satellite or radio link or take control of the system; (iii) one of the military goals is to use robots as force multipliers so that one human can be a nexus for initiating a large-scale robot attack from the ground and the air; and (iv) the delay time in remote piloting a craft via satellite (approximately 1.5 s) means that it could not be used for interactive combat with another aircraft. At a press briefing in December 2007, Dyke Weatherington, deputy director of the U.S. DoD’s Unmanned Aerial Systems Task Force, said, – Certainly the roadmap projects an increasing level of autonomy . . . to fulfill many of the most stressing requirements. Let me just pick one for example. Air-to-air combat – there’s really no way that a system that’s remotely controlled can effectively operate in an offensive or defensive air combat environment. That has to be “the requirement of that is a fully autonomous system” (DoD 2007).

The most recent United States Air Force Unmanned Aircraft Systems Flight Plan 2009–2047 (USAF 2009) opens the strategy for a staged move from current remote piloted systems to fully autonomous systems. It represents a push to shrink the role of the man-in-the-loop. To begin with, autonomous operation will be mainly for

tasks such as take off, landing, and refueling. As unmanned drones react in micro- or nanoseconds the “humans will no longer be ‘in the loop’ but rather ‘on the loop’ – monitoring the execution of certain decisions. Simultaneously, advances in AI will enable systems to make combat decisions and act within legal and policy constraints without necessarily requiring human input” (ibid., p. 41).

The idea of a human on the loop means that the human will be in executive control overall to call in or call off the robots rather than being in control of each individually. In other words, the robots will be essentially autonomous: “SWARM technology will allow multiple MQ-Mb aircraft to cooperatively operate in a variety of lethal and nonlethal missions at the command of a single pilot” (ibid., p. 39). Such a move will require decisions being made by the swarm – human decision making will be too slow and not able to react to the control of several aircraft at once. With the increasing pace of the action and with potential of several aircraft to choose targets at the same time, it will not be possible to have the human make all of the decisions to kill.

The main ethical concern is that allowing robots to make decisions about the use of lethal force could breach both the principle of distinction and the principle of proportionality as specified by international humanitarian law (Sharkey 2008b). Currently and for the foreseeable future, no autonomous robots or artificial intelligence systems have the necessary properties to enable discrimination between combatants and civilians or to make proportionality decisions.

Under the principle of distinction, only combatants/warriors are legitimate targets of attack. All others, including children, civilians, service workers, and retirees, should be immune from attack. The same immunity covers combatants that are wounded, have surrendered, or are mentally ill (Ford 1947). The principle of proportionality applies in circumstances where it is not possible to fully protect noncombatants in an action. It requires that the loss of life and damage to property incidental to attacks must not be excessive in relation to the concrete and direct military advantage.

The discrimination between civilians and combatants is problematic for any robot or computer system. First, there is the problem which is the specification of “civilianness.” A computer can compute any given procedure that can be written as a program. We could, for example, give the computer on a robot an instruction such as “if civilian, do not shoot.” This would be fine if and only if there was some way to give the computer a precise specification of what a civilian is. The Laws of War don’t help. The 1949 Geneva Convention requires the use of common sense to determine the difference between a civilian and combatant, while the 1977 Protocol 1 essentially defines a civilian in the negative sense as someone who is not a combatant:

1. A civilian is any person who does not belong to one of the categories of persons referred to in Article 4 A (1), (2), (3), and (6) of the Third Convention and in Article 43 of this Protocol. In case of doubt whether a person is a civilian, that person shall be considered to be a civilian.
2. The civilian population comprises all persons who are civilians.

3. The presence within the civilian population of individuals who do not come within the definition of civilians does not deprive the population of its civilian character. Protocol 1 Additional to the Geneva Conventions, 1977 (Article 50).

Even if a clear definition of civilian did exist, it would have to be couched in a form that enabled the relevant information to be extracted from the sensing apparatus. All that is available to robots are sensors such as cameras, infrareds, sonars, lasers, temperature sensors, and ladars. While these may be able to tell us that something is a human or at least an animal, they could not tell us much about combat status. There are systems that can identify a face or a facial expression, but they do not work well on real-time moving people. And even if they did, how useful could they be in the fog of war or from the air? British teenagers beat the surveillance cameras just by wearing hooded jackets.

In a war with nonuniformed combatants, knowing who to kill would have to be based on situational awareness and of having human understanding of other people's intentions and their likely behavior. In other words, human inference is required. Humans understand one another in a way that machines cannot. Cues can be very subtle and there are an infinite number of circumstances where lethal force is inappropriate. Just think of children being forced to carry empty rifles or of insurgents burying their dead.

The problem has been put clearly by Major Daniel Davis (2008), a combat veteran of Iraq 1991 and Afghanistan 2005, who writes, "Suggesting that within the next 12-plus years technology could exist that would permit life-and-death decisions to be made by algorithms is delusional. A machine cannot sense something is wrong and take action when no orders have been given. It doesn't have intuition. It cannot operate within the commander's intent and use initiative outside its programming. It doesn't have compassion and cannot extend mercy". Davis also quotes Colonel Lee Fetterman who has a high regard for remote controlled robots: "The function that robots cannot perform for us – that is, the function we should not allow them to perform for us – is the decide function. Men should decide to kill other men, not machines," he said. "This is a moral imperative that we ignore at great peril to our humanity. We would be morally bereft if we abrogate our responsibility to make the life-and-death decisions required on a battlefield as leaders and soldiers with human compassion and understanding. This is not something we would do. It is not in concert with the American spirit" (Fetterman quoted in Davis, *ibid.*).

Turning to the principle of proportionality, there is no way for a robot could perform the human subjective balancing act required to make proportionality decisions. No clear objective methods are provided for calculating what is proportionate in the Laws of War (Sharkey 2009). The phrase "excessive in relation to the concrete and direct military advantage expected to be gained" is not a specification. It is also practically impossible to calculate a value for "the actual military advantage." What could the metric be for assigning value to killing an insurgent relative to the value of noncombatants, particularly children who could not be accused of willingly contributing to insurgency activity? Proportionality calculations should be based on

the likely differences in military outcome if the military action killing innocents had not been taken (Chakwin et al. 2002).

Commanders have to weigh the circumstances before making a decision, but ultimately this is a subjective matter. Clearly the extremes of wiping out a whole city to eliminate even the highest value target, say Osama bin Laden, is out of the question. There has to be circumstantial and subjective estimates about just how many innocent people are equal to the military value of the successful completion of a given mission. A computer system could be used to assist commanders to determine which weapons would cause the minimum of collateral damage. However, after the calculation is completed, a decision must still be made about whether the minimal number of civilian casualties and damage to civilian property is proportional to the military advantage gained.

In the heat of battle, both the principles of discrimination and proportionality can be problematic. Humans do make errors and can behave unethically, but they can be held accountable. Armed autonomous robots could violate both of these principles but could not be held accountable (Sharkey 2008c). There is no way to punish a robot. We could threaten to switch it off but that would be like telling your washing machine that if it does not remove stains properly, you will break its door off. This leaves the question about who is responsible for the long causal chain that includes the following: the manufacturer for the description they gave, the programmer, the designer, the department of defense, the generals or admirals in charge of the operation, and the operator. Can we hold someone accountable, if not then legally these robots cannot be used (Sparrow 2007).

121.6 Some Lessons to Learn

It is quite likely that autonomous robots will come into operation in a piecemeal fashion. Research and development is well underway and the fielding of autonomous robot systems may not be far off. However, to begin with they are likely to have assistive autonomy onboard such as flying or driving a robot to a target destination and perhaps even selecting targets and notifying a human (the Israeli autonomous ground robot, Guardium, already has this functionality). This will breed public trust and confidence in the technology – an essential requirement for progression autonomy (Dahm 2010). The big worry is that allowing such autonomy will be a further slide down a slippery slope to give machines the power to make decisions about who to kill.

Apart from the legal and ethical problems of discrimination and proportionality for fully autonomous armed robots, there are lessons to be learned from the current application of remotely piloted vehicles. We discussed some of the controversy about the issue of moral disengagement of the operators and the PlayStation mentality (Royakkers and van Est 2010). While this is an interesting and plausible narrative, it is not possible to be conclusive because the evidence, outside of the anecdotal, is just not available. It must be noted, nonetheless, that the power of

graphic detail to desensitize should not be underestimated. The narrative about moral disengagement is even more compelling when it comes to with autonomous robot warriors. As Cumming (2006) puts it, “developing technologies of this sort also have the potential to provide for the creation of moral buffers that allow humans to act without adequately considering the consequences.”

Another lesson can be learned from the use of the remotely piloted armed aircraft by the CIA for targeted killings. At best, such targeted killings are legally questionable in terms of the Laws of War as discussed above. Apart from problems with verifying intelligence about targeting and the lack of a transparent judicial process, there is concern that the use of drones has greatly expanded the range of targets that can be picked off by the CIA. Autonomous aircraft that can hover on their own for extended periods and select their own targets could greatly exacerbate the problems. The DARPA Vulture program has just awarded a contract to Boeing (teamed with QinetiQ) to develop a heavier-than-air platform capable of keeping 1,000 lb of payload with 5 kW of power aloft for 5 years. These developments need to be watched very carefully.

It is difficult to design and develop these new technologies, but they are not so difficult to copy. We have already seen the rapid proliferation of drones in response to their perceived military success in the Iraq/Afghanistan conflicts. If armed autonomous robots are fielded in the same way with or without a human in the weapons loop, it will not be long before there is similar proliferation. If it turns out to be militarily advantageous to keep a human out of the loop – for example, in circumstances when it is not possible to maintain a radio or satellite link – then they will be used by all.

Abstract

The underlying thesis of research in ethical autonomy for lethal autonomous unmanned systems is that they will potentially be capable of performing more ethically on the battlefield than are human soldiers. In this article this hypothesis is supported by ongoing and foreseen technological advances and perhaps equally important by an assessment of the fundamental human warfighters in today’s battlespace. If this goal of better-than-human performance is achieved, even if still imperfect, it can result in a reduction in noncombatant casualties and property damage consistent with adherence to the Laws of War as prescribed in international treaties and conventions and is thus worth pursuing vigorously.

122.1 Introduction

The trend is clear: Warfare will continue and autonomous robots will ultimately be deployed in its conduct. Referring to the improving technology of the day

From the Journal of Military Ethics, vol. 9, no. 4 (2010); reprinted by permission of the publisher (Taylor and Francis, Ltd., <http://www.tandf.co.uk/journals>).

and its impact on the inevitability of warfare, Clausewitz stated “the tendency to destroy the adversary which lies at the bottom of the conception of War is in no way changed or modified through the progress of civilization” (Von Clausewitz 1832). More recently, Cook observed “The fact that constraints of just war are routinely overridden is no more a proof of their falsity and irrelevance than the existence of immoral behavior ‘refutes’ standards of morality: the standards are well known, and it also well known that human beings fall short of that standard with depressing regularity” (Cook 2004). Given this, questions then arise regarding if and how these systems can conform as well or better-than-human soldiers with respect to adherence to the existing Laws of War. If achieved, this would result in a reduction in collateral damage, i.e., noncombatant casualties and civilian property. The body of research conducted in Georgia Tech’s unmanned systems laboratory (Arkin 2009; Arkin and Ulam 2009; Arkin et al. 2009) focuses on this issue directly from a design perspective. As robots are already faster, stronger, and in certain cases (e.g., chess playing) smarter than humans, is it that difficult to believe they will be able to treat rival combatants more humanely in the battlefield than those combatants currently do each other?

This is no simple task, however. In the fog of war, it is hard enough for a human to be able to effectively discriminate whether or not a target is legitimate. Fortunately for a variety of reasons, it may be anticipated, despite the current state of the art, that in the future autonomous robots may be able to perform better than humans under these conditions, for the following reasons:

1. The ability to act conservatively, i.e., they do not need to protect themselves in cases of low certainty of target identification. Autonomous armed robotic vehicles do not need to have self-preservation as a foremost drive, if at all. They can be used in a self-sacrificing manner if needed and appropriate without reservation by a commanding officer. There is no need for a “shoot first, ask-questions later” approach.
2. The eventual development and use of a broad range of robotic sensors better equipped for battlefield observations than humans currently possess. This includes technological advances in electro-optics, synthetic aperture or wall-penetrating radars, acoustics, and seismic sensing, to name but a few.
3. Unmanned robotic systems can be designed without emotions that cloud their judgment or result in anger and frustration with ongoing battlefield events. In addition, “Fear and hysteria are always latent in combat, often real, and they press us toward fearful measures and criminal behavior” (Walzer 1977). Autonomous agents need not suffer similarly.
4. Avoidance of the human psychological problem of “scenario fulfillment” is possible, a factor believed partly contributing to the downing of an Iranian airliner by the USS *Vincennes* in 1988 (Sagan 1991). This phenomenon leads to distortion or neglect of contradictory information in stressful situations, where humans use new incoming information in ways that only fit their preexisting belief patterns, a form of premature cognitive closure. Robots need not be vulnerable to such patterns of behavior.

5. They can integrate more information from more sources far faster before responding with lethal force than a human possibly could in real time. This data can arise from multiple remote sensors and intelligence (including human) sources, as part of the army's network-centric warfare concept (McLoughlin 2006) and the concurrent development of the Global Information Grid (DARPA 2007). "Military systems (including weapons) now on the horizon will be too fast, too small, too numerous and will create an environment too complex for humans to direct" (Adams 2001–2002).
6. When working in a team of combined human soldiers and autonomous systems as an organic asset, they have the potential capability of independently and objectively monitoring ethical behavior in the battlefield by all parties and reporting infractions that might be observed. This presence alone might possibly lead to a reduction in human ethical infractions.

Aside from these ethical considerations, autonomous robotic systems offer numerous other potential operational benefits to the military: faster, cheaper, better mission accomplishment, longer range, greater persistence, longer endurance, higher precision, faster target engagement, and immunity to chemical and biological weapons among others (Guetlein 2005). All of these can enhance mission effectiveness and serve as drivers for the ongoing deployment of these systems. But recent research (e.g., Arkin 2009) focuses on enhancing ethical benefits by using these systems, ideally without eroding mission performance when compared to human warfighters.

122.2 Human Failings in the Battlefield

It is not my belief that an autonomous unmanned system will be able to be perfectly ethical in the battlefield, but I am convinced that they can perform more ethically than human soldiers are capable of performing. Unfortunately the trends in human behavior in the battlefield regarding adhering to legal and ethical requirements are questionable at best. "Armies, armed groups, political and religious movements have been killing civilians since time immemorial" (Slim 2008, p. 3). The dangers of abuse of unmanned robotic systems, such as the Predator and Reaper, in war are well documented, which occurs even when a human operator is directly in charge (Sullivan 2010; Filkins 2010; Adams 2010). Battlefield atrocities are as old as warfare. "Atrocity... is the most repulsive aspect of war, and that which resides within man and permits him to perform these acts is the most repulsive aspect of mankind" (Grossman 1995, p. 229).

Humanity's propensity to wage war has gone unabated for as long as history has been recorded. One could argue that man's greatest failing is being on the battlefield in the first place. Immanuel Kant asserted "War requires no motivation, but appears to be ingrained in human nature and is even valued as something noble" (Kant 1985, p. 125). Even Albert Einstein, who remained a pacifist well into his 50s, eventually acknowledged "as long as there will be man, there will be war" (Isaacson 2007, p. 494). Sigmund Freud was even more to the point: "... there is no

likelihood of being able to suppress humanity's aggressive tendencies" (Isaacson 2007, p. 382). This article, however, is concerned for the large part with the shortcomings humanity exhibits during the conduct of war (*jus in bello*) as opposed to what brought us there in the first place (*jus ad bellum*). "The emotional strain of warfare and combat cannot be quantified" (Bourke 1999, p. 232), but at least there has recently been a serious attempt to gather data on that subject. A recent report from the Surgeon General's Office (Surgeon General 2006) assessing the battlefield ethics and mental health of soldiers and marines deployed in Operation Iraqi Freedom is disturbing. The following findings are taken directly from that report:

1. Approximately 10 % of soldiers and marines report mistreating noncombatants (damaged/destroyed Iraqi property when not necessary or hit/kicked a noncombatant when not necessary). Soldiers that have high levels of anger experience high levels of combat or those who screened positive for a mental health problem were nearly twice as likely to mistreat noncombatants as those who had low levels of anger or combat or screened negative for a mental health problem.
2. Only 47 % of soldiers and 38 % of marines agreed that noncombatants should be treated with dignity and respect.
3. Well over a third of soldiers and marines reported torture should be allowed, whether to save the life of a fellow soldier or marine or to obtain important information about insurgents.
4. Seventeen percent of soldiers and marines agreed or strongly agreed that all noncombatants should be treated as insurgents.
5. Just under 10 % of soldiers and marines reported that their unit modifies the ROE to accomplish the mission.
6. Forty-five percent of soldiers and 60 % of marines did not agree that they would report a fellow soldier/marine if he had injured or killed an innocent noncombatant.
7. Only 43 % of soldiers and 30 % of marines agreed they would report a unit member for unnecessarily damaging or destroying private property.
8. Less than half of soldiers and marines would report a team member for engaging in unethical behavior.
9. A third of marines and over a quarter of soldiers did not agree that their NCOs and officers made it clear not to mistreat noncombatants.
10. Although they reported receiving ethical training, 28 % of soldiers and 31 % of marines reported facing ethical situations in which they did not know how to respond.
11. Soldiers and marines are more likely to report engaging in the mistreatment of Iraqi noncombatants when they are angry and are twice as likely to engage in unethical behavior in the battlefield than when they have low levels of anger.
12. Combat experience, particularly losing a team member, was related to an increase in ethical violations.

This formal study, although at the very least disconcerting, is by no means the first report of battlefield atrocities. "Atrocious behavior was a feature of combat in

the two world wars, as well as in Vietnam” (Bourke 1999, p. 163). One sociological study of fighting in Vietnam pointed out that for all men in heavy combat, 1/3 of men in moderate combat, and 8 % in light combat had seen atrocities or committed or abetted noncombatant murder (Strayer and Ellenhorn 1975). These numbers are staggering.

Possible explanations for the persistence of war crimes by combat troops are discussed in Bill (2000), Parks (1976a,b), Danyluk (2000), and Slim (2008). These include:

- High friendly losses leading to a tendency to seek revenge.
- High turnover in the chain of command, leading to weakened leadership.
- Dehumanization of the enemy through the use of derogatory names and epithets.
- Poorly trained or inexperienced troops. This lack of training is not just in being a good soldier but also in understanding the Laws of War.
- No clearly defined enemy.
- The issuance of unclear orders where the intent of the order may be interpreted incorrectly as unlawful.
- Shortage of personnel has been associated in producing stress on combatants that can lead to violations.
- Youth and immaturity of troops.
- An overpowering sense of frustration.
- Pleasure from the power of killing.
- External pressure, e.g., for a need to produce a high body count of the enemy.

There is clear room for improvement, and autonomous systems may help. Bourke points out that modern warfare enables violent acts in ways unlike before. Now, “Combatants were able to maintain an emotional distance from their victims largely through the application of. . . technology” (Bourke 1999, p. xvii). This portends ill for the reduction of atrocities by soldiers. Bombs are presently being dropped in Afghanistan and Iraq by UAV operators from almost halfway around the world in Nevada (Ure 2008). This use of technology enables a form of “numbed killing.” Bourke further notes that there is now a “technological imperative” to make full use of the new equipment provided. Although technological warfare has reduced the overall number of soldiers required to wage war, the price is that technology, while increasing the ability to kill, decreases “the awareness that dead human beings were the end product.” When killing at a maximum range, one can pretend they are not killing human beings and thus experience no regret (Grossman 1995). This physical distance detaches the warfighters from the consequences of the use of their weaponry.

The psychological consequences on U.S. servicemen and women in Afghanistan and Iraq have reached record levels. In 2007 alone, 115 soldiers committed suicide, up from 102 the previous year; 24 % of the suicides were those on their first deployment, and 43 % were those who had returned from deployment. The suicide rates of active duty soldiers as of August 2008 “were on pace to surpass both last year’s numbers and the rate of suicide in the general U.S. population for the first time since the Vietnam war, according to U.S. Army officials” (Mount 2008, p. 1).

This unfortunately was confirmed in July of 2010 (Fifield 2010). A statistically significant relationship has been established between the suicide attempts and the number of days spent deployed in Iraq or Afghanistan. To make matters worse, this is coupled with “a growing number of troops diagnosed with post traumatic stress disorder” (Sevastopulo 2008, p. 1).

These psychiatric casualties are quite significant and common (Grossman 1995): In World War II alone more than 800,000 men were classified unfit due to psychiatric reasons, but an additional 504,000 (approximately 50 divisions) were subsequently rendered unfit as a result of psychiatric collapse after induction; in the 1973 Arab-Israeli war one-third of the Israel casualties were psychiatric in origin, twice the number of dead troops. One WWII study showed that after 60 days of continuous combat, 98 % of all surviving troops suffer psychiatric trauma of some sort (Swank and Marchand 1946). These long-term exposures to combat are a recent trend in battle, emerging in the twentieth century. The psychiatric damage can result in many forms: battlefield fatigue, conversion hysteria, confusional states, anxiety states, obsession and compulsive states, and character disorders (Grossman 1995). The overall effect on the ability to wage war is obvious, let alone the damage to a nation’s surviving citizens.

Creating true warfighters in the first place is a daunting challenge. “No matter how thorough the training, it still failed to enable most combatants to fight” (Bourke 1999, p. 61). In World War II most men simply did not kill. In one U.S. Army interview of 400 men, only 15 % of men had actually fired at enemy positions (at least once) during an engagement despite the fact that 80 % had the opportunity to do so (Marshall 1947). There was no observed correlation between the experience, terrain, nature of the enemy, or accuracy of enemy fire on this percentage.

This applied to both land and air forces. One study of the Korean War indicated that 50 % of F-86 pilots never fired their guns and only 10 % of those had actually hit a target (Sparks and Neiss 1956). During World War II, most fighter pilots never even tried to shoot anyone down, let alone succeeding. Less than 1 % of the pilots accounted for 30–40 % of all downed enemy aircraft (Grossman 1995, p. 31).

One conclusion of this is that human soldiers, although not cowardly, lacked an “offensive spirit.” One possible reason for this lack of aggressiveness centers on the use of long-distance weapons making battlefields “lonely” and the feeling the enemy was not real but a phantom. This dehumanization of the enemy also quells guilt in killing (Bourke 1999).

The soldiers in the field are not alone in their complicity. “Atrocities are the dark secret of military culture” (Danyluk 2000, p. 38). “Servicemen of all ranks were unperturbed by most of these acts of lawless killing” (Bourke 1999, p. 173). In Vietnam, combat commanders viewed the Laws of War as “unnecessary” and “unrealistic” restraining devices which would decrease the opportunity for victory (Parks 1976a, p. 21). A lawyer, defending one general’s decision not to initiate a court martial for suspected war crime violations, stated, “It’s a little like the Ten Commandments – they’re there, but no one pays attention to them”.

Nonetheless the U.S. military aspires to higher ethical performance. General Douglas MacArthur stated:

The soldier, be he friend or foe, is charged with the protection of the weak and unarmed. It is the very essence and reason for his being. When he violates this sacred trust, he not only profanes the cult but threatens the very fabric of international society. (Parks 1976a, p. 18)

In addition, the impact of atrocities on public opinion, as clearly evidenced by the My Lai incident in the Vietnam War, and the consequent effect on troop morale are secondary reasons to ensure that events like these are prevented. Civilians are unfortunately killed during war by other humans for manifold reasons (Slim 2008):

- Genocidal thinking – ethnic or racial cleansing of populations.
- Dualistic thinking – dividing host populations into the “good guys” and the “bad guys.”
- Power dominance and subjugation – power lust and to exert force.
- Revenge – emotional striking back for perceived wrongs.
- Punishment and forced compliance – to shape the behavior of civilian populations.
- Utility – it furthers the war strategically.
- Asymmetrical necessity – tactical killing of civilians due to an inferior military position.
- Profit – mercenary and looting activity.
- Eradicating potential – preemptive removal of civilians who might otherwise become warfighters in the future.
- Recklessness – shooting anything that moves or other forms of Indiscriminate killing.
- Reluctant killing – through human error or accident, collateral damage.
- Collective and sacrificial thinking – killing of groups rather than individuals, they must be sacrificed for a greater good.

These forms of thinking are alien to current artificial intelligence efforts and likely are to remain so. Armed autonomous systems need not nor should be equipped with any of these forms of unacceptable human rationalization or action.

A primary conclusion is that it seems unrealistic to expect normal human beings by their very nature to adhere to the Laws of Warfare when confronted with the horror of the battlefield, even when trained. As a Marine Corps Reserves Captain commented, “If wars cannot be prevented, steps can be taken to ensure that they are at least fought in as ethical a manner as possible” (Danyluk 2000, p. 38). One could argue that battlefield atrocities, if left unchecked, may become progressively worse, with the progression of standoff weapons and increasing use of technology. Something must be done to restrain the technology itself, above and beyond the human limits of the warfighters themselves. This is the case for the use of ethical autonomy in unmanned systems.

122.3 A Way Forward

Research in our laboratory has provided the motivation, philosophy, formalisms, representational requirements, architectural design criteria, recommendations, and test scenarios to design and construct an autonomous robotic system architecture

capable of the ethical use of lethal force (Arkin 2009). These first steps toward that goal, however, are very preliminary and subject to major revision, but at the very least they can be viewed as the beginnings of an ethical robotic warfighter. The primary goal remains to enforce international humanitarian law (or the Laws of Armed Conflict (LOAC)) in the battlefield in a manner that is believed achievable, by creating a class of robots that not only comply with the restrictions of international law but in fact outperform human soldiers in their ethical capacity under comparable circumstances. If successful this will result in the saving of noncombatant life and property, ideally without erosion of mission performance. It is too early to tell whether this venture will be successful. There are daunting problems remaining:

- The transformation of international protocols and battlefield ethics into machine-usable representations and real-time reasoning capabilities for bounded morality using modal logics.
- Mechanisms to ensure that the design of intelligent behaviors only provide responses within rigorously defined ethical boundaries.
- The development of effective perceptual algorithms capable of superior target discrimination capabilities, especially with regard to combatant-noncombatant status.
- The creation of techniques to permit the adaptation of an ethical constraint set and underlying behavioral control parameters that will ensure moral performance, should those norms be violated in any way, involving reflective and affective processing.
- A means to make responsibility assignment clear and explicit for all concerned parties regarding the deployment of a machine with a lethal potential on its mission.

Hopefully the goals of these initial and limited efforts will fuel other scientists' interest to assist in ensuring that the machines that roboticists create fit within international and societal expectations and requirements. My personal hope would be that they will never be needed in the present or the future. But mankind's tendency toward war seems overwhelming and inevitable. At the very least, if civilian casualties can be reduced in compliance with applicable protocols of the Geneva Conventions and the ideals enshrined within the just war tradition, the result will have constituted a significant humanitarian achievement, even while staring directly at the face of war.

Abstract

A variety of ethical objections have been raised against the military employment of uninhabited aerial vehicles (UAVs, drones). Some of these objections are technological concerns over UAVs’ abilities to function on par with their inhabited counterparts. This chapter sets such concerns aside and instead focuses on the supposed objections to the use of UAVs in principle. Several such objections

currently on offer are examined and shown all to be wanting. This chapter instead defends the view that society has a duty to protect an agent engaged in a justified act from harm to the greatest extent possible so long as that protection does not interfere with the agent's ability to act justly. UAVs afford precisely such protection. Therefore, a nation is obligated to employ UAV weapon systems if it can be shown that their use does not significantly reduce a war-fighter's operational capability. Of course, if a given military action is unjustified to begin with, then carrying out that act via UAVs is wrong, just as it would be with any weapon. But the point of this chapter is to show that there is nothing wrong in principle with using a UAV and that, *ceteris paribus*, using such technology is, in fact, obligatory.

123.1 Introduction

Lethal employment of unmanned (or, as U.S. Air Force personnel prefer, "uninhabited") aerial vehicles (UAVs) has risen precipitously by a few Western nation-states (most notably the United States) across several theaters of operation (Afghanistan, Pakistan, Yemen, and other locations). The emergence of this technology has sparked widespread debate over the ethical justification of its use. Some claim these drones create a particularly asymmetrical form of warfare that is somehow ignoble or dishonorable. Others contend that UAVs impede certain *jus in bello* principles. Some claim that drones create psychological conflicts for their operators (who are often thousands of miles away) causing unacceptable cognitive dissonance in the mind-set of the warrior. Still others raise concerns over drones carrying out targeted killings by nonmilitary government agencies (such as the CIA) and other concerns over their present employment. There is a worry that UAVs could lead to autonomous weapons that make lethal decisions on their own. Finally, some argue that by removing the pilot from the theater of combat, a degree of asymmetrical warfare is attained such that the risk threshold for a given state is lowered too far – that it becomes too easy for a state using drones to go to war; thus, their use is ethically pernicious.

This chapter defends the unorthodox view that there is an ethical obligation to use UAVs. In principle, there is no need for special ethical concern for this weapon system as opposed to any other more standard weapon technology. All of the concerns just listed either miss their mark and do not challenge the ethical obligation to employ UAVs in principle or else do not rise to the level needed to override the principles which form the basis of ethical obligation for UAV employment. Remotely controlled weapon systems are merely an extension of a long historical trajectory of removing a warrior ever farther from his foe for the warrior's better protection. UAVs are only a difference in degree down this path; there is nothing about their remote use that puts them in a different ethical category. My argument rests on the premise that if an agent is pursuing a morally justified yet inherently risky action, then there is a moral imperative to protect this agent if it possible to do so, unless there exists a countervailing good that outweighs the protection of the agent. Thus, I will contend that, as a technology that better protects (presumably) justified warriors, UAV use is ethically obligatory, not suspicious.

After some preliminaries, I will first present the argument for the ethical obligation to use remotely controlled weapons. Then I'll walk through the various ethical concerns which are supposed problems for UAV implementation and show how each of these worries is misplaced or fails to adequately counter the ethical obligation for their use.

123.2 Remote Weapons as Ethically Obligatory

Media coverage and public debate over the military use of uninhabited remotely controlled weapons is currently *en vogue*. It is surprising then, given such a backdrop, that the case for the ethical obligation to employ UAVs has yet to have been definitively made. That is precisely what I intend to do. First, some distinctions must be made regarding what the target of my claims in this chapter will be. Primarily, I am referencing those aircraft presently employed by the U.S. (and other) militaries commonly known as “unmanned aerial vehicles” or drones. To avoid unnecessary gender bias, I prefer the locution of uninhabited aerial vehicles (UAVs) which I will use throughout. Examples include the General Atomics MQ-1 Predator and the General Atomics MQ-9 Reaper. UAVs have been employed for some time as reconnaissance aircraft, but only fairly recently have such platforms been used for lethal engagement. Critically, when referencing UAVs I only intend those aircraft which are under human control for, in the minimum, any particular lethal action the machine executes. Autonomous weapon systems, which can execute lethal actions apart from a human decision to do so – that can operate “on their own” – will be addressed below in objection 1. Finally, my discussion here regarding the ethical obligation to employ UAVs could be applied, *mutatis mutandis*, to any remotely controlled lethal weapon system, including land- or sea-based remotely controlled weapons.

I contend that in certain contexts UAV employment is not only ethically permissible but is, in fact, ethically obligatory. The basis for this claim rests upon what I call the principle of unnecessary risk (PUR). The PUR proceeds as follows: If X gives Y an order to accomplish good goal G, then X has an obligation, *ceteris paribus*, to chose a means to accomplish G that does not violate the demands of justice, make the world worse, or expose Y to potentially lethal risk unless incurring such risk aids in the accomplishment of G in some way that cannot be gained via less risky means. That is, it is wrong to command someone to take on *unnecessary* potentially lethal risks in an effort to carry out a just action for some good; any potentially lethal risk incurred must be justified by some strong countervailing reason. In the absence of such a reason, ordering someone to incur potentially lethal risk is morally impermissible. Importantly, the PUR is a demand not to order someone to take unnecessary risk *on par* with alternative means to accomplish some goal G. This is what the *ceteris paribus* clause is meant to capture. That is, in some cases, the only possible way to accomplish G will be to order Y to undertake a particular means which exposes Y to potentially lethal risk. In such cases, the PUR is not directly applicable; whether or not the order is justified must be determined on other grounds. The PUR simply demands that no *more* risk than is required for the accomplishment of G (no unnecessary risk) is ordered by X to be incurred by Y.

I take the PUR to be uncontroversial. In fact, it is possible that an even stronger form of PUR could be developed that morally bars not only potentially lethal risk but any risk of bodily harm whatsoever. Further, there may be a reflexive form of the PUR available that could entail self-regarding duties not to incur potentially lethal risk unnecessarily. But some may complain that an individual has the moral permission to incur lethal risk in carrying out act X in pursuit of good A even if the risk in no way aids the accomplishment of A (or some other good B) nor is demanded by justice. To avoid such controversy, I employ here the more modest form of PUR as I have developed it. So even if some wish to contend that it is morally permissible for an individual to take unnecessary potentially lethal risks upon his or herself in accomplishing some good, it still seems that the PUR holds with no problems, focused as it is upon commanding others to action. That is, if some argue that there are no moral prohibitions against recklessly endangering one's own life for no good reason, certainly morality demands that there is a strong moral prohibition against unnecessarily endangering another's life.

I will note here another important approach that could be used to argue for the obligation to employ UAVs over inhabited aerial vehicles. Namely, UAVs are, on par, cheaper to produce and deploy than inhabited planes that accomplish similar missions. Thus, the argument could run; we are obligated to spend as little shared resources as are necessary on any given collective venture (such as a military undertaking), since those resources are scarce and could be used for other worthy goals. A principle of unnecessary waste of scarce resources (PUWSR) could be formulated to capture the normative appeal of such an approach. The PUWSR would contend that by not employing UAVs to the greatest extent possible, militaries are wasting scarce resources and that UAVs should, therefore, be used in place of inhabited aircraft so as to be better stewards of the said shared resources. For, after all, any money not spent on a military venture could be allocated towards other important demands of social justice, such as (say) an egalitarian concern for equal opportunity of welfare. Such a principle, then, could be used to put normative pressure on the financial budgets of Western militaries and demand that efficiency of cost is an important moral issue. I laud such approaches – and I find financial concerns to be particularly relevant in the case of UAV underemployment – but in this chapter I set aside such arguments and focus instead on what I see as the stronger normative principle of unnecessarily risking an agent performing a morally justified act. I do this because appeals to principles like the PUWSR, while legitimate, are often more easily overridden by other competing normative concerns. That is, even a relatively significant cost difference between two competing methods for carrying out a given act could quickly become moot were there any relevant differences warranting moral concern between the two courses of action. Of course, in this case (UAVs versus inhabited aircraft) whether there are such differences will often be an empirical question. And if, as I assume in this chapter, UAVs can carry out similar missions without any significant loss in capability, then concerns over cost would apply just as well. But I still view the PUR as a stronger moral claim – one that demands a higher justificatory bar to override – than principles such as the PUWSR; thus, it is upon the PUR that I base my central claims in this chapter.

Returning then to the PUR, an example may help demonstrate its modest moral demands and *prima facie* appeal. Imagine a group of soldiers are fighting in a just war against an unjust enemy. The (unjust) enemy soldiers are, say, invading the just soldiers' country and committing horrific crimes against humanity in the process. In the defensive effort a group of just soldiers, led by Captain Zelda, engage the enemy who are a short 50 yards away. Assume that engaging these enemy soldiers is a just action in pursuit of some good (in this case the good of defending their homes, families, themselves, and other innocents). Captain Zelda has an idea. She decides to remove her bulletproof vest, throw down her rifle, and charge the enemies with nothing more than a large rock and chutzpa. She turns to the troops under her command and orders them to do likewise. Set aside whether or not such an action is morally permissible for Captain Zelda to pursue individually. Also assume that charging the enemy in this fashion would in no way aid in accomplishing the good of successfully attacking the enemies yet would dramatically increase the lethal risk her troops incur. The PUR says that it is morally impermissible for her to order her fellow troops in her squad to take off their bulletproof vests, throw down their rifles, and charge the enemy with only a rock since there is no good reason to do so. The PUR holds that it is morally impermissible for Captain Zelda to endanger the lives of her troops any more than is necessary for the accomplishment of good A. My argument below for the moral obligation to employ UAVs rests on the PUR as a sound moral principle.

Note that such an action as Captain Zelda's planned foolhardy charge *may* contribute to some other thing, Q, which she takes as a good, such as an adrenaline rush or perceived valor gained by taking such inordinate risks. In such a case, one could try to argue that the act passes the PUR since it aims at some other (purported) good. But the PUR is not in the business of determining whether or not certain goals are goods worthy of being sought. It is a structural principle that functions on permissible commands to others only after it has been determined what the morally proper good to pursue should be. So, granting a proper good, the PUR demands that one commands others to incur lethal risk (or increased lethal risk) only in pursuit of that good (or some equal or greater good) if it is necessary in the way defined. That is, the risk one orders another to incur must track exactly with the necessity of that risk in relation to the accomplishment of the purported good. In this case, we are agreeing that the good sought (or the good that *should* be sought) is the successful attacking of the enemy; hence, Captain Zelda's actions are impermissible by way of the PUR for they do not aid in the accomplishment of the proper good nor are they demanded by justice or some other good. If Captain Zelda engages in reckless warfare and orders others to do likewise not because of necessity but because of some personal pleasure gained by the excitement of risk-taking and combat, then we would conclude her actions to be morally impermissible for other reasons outside of the PUR. That is, it may very well be that Captain Zelda orders her troops to make such a brash charge in the pursuit of something she takes as a good. In that case, the reason her action is wrong is not due to the PUR but because she is mistaken that this is a good worthy of being sought and ordering others to seek (say, the adrenaline rush of risky combat). But, if we agree that the good that *should* be sought

is the attacking of the enemies, her orders are impermissible via the PUR because her commands in no way aid in the accomplishment of attacking the enemies even though they cause her troops to incur (greater) lethal risk.

Granting the PUR then, consider the following claim, OP:

(OP) For any just action taken by a given military, if it is possible for the military to use UAV platforms in place of inhabited aerial vehicles without a significant loss of capability, then that military has an ethical obligation to do so.

The position defended here is that OP is true. It could, of course, very well turn out that OP is only vacuously true because the antecedent is false. This chapter will not primarily be arguing for or against the truth of OP's antecedent, but instead assume it is true and argue that the normative consequent follows. The antecedent of OP could be false for any number of reasons. First, it could turn out to be technologically infeasible to transition some military aircraft into remotely piloted vehicles without a significant loss of capability, for any number of reasons. Or it could be near impossible to do so due to budgetary constraints. Further, it could be that the antecedent of OP is false because remotely controlled weapon systems cannot practice target discrimination as effectively as inhabited vehicles can, and this would constitute a significant loss of capability. Or it could turn out that for some as of yet unforeseen reason remotely piloted weapon systems are not as capable in some other manner as inhabited vehicles. In any such case, the antecedent is false, and OP is vacuously true. There are very good reasons to believe, however, that the antecedent of OP could be true and even likely, as I will mention at points below. The central aim of this chapter, however, is to establish that the normative consequent follows if the antecedent is true. Further, the antecedent of these claims is an empirical question – one that can be tested for its veracity. What I am investigating is whether there is any principled reason for *not* employing UAVs. I contend that there is not and further (based on the PUR) that there is a strong moral obligation to use them in place of inhabited aircraft. If there is such an obligation, then OP follows.

Note that the “in place of” criterion of OP is crucial for its derivation from the PUR. A given commander in a combat context is obligated by the PUR to order her troop to use weapon Z in place of W if and only if Z reduces the risk placed on that soldier in comparison with and as an alternative to W. It is the risk differential between options Z and W that is the source of the obligation. To put it another way, because Z exists and is presently available for the commander to order her troop to use *in place of* W, the commander is obligated *not* to order the use of W so long as Z is a viable alternative that meets the other criteria (such as not violating the demands of justice). That is to say, the ordering to use Z is (presumably) permissible in a just war-fighting context; it becomes obligatory only as an *alternative* to W. But, if only W exists (or is the only option for other reasons, such as the demands of justice), then it could very well be permissible to order the use of W. Both W and the less risky Z must be viable options for the obligation to use Z to instantiate via the PUR.

To build the case for OP's consequent, consider the following scenario. Two small towns, Prudentville and Recklessville, each have a local police force that includes a highly trained “bomb squad.” Each bomb squad has been very successful in disarming and disposing malicious explosive ordinance throughout the years with

few (but some) casualties. Recently, both towns acquired remotely controlled robots that can be used to disarm explosives while being operated from afar. Under the control of a trained explosive ordinance disposal (EOD) technician, these robots are just as capable at disarming bombs as the EOD techs are themselves working “hands-on.” And with the robots, of course, the EOD technicians are not at any risk of injury or death. After some initial experimentation to ensure use of the robots did not cost them any bomb-disarming capability, Prudentville decides to have their bomb squad use the robots in any situation where it was possible to do so. They viewed the decision as a “no-brainer”: Saving the life of even one bomb technician would be well worth the cost of using the robot. Recklessville decides not to have their EOD techs use the robots, even though they have them available and are capable of doing so. Thus, they put their bomb techs at risk for no reason (or no *good* reason, at any rate) and violate the PUR.

Take the above story as a guiding normative analogy for claim OP. If it is possible for the bomb squad to use a robot to defuse the bomb remotely, with no significant or relevant loss of capability, then via PUR the bomb squad has a clear ethical obligation to use the robot in place of a human handling the bomb directly. The situation is relevantly analogous with the current and future use of remotely controlled military aircraft. That is, if it is possible for a state to have its military use remotely controlled weapon systems to carry out combat missions instead of inhabited weapon systems, with no significant or relevant loss of capability, then via PUR (assuming military missions carry potentially lethal risks) the state has a clear ethical obligation to do so. This is simply because by operating at a much greater distance from combat, the operator of the weapon system is exposed to significantly less risk. And if there is no compelling reason to expose a soldier to risk, then it is wrong to do so. Hence, OP.

One important caveat: The justification of remotely controlled weapons in war here assumes that their employment is done as part of a fully justified war effort meeting both *jus ad bellum* and *jus in bello* criteria. Thus, if the military in question is justified in a particular military strike in the first place, they should protect the just warrior carrying out the action to the greatest extent as is possible – up until protecting the warrior impedes her ability to behave justly in combat, as I will argue below. Granted, if a given military action is unjustified, then it is unjustified whether it is done by a pilot flying an aircraft remotely or otherwise. That is, my argument that the employment of UAVs is ethically obligatory follows out of the PUR in that a given military action in question must be a proper good in the first place. If the act is morally unjustified to begin with, then it is morally impermissible for other reasons outside of the scope of the PUR. Notice, for example, that this leaves open the possibility that universal pacifism may be the correct moral outlook towards warfare, and yet OP still holds (although vacuously, because a pacifist will hold that there simply are no justified military actions).

A related point is that some may here object that my analogy between a bomb squad and a military force fails for the bomb squad is trying to disarm a bomb, and thereby *prevent* the loss of life, whereas a military strike is attempting to *take* life. Yet the point of connection for the analogy is not what, specifically, the given action is attempting to carry out (be it disarming a bomb or delivering a bomb)

but simply that a particular action is justified and aiming towards *some* worthy good combined with being inherently risky to the agent engaging in the action. Again, the analogy to UAV use rests on a presumption that a given military strike employing a UAV is justified to start with – if it is not, then the UAV strike is morally impermissible, of course. So the case with the bomb squad is intended to focus on the moral principle of unnecessary risk in the execution of *some* good. The bomb squad, commanded by their town, undertakes morally justified but risky action F aiming to accomplish good goal G. If G can be accomplished just as effectively but with less risk to the bomb squad by a means other than F (such as by using a robot), then there is a moral obligation to use the robot. The same reasoning applies, *mutatis mutandis*, for a given military force. A military, commanded by their state, undertakes morally justified but risky action F aiming to accomplish good goal G. If G can be accomplished equally as effectively but with less risk to the military members (such as by using an uninhabited drone), then there is a moral obligation to use the drone. That G for the bomb squad case is the protection of life while in the UAV case G is the taking of life is not a morally relevant difference for the analogy. What matters is that G is a good worthy of pursuit.

To put the position another way still: Ordering a war-fighter to take on risk in any activity must be justified. If a given action can be equally well accomplished via two different methods, one of which incurs less risk for the war-fighter's personal safety than the other, then a justification must be given for why this safer method is not used. If there is no good reason not to use it, then we are obligated to employ the safer method. For all cases of ordering a war-fighter to undertake any given risky action, there should be a reason that demonstrates why the risk is necessary for the accomplishment of the given objective. If one grants that removing a pilot from the theater of combat by using a UAV instead of an inhabited weapon platform greatly reduces the risk to that pilot, then there should be a presumption for using a UAV (or any remote weapon) whenever it is possible to do so in a way that does not compromise the capability of a given warrior to behave justly. The burden of proof, then, is on those who argue that we should not employ UAVs or a similar remote technology. Such a position needs to justify why we should have pilots take on such risk. As mentioned above, there are a variety of objections usually offered as to why UAV employment is ethically suspicious. I shall now review each of these in turn and show why they fail to overcome the claim that UAVs are, in principle, ethically obligatory.

123.3 Objection 1: The Move to Independent Autonomous Weapon Systems

Some worry that UAVs lead us down a road towards independent autonomous weapons (IAWs), robots that make lethal decisions on their own. Where to draw the line on when a weapon system is “autonomous” is notoriously difficult. For simplicity's sake, one might consider any weapon that makes a decision on its own accord to launch a particular lethal attack as “independently autonomous” (or

“fully” autonomous as is sometimes used). Thus, a cruise missile that guides itself to a target would not be an IAW because a human agent made the decision to launch it and for it to go attack the given target, but a Predator drone programmed so as to make the particular decision to fire on a specific target on its own accord would become an IAW. So long as there is a “human in the loop” (to use the common military parlance) for each particular lethal decision, the system may be considered nonautonomous for the purposes of this chapter. That is, so long as a human agent makes the decision whether or not to employ lethal force, the weapon is not an IAW as I use the term. The objection’s argument against the employment of UAVs runs like this: IAWs are morally impermissible. UAV development will lead to IAWs. Therefore, UAV development is impermissible.

123.4 Response

As an objection against UAV usage goes, this fails to counter the moral obligation for their employment. In fact, we can grant the first premise (that “IAWs are morally impermissible”) but dispatch the objection by arguing that its second premise is presently unsubstantiated (that “UAV development will lead to IAWs”). One could agree with the objection that we should not develop IAWs and that we should not allow development of UAVs to lead us down the road towards IAWs. Indeed, it is plausible that it could be difficult to stop such progression, but it is not true that development of UAVs will *necessarily* lead to the development of IAWs. Thus, we need empirical evidence to show that this is the case. The objection is a kind of slippery slope objection because it assumes that the development and employment of UAVs must lead to the development and deployment of IAWs. Slippery slope objections are problematic because they fail to acknowledge a plausible middle ground stopping point. Namely, this objection misses the possibility of maintaining the employment of UAVs while at the same time working for the banning of IAWs (something I recommend Western nation-states do). Thus, at present, this objection fails as an argument against the ethical obligation to employ (and develop) UAV technology.

I raise this objection first so as to make an important distinction for the scope of this chapter. In this chapter, I am only arguing for the moral obligation to use remote weapons that are explicitly nonautonomous, at least regarding any lethal decisions. On my view, the distinction between IAWs and nonautonomous remote weapons is of paramount importance in this debate and is often neglected. One reason it is so important is that if this distinction is neglected and, even more importantly, if this distinction is not enforced and efforts to develop IAWs are not stopped, then objection 1 stands (assuming that one grants its first premise). That is, to be clear, it is entirely possible that the use of UAVs will in fact lead to the use of IAWs. If this can be shown to be the case and if it cannot be stopped, then, since I do grant the first premise, I see it as a legitimate objection against the employment of UAVs. But my hope is that the development of IAWs can be stopped even while UAVs are employed and developed. I do not here have space to argue against the moral

permissibility of IAWs – that has been done effectively elsewhere (see Sparrow 2007; Asaro 2006, 2007b; Himma 2007).

Some may object that my acceptance of the premise that “IAWs are morally impermissible” is inconsistent with my use of PUR to ground the moral obligation to use UAVs. The objection would contend that many weapon systems which could (arguably) be considered IAWs offer far better protection of a just war-fighter and are thereby obligatory via the PUR. Examples could be weapon systems such as the Phalanx CIWS or the SeaRAM employed by the U.S. Navy when they are used in fully autonomous mode. Without such weapon systems many sailors would potentially be at unnecessary risk, or so this objection claims. But this objection fails to appreciate that the PUR, although a strong *prima facie* moral principle, can be overridden by a strong enough countervailing normative reason. In this case, although I do not argue for it here, I find the principled objections to IAWs to be sufficiently strong such that they override the moral demands of the PUR. That is to say, it is perfectly compatible and in no way logically inconsistent to hold (as I do) that some nonautonomous weapon systems (such as UAVs) are obligatory via the PUR and at the same time hold that IAWs are impermissible on grounds specific to their autonomous nature which overrides the PUR. In any case, regardless of whether or not one accepts the first premise of objection 1, the objection on the whole fails because it is a slippery slope argument that is inadequately substantiated.

123.5 Objection 2: UAV Limitations Lead to *Jus in Bello* Violations

Some grant that remotely controlled weapons better protect the just war-fighter but argue that they do so at the cost of a decreased ability to discriminate combatants from noncombatants and other *jus in bello* compromises.

123.6 Response

Certainly, if an UAV operator engaging the battlefield from thousands of miles away through a video feed is unable to properly adhere to the *jus in bello* principles of discrimination and proportionality, then such drones should not be used. Indeed, if using a UAV in place of an inhabited weapon platform in anyway whatsoever decreases the ability to adhere to *jus in bello* principles, then a UAV should not be used. This is consistent with OP since adhering to principles of discrimination and proportionality is a key aspect of a weapon system’s capability. And the just warrior’s increased protection (which a UAV provides) should not be bought at an increased risk to noncombatants. Martin Cook (2004) makes this point effectively when he discusses the NATO air campaign waged in Kosovo. It seemed to some that by conducting missions at 15,000 ft, NATO was more concerned with force protection than noncombatant discrimination (see Cook 2004: 126–127). Had the combat missions been flown at a lower altitude, they would have put the pilots

at more risk but would have been significantly better at discriminating between, say, an ambulance and a military transport. It is the duty of the just war-fighter, I contend, to take additional risk upon herself if such risk is required in order to better shield innocents from harm. Thus, in arguing for OP, part of the assumption of the antecedent is that the use of UAVs does not hamper the war-fighter's (technical) ability to discriminate between combatants and noncombatants nor make judicious decisions of proportionality. Such a technical weakness would constitute a "significant loss of capability."

However, there is good reason to think just the opposite is true: that UAV technology actually *increases* a pilot's ability to discriminate. For example, the Israeli government-owned Rafael Armament Development Authority claims that with the new Spike ER precision missile, which is designed to be used by UAVs, they have achieved "urban warfare precision" (Rafael Advanced Defense Systems 2010). The missile can be launched in a fire, observe, and update mode (as opposed to a "fire and forget" mode) that "allows the UAV operator to update the missile, aim, point, or steer the missile off course if the intended target turns out to be a civilian" (Rafael Advanced Defense Systems 2010). The report goes on to quote an Israeli pilot who has used the weapon system: "The beauty of this seeker is that as the missile gets closer to the target, the picture gets clearer... The video image sent from the seeker via the fiber-optic link appears larger in our gunner's display. And that makes it much easier to distinguish legitimate from non-legitimate targets" (Rafael Advanced Defense Systems 2010).

And recent studies bear out that UAVs appear to have, in fact, greater technical capabilities at making determinations of combatant status. Avery Plaw (2010) has recently compiled a database combining reports from a variety of sources on the results of U.S. UAV attacks carried out in Pakistan from 2004 to 2007. This data shows that UAV strikes were far better at noncombatant discrimination than all other methods used for engaging Taliban fighters in the region. For example, the UAV strikes resulted in a ratio of over 17 to 1 of intended militant targets to civilian deaths compared with a 4 to 1 ratio for Pakistan SWAT team offensives or a nearly 3 to 1 for Pakistan Army operations in the same region during the same time period. Or, compare the 17 to 1 ratio for the UAV employment to the shocking 0.125 to 1 militant to civilian causality ratio estimate for all armed conflict worldwide for the year 2000 (Plaw 2010). If these numbers are even close to accurate, it seems that there is strong evidence which directly contradicts the central premise of objection 1. That is, UAVs are better, not worse, at noncombatant discrimination.

Regardless, however, whether or not UAVs are as technically capable of making determinations of proper target discrimination is an empirical question. If it turns out that UAVs are not as capable, then OP's antecedent is false, and the claim is vacuously true. At present, however, all available evidence points strongly towards there being no reduction in the technical ability for UAV pilots to discriminate as opposed to inhabited aircraft pilots' ability. But, being that this is an empirical matter, there is no in-principle objection here to UAVs being ethically obligatory for military use.

123.7 Objection 3: Cognitive Dissonance for UAV Operators

This objection worries that the use of drones leads to psychological conflicts for their operators causing cognitive dissonance in the mind-set of the warrior. The worry can manifest two separate ethical concerns, first that it is wrong to do this to UAV operators – for them to kill the enemy from their “desk” at work and then go home to dinner and their child’s soccer match – and that this places an unjust psychological burden on them. The second and greater concern is that this cognitive dissonance will weaken the operator’s will to fight justly in a number of ways (e.g., the operator not taking the warfare as “real” or serious enough but instead viewing it as a video game and the operator suffering mental problems and PTSD which, because of their distance from the battlefield, could go untreated and unrecognized, causing further problems and leading to inappropriate decisions).

123.8 Response

The argument that the ethical justification for UAVs is threatened if UAV operators are more likely to behave unjustly in their combat actions due to this cognitive dissonance is unsound. First, it can be argued that the temptation for the war-fighter to commit *jus in bello* violations would actually lessen, perhaps significantly so, once the war-fighter is not at risk. The remote pilot can take more time in evaluating a target before firing – to ensure that target is an enemy combatant – than they would be able to otherwise; for in the worst case scenario, a machine is lost, not a human pilot. Returning to the bomb squad analogy, in using a robot, the EOD technicians do not experience the same level of stress because there is no danger to themselves; thus, they are not as nervous and, presumably, more successful. The same could hold true for UAV pilots making judicious decisions in combat. Once fear for their own safety is not a pressing concern, one would assume the operator would be more capable, not less, of behaving justly.

But perhaps not. Maybe the distance and disjunct of this level of remote weaponry do create a significant and genuinely new kind of stress on the war-fighter that might compromise their abilities to behave justly. There is significant empirical work here yet to be done. But even if we grant that displaced combat negatively affects UAV pilots’ abilities, first note that there are means of overcoming this problem and, second, that this issue is not a knock against the ethical justification of UAVs themselves. If necessary we could, for example, move all UAV operators much closer to the theater of combat, forcing them to live in a deployed environment, along the same time zone as the combat, and under more standard battlefield conditions and stresses. Further, note that all UAV action has the ability to be recorded and monitored. By default since it is remotely controlled, whatever data feed a UAV pilot received can easily be overseen by many others simultaneously and later for review and critique. This added level of accountability could be used to get, if necessary, further added layers of scrutiny over lethal decision making – even

demanding more than one officer agree to a kill, for example. Indeed, an entire team of officers and human rights lawyers could oversee every single lethal decision made by a UAV, if desired or deemed necessary. The point is that there are a variety of ways to overcome any concerns that the pilots of UAVs would be somehow less judicious on average than inhabited weapon systems would be. All of these argue against this cognitive dissonance problem as being somehow insurmountable, much less negating the ethical obligation for UAV use in principle. Moreover, even if there is some psychological harm done to UAV pilots that we cannot overcome, it certainly seems that such harm would be less damaging than the expected harm that could come about via inhabited flights.

123.9 Objection 4: Targeted Killing by UAVs

Recent press has raised concerns over the use of UAVs for targeted killings, particularly as is currently being done by the CIA in Pakistan, Yemen, and other theaters of operation. The specific objection is that assassinations fall outside the bounds of acceptable just-war theory practice and that UAVs somehow make this practice too easy or contribute to it in some unacceptable manner.

123.10 Response

Although ethical concerns over assassinations and further underlying concerns regarding a nonmilitary government agency carrying out independent lethal operations in a foreign theater are both of great moral significance themselves, none of these concerns are endemic in any significant way to remotely controlled weapon systems. The CIA could be carrying out these same missions with a trained sniper or an inhabited aircraft. It is this particular *policy* that is of proper ethical concern here, not UAV technology or use in general. Some might argue, however, that the UAV makes targeted killing of this sort particularly pernicious because, first, an aerial vehicle flying over airspace is in some principled way different than sending in a ground special ops troop. Second, the objection claims that the battle for the “hearts and minds” of local nationals in a given theater is significantly worsened by what they view as ignoble warfare; UAVs are thought to be “cowardly.” And, third, the objection continues, there are some ways in which UAV technology makes such policies easier to execute because of the abilities unique to current UAV platforms.

As to the first concern, this is admittedly an interesting case that could appear to be peculiar to UAVs. Namely, if a nation-state sends a UAV over another sovereign nation-state’s airspace, they have not sent an actual person or agent over the airspace. This could perhaps leave room for a contrived argument that because no actual person crossed a border, no infringement on national sovereignty occurred. Although I am intrigued by this distinction for UAV weaponry, I do not find it persuasive. For a UAV strike in terms of sovereignty issues amounts analogously to a long-distance artillery shell fired across the border or other forms of attack

that do not involve an agent crossing an actually geographic border such as cyber warfare. In such cases, yes, no actual person violated the territorial integrity of the sovereign state in question, but, of course, all nations would still (rightly) view such acts as a direct violation of their sovereignty. So, contra the worry, UAVs do not create a special class of weapons that can escape traditional just-war theory scrutiny or respect for territorial integrity and national sovereignty through an odd loophole.

As for the second concern, two points are in order. First, I would argue that it is at least possible that if UAVs are used in line with the rules of warfare, and civilian casualties are not increased (and perhaps even lessened) due to their usage, then there might be no *greater* resistance from a local populace than would be encountered for more conventional weapons. There is some empirical evidence (albeit limited) to back up this possibility (Plaw 2010). Further, the possibility has some intuitive plausibility when we note that the majority of negative responses to UAVs by local populations have come, as usual, when they have inadvertently hit civilian targets – but we have seen this same response in other conflicts when similar strikes were delivered from (say) a B-52 flying at altitude dropping munitions. Again, this seems to point to the possibility that the particular platform dropping the bomb (inhabited or uninhabited) is not what generates a negative response from the people below but whether the attack was justified and hits legitimate targets.

But perhaps this response fails. There is, admittedly, some strong empirical evidence suggesting just the opposite: that local populations' particular resistance to UAVs is precisely due to the fact that they are uninhabited. But so be it. For even if the first response fails, recall that my argument for the ethical justification of UAVs requires that there be no reduction in just war-fighting capability. So even if it *does* turn out that in a given theater of operation UAVs do, in fact, cause significantly greater resistance from the local populace as compared to the resistance that similar inhabited vehicles would generate (perhaps because the population thinks they are cowardly or some similar response), then they should not be used on OP grounds. Such a limitation would clearly fall under the "significant loss of capability" clause of OP. And, of course, this is an empirical question, not an in-principle objection to UAVs.

The third concern – that UAV technology makes such actions easier to carry out – similarly does not offer a principled objection to the moral obligation to use UAVs. It is true that the extended ability of platforms such as the Predator to "hover" and stay in a localized area for long hours, even days, and observe targets, is a clear combat advantage. Many inhabited aircraft do not have such capacities. And, further, some of the remote areas where such strikes are carried out by UAVs are such that they would be inaccessible to similar inhabited weapon platforms. But these facts about the superior capabilities of UAVs do not count against OP. Just as the advent of airpower brought with it many new and often superior ways war-fighters could engage in combat (both justified and not), such advantages do not imply anything inherently wrong with airpower *qua* airpower. Further, the mere existence of such advantages does not force policy makers to misuse these capabilities. Certainly, it would be impossible to drop bombs on innocent civilians if planes did not exist. But that some drop bombs on innocent civilians do not make airplanes morally

suspicious but rather those who so use them to drop bombs. The same holds true for the new capabilities brought about by UAVs.

Thus, there is nothing peculiar to UAVs in regard to the ethical concerns over their present use in targeted killings around the globe. It is the morality of the United States' recent policy of targeted killings we must debate here, not the ethical justification of UAVs.

123.11 Objection 5: UAVs Create Unjust Asymmetry in Combat

This objection normally runs as follows: The use of remotely controlled weapons by one force against another force that does not have similar technology crosses an asymmetry threshold that makes the combat inherently ignoble. That is, the extent of asymmetry in the combat abilities between two opposing sides becomes so great when one side employs remote weapons that the fight is intrinsically unfair and that, in turn, makes the use of the said remote weapons morally impermissible. This position is usually held because in such circumstances one side literally does not take *any* life-or-death risks whatsoever (or nearly so, since its war-fighters are not even *present* in the primary theater of combat), whereas the opposing side carries all the risk of combat.

123.12 Response

As an objection against the ethical justification for remotely controlled weapons broadly, and UAVs in particular, this commonly heard argument fails. First, if someone holds that justified combat should be a "fair fight" between sides, at least to some degree, then I would argue that contemporary military engagements crossed that threshold long ago. How fair is the present fight between an F-22 pilot flying at altitude delivering a precision missile and a tribal warrior wielding an RPG? If there is a moral problem here due to asymmetry, it seems to have occurred long before UAV implementation and is not endemic to them. But, second, even *if* the actual removal of the warrior from the theater of combat represents a truly new level of asymmetry in combat (and perhaps it does), this alone is still no argument against doing it. This is because if one combatant is ethically justified in their effort, and the other is not, then it is *good* that the just warrior has the advantage and is better protected.

Here I am following Jeff McMahan's recent work rejecting the moral equality of combatants (see McMahan 2009). That is, the warrior fighting for a just cause is morally justified to take the life of the enemy combatant, whereas the unjust fighter is not justified, even if they follow the traditional principles of *jus in bello* such as only targeting combatants and the like, to kill the justified fighter. Thus, there is no chivalrous reason for a just combatant to "equal the playing field" or "fight fair." If combatant A fights under a just cause, while combatant B fights for an unjust cause, combatant A owes nothing to combatant B by way of exposing herself to

some minimal threshold of risk. Thus, it is *right* for combatant A to reduce their risk in their engagement with the unjust enemy.

But even if one disagrees with McMahan's position and the rejection of the MEC, they still do not have grounds to object to the protecting of a soldier under the "fair fight" objection. An MEC advocate would still presumably agree that a military pursuing a justified action as part of a just war is justified to do all they can to protect their soldier so long as that protection does not hinder the soldier's ability to follow *jus in bello* principles. The only difference is that an MEC advocate will think the unjust aggressor state enjoys the same allowance to protect their war-fighter similarly. That is, even if one thinks that soldiers enjoy a symmetrical position of the right to individual defensive measures in a given conflict, this in no way prevents either side from maximizing their personal defense so long as it is not at the cost of *jus in bello* precepts; indeed, such precepts (under MEC) would explicitly allow it. Thus, again, the argument for a "fair fight" fails on two counts. First, it is already overcome by earlier technological advancements because present military operations are already far from fair even without the asymmetry of UAV weapon systems and thus the issue here is not with UAVs properly speaking. And, second, the desire for a "fair fight" is simply a weak claim in the first place, something akin to an archaic demand of military commanders in the eighteenth-century warfare to line up their troops across from one another for a "dignified battle." There is simply no normatively compelling reason to think a justified military force need have a fair fight anymore than we would think a police force ought not use bulletproof vests to offer dangerous criminals a fair fight.

But perhaps this still does not give the objection its due. Paul Bloomfield once remarked that simply the idea of "being killed by remote control" is powerful and disturbing. The intuition seems to be that killing someone in such a manner is profoundly disrespectful, that a human being deserves to be able to at least point at his or her killers (and condemn them, if they are unjust) even if his or her killers are cruising 20,000 ft above in a plane. The thought is that at least a human being in a plane high above is less of a "faceless" death wrought upon someone than a robot being operated remotely would be. Or consider the sentiment Uwe Steinhoff raises in discussing remote weaponry generally and how the odd risk asymmetry it creates (making the targets of attack "defenseless") does not feel like "honorable" warfare:

To be sure, I do not deny that there is something fishy about attacking the defenseless. What is fishy about it might be captured very well in this passage: 'The pilot of a fighter-bomber or the crew of a man-of-war from which the Tomahawk rockets are launched are beyond the reach of the enemy's weapons. War has lost all features of the classical duel situation here and has approached, to put it cynically, certain forms of pest control.' (Steinhoff 2006: 7).

It must be admitted that there does appear something ignoble or dishonorable in such a vision of warfare as "pest control" that Münkler's quote describes. Perhaps it is that such distance makes warfare seem too clinical or coldhearted. Many will have sympathy with such a sentiment when envisioning UAV warfare – myself included. But whatever this sentiment is, it does not amount to a normative argument; such a "feeling" does not constitute a moral reason for rejecting UAV use.

Something being disturbing does not by itself make it wrong. This sense of the ignobility must be elucidated into a coherent and compelling ethical argument against using UAVs; mere displeasure at imagining their employment does not help us. As Steinhoff writes:

Judged from a traditional warrior's code of honor, a code that emphasizes, among other things, courage, there is nothing honorable in killing off defenseless enemies (whether it is therefore already *dishonorable* is yet another question). But honor and morality are not the same, and honor and the laws of war are not either. In short, the prohibition of assaults upon the defenseless is neither an explicit nor an implicit principle of the laws of war or of just war theory. (Steinhoff 2006: 8).

Steinhoff is certainly right in this. I would add that a crucial element in how one “feels” about imagining such warfare depends on whether or not the precision missile strike in the picture envisioned is justified or not. Is it a military strike as part of a fully justified defense against an aggressing, unjustified, destructive enemy force? Is the strike hitting a legitimate and morally culpable target? If it is, such factors temper our view of the strike considerably and move us away from the “pest control” picture. In such a case, we should desire that the just warrior be well protected from any possible threat that this enemy might proffer – protection that the UAV affords.

123.13 Objection 6: Reduction of the *Jus Ad Bellum* Threshold

The worry here is that the asymmetry in combat abilities created by the advanced technology of UAVs, and in particular by the massive reduction of risk to the UAV pilot, makes it too easy for the nation employing UAVs to go to war. That is, the asymmetry created by UAVs lowers the *jus ad bellum* threshold such that more unjust wars might be conducted because the risks of war to a nation-state could become so minimal.

123.14 Response

This objection, on first glance, may appear to be the strongest objection to the implementation of UAVs. The worry that it will be easier to go to war if we have technology X and thus more tempting to enter into unjust wars (making more unjust wars more likely) is intuitively plausible. But this kind of argument ultimately fails for the objection does not succeed in negating the present moral imperative to use UAVs as derived from the PUR. To see why this is, consider two possible worlds, Alpha and Beta. In Alpha, nation-state Zandar has developed the technology to make bulletproof vests for its military members to wear in combat which significantly decreases the risks they incur in battle. Zandar, in accordance with the PUR, produces these bulletproof vests and has its military members wear them. In world Beta, nation-state Zandar has developed the same technology and has the bulletproof vests available. However, they reason that if they use these bulletproof vests, war

would “cost” them less in terms of risks to their own troops and, thus, be easier (and thus more tempting) to wage. In such circumstances, Beta-world-Zandar worries, more unjust wars are more likely. So they decide not to use bulletproof vests in order to make war more costly to wage (by intentionally increasing the risk to their soldiers) in the hopes that this will lessen the likelihood that they will engage in an unjust war in the future. Aside from this one decision, the worlds Alpha and Beta are identical.

Let us assume that it turns out Beta-world-Zandar’s reasoning was correct. That is, going forward from this juncture there does, indeed, end up being some greater number of unjust wars waged in world Alpha than in world Beta. The use of the bulletproof vests in some way lowered the threshold for going to war for Alpha-world-Zandar enough that it made a positive difference on the total number of wars fought – which included some unjust wars. I still contend that Beta-world-Zandar’s decision was morally impermissible. This is because the normative force of the PUR upon present actions is too strong to overcome such weak predictive calculations of future possibilities.

I will show why this is shortly, but first note that the scope of this issue far exceeds UAVs and bulletproof vests, of course, but strikes at *any* asymmetry in military technological development whatsoever. Any improvement to a given military’s capabilities that gives it an advantage over its potential enemies will face the same objection offered here against UAVs. But that would mean that this objection could be used to block the development and implementation of *any* military technology that creates any asymmetry. Further, the objection could actually be employed to work backwards: that current militaries should intentionally reduce military capabilities in order to make war more costly to them since doing so would place their soldiers at greater risk. Following this logic could even lead to the conclusion that a state should have their militaries throw away their weaponry and all defensive technology, for certainly a neutered military would be less likely to engage in unjust wars in the future. I grant that this worry about asymmetry created by improvements in military technology making it easier to go to war may well be a legitimate concern. But it is a logic that quickly runs to demanding no military technology whatsoever in the hopes of avoiding future unjust wars. Perhaps this is correct. Perhaps there should be no militaries. But notice that we are now a far cry from arguing over UAV technology. We are arguing over the existence of any military weaponry or advancement whatsoever. If so, then this is not actually an objection *specific* to UAVs in principle. Moreover, if objection 6 is correct in this way, then OP still stands – it is just a vacuous claim: as would be *any* claim about the possibility of justified use of military weaponry of any kind.

But the problems with the objection run even deeper. As I alluded to above, the reasoning by Beta-world-Zandar not to use the vests, notice, rests on epistemically dubious calculations that are predictive about *themselves* doing something wrong in the future (“we might be more likely to do wrong action X down the road”) over epistemically solid calculations to protect their own just war-fighters presently (“our soldiers will be safer *today* if they wear the vests”). Notice what odd moral reasoning would be occurring were objection 6 to work: *Because* we will most likely

behave unjustly in the future, we should behave unjustly in the present (by violating the PUR in choosing not to protect our warriors as best we can) in order to try to prevent ourselves from acting unjustly in the future. If that holds, we have a strange account of moral epistemology at work, to say the least. We should forego taking presently morally correct action A in order to help restrain our future selves from the likelihood of committing morally wrong action B. In other words, we should do something wrong now in order to (hopefully) better stop ourselves from doing something wrong in the future.

This seems odd, although there could perhaps be cases where such decisions are the right actions – the lesser of two evils, perhaps. But notice that the Beta-world-Zandar decision is not a straightforward case of present self-restraint to limit future potential wrongdoing for, presumably, *usual* cases of present self-restraint are not acts that are themselves impermissible. For example, imagine a man, Tom, who knows he tends to get very angry and do intemperate things. Tom decides he should lock up his gun in a safe and give the key to it to a trusted friend. Tom does this present act to restrain his future self from doing something wrong. But Tom's locking up his gun is not an impermissible act viewed on its own. Violating the PUR by not protecting just war-fighters is a presently impermissible act viewed in isolation. Thus what makes the reasoning of Beta-world-Zandar's decision so strange: They are intentionally putting their soldiers at greater risk now (which would be considered impermissible in isolation) in order to restrain themselves from doing something impermissible in the future. The comparison back to Tom would be if Tom decides to punch his friend Sam now (which is impermissible) because it will help him not do something worse in the future (such as kill Bob). If that is actually the case, then this *could* be the right thing to do. But notice that we would require a rather high level of epistemic certitude for Tom's knowledge of this scenario – and that there is no other means to avoid killing Bob – in order to deem his act justifiable. That is, if Tom has near *certainty* that the only way to prevent himself from killing Bob in the future is by punching Sam now, then perhaps it is a justified act. But one wonders how Tom could *ever* have such epistemic certitude predicting future acts. The same is true for Beta-world-Zandar.

But perhaps it is still possible that such a decision is justified. This is because, one could argue, I am here equivocating on the moral weight of the present wrong of failing to protect just war-fighters and the future potential wrong of more unjust wars. If they are of vastly different moral significance and consequence, then perhaps it is justifiable to do a lesser wrong now in order to increase even the slightest chance of avoiding a much greater wrong in the future. I grant this possibility. Indeed, one could argue that such a decision is directly in accord with the PUR since the good of avoiding future wars is a greater good than the present protection of just soldiers (i.e., some would argue that such a calculus is demanded by justice).

The trouble with applying this to our present case is the high degree of epistemic uncertainty we have in predicting future states of affairs, particularly future decisions to go to war. That is, even if the wrong of sacrificing the protection afforded to just soldiers is a lesser evil than the possibility of future unjust wars,

we have complete confidence in the *present* wrong occurring but we would be far less than certain of the future wrong occurring. In other words, the *odds* of that future wrong occurring will matter and it is unclear how we could reliably predict such odds. The odds need not be equal between the wrongs, of course. If the greater evil was great enough, we could perhaps need only a relatively small chance of its occurrence to outweigh even the certainty of a lesser evil. But, again, it is unclear if we can even have *that* small level of epistemic confidence that a given weapon technology (be it bulletproof vests, M-16 rifles, or UAVs) would lead to greater instances of unjust wars or at least not the level of confidence we would need to trump the demand not to commit the present wrong.

So even if it turns out that future worlds would be ones with less war were we to intentionally limit our own military technological development, we cannot have enough epistemic certainty in knowing this presently to overcome the demands to protect the just war-fighter. Short of a crystal ball, I cannot imagine how we could ever have the level of certainty for predictive knowledge claims of future group behavior that would be necessary to claim that the future *possible* good should outweigh our present moral duty not to unnecessarily risk others. Perhaps it can be done, but this must be demonstrated before we intentionally bring unnecessary risk upon others. That is, one would have to show how we can have such epistemic confidence that we are not violating the PUR (via the demands of justice override) in not presently protecting just war-fighters. The burden of proof will be on those claiming that we must presently undertake an act that we would usually consider impermissible in isolation in order to avoid a future evil that we do not have complete confidence in. Hence, although it is certainly possible that use of UAVs could lower the costs of going to war for a given state and, thereby, lower the threshold for going to war such that a state might have an increased likelihood of engaging in a war that is unjust, such predictions cannot be the basis for demanding an intentional violation of the PUR given our present epistemic limitations. This is an unhappy conclusion. While I have great sympathy for the worry, it seems the PUR is too strong to overcome with such shaky future predictions as to the unethical decisions a future state would make. And, again, if we allow this block against UAVs, it would set in motion a moral principle that would not stop at UAVs but encompass all military technology – not just its future development but retroactively demand that present military technology creating force asymmetry be intentionally reduced. If this is sound we could eventually be back at demanding that Captain Zelda *should* be required to fight with no bulletproof vest, no rifle, and with only a rock in order to make war “cost us more” so that we would be less likely to engage in an unjust one. But this is absurd. If a war is just, we are obligated to protect the just war-fighters engaging in it. UAVs do precisely that.

123.15 Conclusion

UAVs will have an increasingly large presence in military operations on all levels; this much appears increasingly inevitable. Here I have made the case that any new

technology that better protects the just war-fighter is at least a *prima facie* ethical improvement and is morally required to use unless there are strong countervailing reasons to give up that protection. I have argued that if using UAVs (as a particular kind of remote weapon) does not incur a significant loss of capability – particularly the operators’ ability to engage in warfare in accordance with *jus in bello* principles – then there is an ethical obligation to use them and, indeed, transition entire military inventories to UAVs anywhere it is possible to do so. In fact, I endorse the stronger claim that such a proposed transition would not only be feasible without a significant loss of capability but would actually *increase* weapon systems capability *and* the ability to fight justly. All of the concerns regarding UAVs presently on offer do not negate this ethical obligation to use uninhabited weapon systems and should be properly viewed instead as indictments against mistaken policy decisions and specific instances of force application – not as principled objections against UAVs themselves for none of the concerns are endemic to UAVs in any significant way.

Finally, this chapter defends the ethical obligation to use UAVs for a putatively just military action in the current context, whereas one might object that much, if not all, *actual* UAV employment is part of military actions that are morally questionable or outright impermissible. The particular contemporary circumstances and misuses of UAVs, however, do not trump the moral principles underlying the ethical obligation to employ UAVs for *just* actions. Indeed, this highlights the central point well: The first question for the morally permissible use of *any* weapon technology is, of course, whether the military action itself is morally justified. If it is not a justified undertaking in the first place, then it does not matter if it is carried out via a crossbow, a sniper rifle, or a UAV; it is morally impermissible regardless. If the act is morally justified, however, we are obliged via the demands of the PUR to protect the agent ordered to carry out that action as best we can, be it a police officer apprehending a dangerous criminal, an EOD technician disarming a bomb, or a justified warrior fighting an unjust enemy. Hence, the ethical obligation to employ UAVs.

Abstract

Unmanned systems in military applications will often play a role in determining the success or failure of combat missions and thus in determining who lives and dies in times of war. Designers of UMS must therefore consider ethical, as well as operational, requirements and limits when developing UMS. The ethical issues involved in UMS design may be grouped under two broad headings: Building Safe Systems and Designing for the Law of Armed Conflict. This paper identifies and discusses a number of issues under each of these headings and offers some analysis of the implications of each issue and how it might be addressed.

124.1 Introduction

A significant proportion – perhaps even the majority – of contemporary robotics research is funded by the military. The US-led invasion and occupation of Iraq and Afghanistan demonstrated the military worth of – and greatly increased the demand for – uninhabited air vehicles (UAVs) such as Global Hawk, uninhabited combat aerial vehicles (UCAVs) such as Predator and Reaper, and also robots for bomb and IED disposal (Butler 2007; Hockmuth 2007; Office of the Secretary of Defense 2005a,b, 2012; Singer 2009). Unmanned systems (UMS) in the form of UAVs, UCAVs, unmanned ground vehicles (UGVs), unmanned undersea vehicles (UUVs), and unmanned surface vehicles (USVs) are currently being developed and deployed by nations including the U.S., Israel, South Korea, Britain, France, Germany, Denmark, Sweden, China, and India (Card 2007; Kenyon 2006; Legien et al. 2006; McMains 2004; Masey 2006; Office of the Secretary of Defense 2005a, Appendix A; Office of the Secretary of Defense 2005b, pp. 38–40; Peterson 2005). As a consequence, many engineers, computer programmers, and roboticists are now working on systems for military applications.

The use of robots in military applications generates a large number of important ethical issues (Veruggio and Operto 2006, 1517) – indeed, so many that they defy treatment in a single paper. Will these systems make conflict more likely by promoting the idea that wars can be waged without casualties? Will they encourage asymmetric warfare by rendering it impossible for any but the most high-tech of militaries to triumph in conventional battle? What are the implications for just war theory if nations can fight wars without putting the lives of their warfighters at risk and, conversely, what does just war theory have to say about the war being waged in this fashion? Will the development of robot weapons generate an “arms race to autonomy” thus effectively forcing the deployment of weapon systems in “fully autonomous mode”? Who should we hold responsible for killings committed by autonomous weapon systems? The author has dealt with some of these issues elsewhere (Sparrow 2007, 2009, 2011, 2012, 2013).

It is possible that the answers to some of these larger questions may give us reason to doubt the wisdom and the ethics of developing robots for particular military applications. Indeed, while it may not prove a welcome recognition amongst many of the audience for whom this paper is written, there is clearly a question about the ethics of computer scientists and engineers choosing to work on military applications of robotics at all (Sparrow 2012). There are many more urgent human needs than any that will be met by military robots (Anonymous 2007). In the context of contemporary global inequality, widespread poverty, and looming environmental catastrophe, the amount of human ingenuity, labor, and physical resources devoted to the military is, frankly, morally obscene. It is also a live question whether the objective of achieving national security or a just peace could not be better served by nonmilitary spending (Baard 2003). Researchers face a personal choice about whether they wish to participate in and contribute to such an unsatisfactory state of affairs (Mitcham 1989). Whether they should speak out

against their members working for the military is also an important question for professional associations of engineers, computer scientists, and roboticists (Baard 2003). However, as this argument has been made at length elsewhere, it will not be discussed here (Sparrow 2012).

Thus, this paper focuses on a subset of the larger issues raised by the development of robot weapons: those questions that confront those that *have* chosen to work as the designers of these systems. The ethical issues involved in UMS design may be grouped under two broad headings: Building Safe Systems and Designing for the Law of Armed Conflict. This paper identifies and discusses a number of issues under each of these headings and offers some analysis of the implications of each issue and how it might be addressed.

It must be acknowledged at the outset that not all of the issues treated in this paper are unique to UMS. Many of them clearly also arise in relation to the use of long-range and/or precision munitions more generally. Genuinely new issues may arise if future unmanned systems develop the capacity for truly autonomous decision-making due to advances in “Strong AI” (Sparrow 2007). However, it is difficult to assess the likelihood that this will come about; past predictions about the prospects for genuine machine intelligence of the sort necessary to allow machines to constitute autonomous moral agents have repeatedly been shown by events to have been overly optimistic. In the meantime, however, the many important ethical questions involved in the design of existing UMS, which lack the capacity for morally autonomous action, are not any less important or urgent by virtue of not being entirely unique. Moreover, as is noted at several points below, familiar issues may arise in new guises or may arise with increased urgency in relation to the design of unmanned systems as compared to manned systems. The approach in this paper is therefore to examine and highlight the ethical issues involved in the design of UMS without denying that similar issues may arise elsewhere in engineering and especially in the design of other sorts of long-range weapon systems.

124.2 Building Safe Systems

Before it will be ethical to field UMS, they must be safe to operate and maintain and safe to fight alongside. More precisely, they must be as safe as comparable manned systems capable of achieving similar performance in comparable roles. Their routine operation should not pose more of a threat to the health and safety of the operators than the systems they might replace. As far as is possible, they should not expose their operators to enemy line-of-sight fire. They must be capable of combined operations with manned systems during military exercises and wartime and also of being used for training and in peacetime operations alongside civilian systems (Barry and Zimet 2001; Hockmuth 2007, p. 73). This requirement is especially burdensome on UCAVs and UAVs which must be capable of sharing airspace with both military and civilian aircraft (Hockmuth 2007; Kenyon 2006; Kochan 2005; Lazarski 2002; Wise 2007). UMS, their operators, and other military

forces they intended to operate alongside of must be linked by reliable and robust communication systems in order to minimize the possibility of dangerous accidents (Barry and Zimet 2001; Kenyon 2006, p. 44). They must be capable of reliable “friend or foe” identification in order to avoid causing casualties by “friendly fire” (Kainikara 2002; Marks 2006). Less obviously, as is discussed below, UMS must be safe to use around enemy noncombatants (Arkin 2007, p. 4). All of these requirements are likely to become more demanding as the scope of autonomous action available (and allowed) to UMS increases.

Because the relevant safety comparison between manned and unmanned systems involves comparing “systems capable of achieving similar performance in comparable roles,” this comparison actually speaks strongly *in favor* of the application of UMS in roles which currently involve a high risk to human life (Strawser 2010). Thus, for instance, the use of UMS in bomb and IED disposal and mine clearance is not merely ethical but ethically mandated where possible – even with existing systems. Similarly, once they develop the capacity, UMS may quickly become the option of choice for conducting suppression of enemy air defenses (SEAD) and intelligence, surveillance, and reconnaissance (ISR) missions (Barry and Zimet 2001; Mustin 2002; Office of the Secretary of Defense 2005b, Appendix A; Peterson 2005; Sullivan 2006).

Initially, at least, the problem of making robots safe is for the most part a technological rather than an ethical challenge. It will be possible to greatly improve the safety of military robots by improving the technology in ways that can be specified independently of any commitments on controversial ethical questions. However, as the rest of my discussion makes clear, the use of UMS in armed conflict may generate a range of unanticipated problems and consequences involving harm, or the risk of harm, to various parties, the avoidance and/or mitigation of which will require making difficult choices between competing and sometimes incommensurable values. Designing “safe” systems will therefore require making ethical decisions.

124.2.1 Keeping Humans Out of Harm’s Way?

The literature on military robotics typically emphasizes the value of UMS in keeping human beings out of harm’s way and thus saving (“friendly”) human lives (Boland 2007; Chapman 2002; Featherstone 2006; Fielding 2006; Kainikara 2002; Legien et al. 2006; Office of the Secretary of Defense 2005a; Peterson 2005; Scarborough 2005; Sherman 2005; Veruggio 2006, Sect. 7.7.2). Yet, as UMS become more central to war fighting, it is likely that circumstances will arise in which this relationship will be reversed; human beings will start to be placed in harm’s way as a result of the operations of robots.

There are three scenarios in which this might be expected to occur.

First, as soon as robots can play a useful role in military operations, warfighters will rely on them to complete the tasks to which they have been assigned. For instance, where a robotic mine clearer has swept a minefield, warfighters will expect the area to be free of mines. If robots have been used to secure and patrol

a perimeter, warfighters will expect the area to be clear of the enemy. If robots have been sent to conduct reconnaissance, then warfighters will assume that they have reliable knowledge of enemy assets. Consequently, if robots fail in these tasks, these expectations will be confounded and human lives may be placed at risk.

Second, human lives might be placed at risk in order to defend, service, or recover UMS which are threatened in combat or other operations and also to prevent the enemy gaining valuable intelligence if they should capture a UMS. As UMS develop, they are likely to become increasingly sophisticated and expensive systems and consequently important military assets. Where a high-value UMS is in jeopardy due to a malfunction, or to enemy action, there will be a significant temptation for the commanding officer to commit human forces to protect or recover it. If the system is valuable enough and the apparent risk is low enough, the commanding officer may even be obligated to do so (Wall 2006). It seems likely that, given the extent of the operations in which Predator UCAVs have been engaged and the \$4.5-million-plus price tag of each Predator, such circumstances have already arisen in the current conflicts in Iraq and Afghanistan. Of course, similar scenarios may also arise with military systems without a robotic or remote component. However, these “rescue” or “salvage” missions are more likely with the use of UMS because the nominal capability of these systems to carry out operations without incurring friendly casualties is likely to lead them being deployed in circumstances and in pursuit of objectives where manned systems would not be deployed (Mustin 2002).

Third, the availability of UMS may mean that military conflicts are initiated with the intention that they can be completed without placing warfighters in harm’s way only to discover that victory can only be achieved – or the operation aborted without disaster – with the involvement of human beings in the theater of operations. This may occur either because the weapon system malfunctions or because winning victory turns out to be beyond the capabilities of the UMS due to changed circumstances, including enemy action, or because the operation was ill-conceived in the first place. As a result, human warfighters, especially Air Force pilots and Special Operations forces, may find themselves involved in conflicts because robots have failed to achieve their objectives (Mustin 2002).

The obvious way to minimize these risks is to design and manufacture robots that are more reliable, effective, and also flexible, so that they seldom break down or fail in their missions, and to include robust anti-tamper measures to minimize the need to recover weapons that have been lost in enemy territory. A complex and interesting set of trade-offs then arises. More sophisticated robots are likely to be better able to complete their missions but also more expensive and therefore more likely to drag human beings into combat to repair or recover them when they do fail. Less versatile – and therefore less expensive – robots might be more “disposable” and consequently less likely to put human lives in jeopardy as a result of the need to recover them but also less reliable and more likely to involve humans in combat if they fail in their missions. On the other hand, “better” robots may be more likely to be sent on more ambitious missions and have an increased risk of failure as a result. People may also be more inclined to rely more heavily on what they perceive to be “better” robots. More elaborate and/or ambitious missions may also be more likely to require human intervention to complete or “salvage” them. It will be

important for designers of UMS to think through these trade-offs before setting out to build robots that might avoid the dangers highlighted here.

124.2.2 The Psychological Stresses on Remote Operators

An issue, which is related to the safety of UMS, that is worthy of singling out for special attention is the possibility that the deployment of UMS in armed conflict will expose their operators to new forms of psychological stress. Designers will need to consider the impact of operating UMS on their operators when designing them.

At first sight, the use of UMS might be expected to *reduce* stress and trauma in warfighters by taking them off the battlefield. However, while the use of UMS may reduce physical trauma and some sorts of mental and emotional trauma, it also seems likely to generate significant psychological stress related to the operator being simultaneously “present” in and absent from the battlefield. Through their link with the UMS, operators may witness, and may even participate in, events which are psychologically distressing. In particular, operators in UMS may find themselves witnessing events in which they are powerless to intervene because of the limited capacities of the systems they are operating. Thus, for instance, a UMS operator may witness at close quarters the warfighters they were fighting alongside of being killed, massacres of civilians, or other war crimes, yet be helpless to prevent them.

Of course, human beings involved in war have always been subject to the danger that their experiences will scar them psychologically. It is also true that modern-day warfighters, especially pilots, tankers, gunners, and submariners, already experience many aspects of combat through various electronic or other sensing systems, which mediate that experience (Shurtleff 2002). However, what may be new with the application of UMS is a near-complete disjunct between the simultaneous experience of the consequences of war and the experience of the process of fighting it. In the past there has always been a significant gap between the consequences of war and the experience of fighting at, for most of its participants. In the future, however, the operators of UMS may find themselves simultaneously inhabiting a pleasant office space and the chaotic streets of an urban environment in the midst of violent battle. Operating a UGV or UAV may provide them with a “point of view” in the midst of the battlespace that exposes them to a vivid experience of the chaos of modern war and its consequences (Bender 2005). According to Capt. Steven Rolenc, spokesman for Predator operations at Nellis Air Force Base (Quoted in Sherman 2005, p. 35),

(When) “you put your hands on the controls and your eyes on the screens, you feel as though you’re flying over Iraq or flying over Afghanistan. You get yourself into that reality. It’s not a video game. It’s the real deal.”

Similarly, Air Force Major Shannon Rogers (quoted in Donnelly 2005) claims that

Physically, we may be in Vegas, but mentally, we’re flying over Iraq. It feels real.

Yet when they “log off” the operating system for the UMS, the operators may return to a peaceful office environment and perhaps even, later that day, to their families (Shachtman 2005a). This geographic and psychological distance between the operators and the environment in which they are operating may negatively affect the coping mechanisms that warfighters currently use to process the stresses they experience in combat. In ordinary warfare, the larger context of being physically present in the theater of operations may allow warfighters to prepare for combat through a process of anticipation which makes reference to local circumstances and to deal with them afterwards through conversation and interaction with others who may have shared similar experiences. Fighting a war in a country that one has never set foot in, alongside people one has never met, may be uniquely difficult in terms of the opportunities for warfighters to “process” their experiences.

It may well prove preferable to expose operators to these stresses rather than the stresses they would experience if they were actually present in the battlespace. However, armed forces that operate UMS would be well advised to monitor of the impact of any such stresses on the operators of UMS and to be open to the possibility that the combination of close proximity to, and extreme distance from, violence and its consequences made possible by the development of UMS may have a unique affect on the mental and physical well-being of their operators. According to several reports, these effects are already being felt by the U.S. Air Force operators of Predator UCAVs who pilot these vehicles through the skies of Iraq and Afghanistan by satellite link from the U.S. mainland (Donnelly 2005; Kaplan 2006). The result has been physical and emotional exhaustion amongst the operators and also significant stresses on their families (Kaplan 2006).

It seems likely that the extent and consequences of such stresses will be, at least in part, a function of the design of UMS. In particular, two features of systems may play a role in determining the level of stress to which their operators are exposed.

Firstly, the nature of the interface used to operate the system will play an important role in the stress levels of operators. Systems which provide only abstract and mediated images of the battlespace might be expected to induce little, if any, trauma in those who operate them. On the other hand, the development of more sophisticated virtual reality displays, which will immerse the robot’s operator in the robot’s point of view, might be expected to increase the stress to which operators will be exposed. Designers will therefore need to consider these important human factors when designing the human-machine interface for UMS.

Secondly, the capacities of the systems to intervene in the events that they allow the operator to witness are likely to be relevant. However, the relationship between this capacity and the stress on the operators is unlikely to be straightforward. There are, in fact, two different possible types of stress that operating a UMS may produce: stresses relating to being a *witness* of traumatic events and stresses relating to being a *participant* in traumatic events.

The most intensive source of psychological stress on the operators of UMS is likely to be regret arising from what the operator did – or failed to do – during combat operations. Systems that provide *no* capacity to intervene may therefore provoke *less* stress than those that do offer some capacity to shape the outcome of

events in the battlespace. However, even these “passive” systems may traumatize their operators if they are forced to witness atrocities of various sorts; machines that provide the experience of “being there” are likely to be especially problematic in this regard.

Once the system *does* offer its operator some way to affect the battlespace, then the operator is likely to feel responsibility for the exercise of this power and to be prone to regret if they come to believe that they should have done otherwise than they did. It is therefore tempting to conclude that the “best” systems would be those that provided their operators with the largest possible scope of action so that they could prevent or avoid outcomes that might otherwise traumatize them. That is to say, that more powerful systems, which make possible a wider range of actions, would be less likely to expose their operators to “participant” trauma. However, if the operator has more power to affect things, then he/she may also have more to regret. In particular, operators may come to regret what they did do, as much as what they didn’t. Increasing the capacities of systems therefore provides no easy solution to the problem of the stresses to which operators are exposed. However, it is apparent that, in terms of the risk of psychological trauma to operators, the *worst* systems will be those that leave the operator with the sense that they could have altered the outcome of the scenario when in fact they could not have. This conclusion is more significant than first appears because, despite the “hype” surrounding them, many unmanned systems are severely limited in the range of actions that they make possible. A particularly important limitation of such systems in this context is their inability to provide emergency medical care to wounded warfighters and/or civilians where required. It will therefore be crucial to ensure that operators have realistic understandings of the effective capacities of the systems that they are operating, in order to minimize the chance that they will regret circumstances that they were in fact unable to alter.

Because of the difficulties involved in locating unclassified research on the operations of UMS in military roles, these remarks are necessarily, to some degree, speculative. However, at the very least, it is clear that good design in relation to these issues must be guided by the results of empirical research into the appropriate questions in the fields of human-robot interaction and combat psychology.

124.3 Designing for the Law of Armed Conflict

The ethical use of UMS in armed conflict, like that of other weapons, will need to be governed by the law of armed conflict (LOAC) (Gulam and Lee 2006; Lazarski 2002). The details of the application of the LOAC to the operation and design of UMS is a matter for military lawyers (Dalton 2006; Gulam and Lee 2006; Royal Australian Air Force 2004, pp. 74–75). However, several core requirements of the law of armed conflict do place significant constraints on the ethical use and design of these systems and are therefore worth considering here.

124.3.1 Can Robots Meet the Criteria of Discrimination and Proportionality?

It is clear that, at a bare minimum, any ethical use of UMS will need to comply with the principles of discrimination (Bender 2005) and proportionality, which derive from the just war doctrine of *jus in bello* (Schmitt 2005). That is to say, UMS must be capable of discriminating between legitimate and illegitimate targets and of applying force proportionate to the pursuit of legitimate military ends (Arkin 2007, p. 2). These are perhaps the principal design challenges involved in the future development of UMS, especially UMS that are intended to have the capacity to operate autonomously (Marchant et al. 2011).

One possible “work-around” to these problems is to deploy UMS in such a way as to exclude the possibility that they will attack illegitimate targets. For instance, armed sentry robots could patrol inside a perimeter fence with suitable warnings on it to prevent any possibility of noncombatant presence (Arkin 2007, pp. 92–93). However, it may be difficult to reliably prevent robots from acquiring illegitimate targets in this way, especially during wartime. Moreover, limiting the use of UMS to circumstances where they will not come into contact with noncombatants will severely limit their military value. John Canning (2005, 2006) has championed another version of this approach, in which autonomous weapon systems would be tasked with targeting only enemy weapon systems rather than enemy warfighters, thus minimizing the chance of killing noncombatants. Similar problems seem likely to beset this approach. In many circumstances, it will be difficult to distinguish, for instance, an armed tribesman carrying an AK-47 because this is the local cultural practice, from a hostile insurgent. There is also the danger that the number of noncombatants killed when an attack is launched against an enemy weapon system (for instance, a mortar fired from a hospital car park) will be such as to render the force used disproportionate. Unwillingness to risk these outcomes, on the other hand, will significantly limit the context in which automated weapon systems may ethically be used.

Another possible solution – to the problem of *discrimination* at least – is to try to equip the systems themselves with the capacity to make the requisite judgements as to when a target is legitimate (Arkin 2009). Some weapon systems, including antitank, anti-aircraft, anti-ship, and counterfire systems, may be capable of distinguishing between military and civilian targets. If the target recognition algorithms on weapons of this sort are sufficiently reliable, it might appear that there would be fewer ethical barriers to deploying them (Arkin 2009).

However, even with these weapons, there is the possibility that a potential military target may have indicated its desire to surrender or may no longer pose sufficient military threat to be a legitimate target of attack (Fielding 2006). The fact that the principle of discrimination is extremely context dependent suggests that autonomous weapon systems would have to have a very high level of autonomy indeed to be able to make the judgements necessary in order to comply with its requirements (Guarini and Bello 2012). Similarly, decisions about what constitutes

a level of force *proportionate to the threat* posed by enemy forces are extremely complex and context dependent, and it seems unlikely that machines will be able to make these decisions reliably for the foreseeable future. Barring some remarkable breakthrough in artificial intelligence research, it will therefore be necessary to include a human “in the loop” before deploying lethal ordnance from a UMS in order to ensure that the use of UMS does not violate the LOAC in this regard (Gulam and Lee 2006; Fitzsimonds and Mahnken 2007; Kenyon 2006, p. 43).

If the application of UMS is going to rely on a “human in the loop” in order to ensure that it complies with the requirements of discrimination and proportionality, the operation of UMS must provide their operators with sufficient information to be able to make the necessary judgements reliably. Given the limited situational awareness available to operators of UMS (Kainikara 2002; Mustin 2002), this may require that operators have access to independent sources of information about the nature of the targets they are attacking. This, in turn, has implications for the nature and capacities of the communication systems that are required in order to be able to use UMS ethically (Thorton 2005).

124.3.2 Locating Responsibility

As the author has argued more extensively elsewhere (Sparrow 2007), the application of the law of armed conflict to the use of UMS requires that a clear chain of responsibility can be established between the consequences of any such use and the person who is responsible for them (Arkin 2007, pp. 76–83; Asaro 2007; Foster 2006; Roff 2013). If violations of ethical standards occur, it must be possible to identify the sources of violation in order that such violations can be addressed and, if necessary, the relevant party criticized, disciplined, or prosecuted. This will be a significant challenge given that multiple parties may be involved in the operations of UMS (Featherstone 2007; Sullivan 2006).

The need to be able to determine responsibility for the activities of UMS has implications for engineers, roboticists, and computer scientists working on UMS in at least three dimensions.

Firstly, the designers are an obvious and important possible endpoint for the allocation of responsibility for the consequences of the operation of these systems. Thus, for instance, if a design error in a UMS results in the killing of civilians or friendly forces, then the designers will be partially responsible for these deaths. That the designers of UMS might be – and might be held to be – responsible for the deaths of innocents should serve as a reminder of the gravity of their role and an incentive for them to perform this role diligently.

Secondly, a concern for the attribution of responsibility will have implications for the appropriate organization of the process of designing and operating unmanned systems, which should be such as to clearly allocate responsibility for each distinct function of the mechanism and also for the function of the system as a whole. If a problem arises with the operations of an unmanned weapon system, it must be possible to identify those responsible (Marino and Tamburrini 2006). Of course,

this is but one instance of the application of more general principles of good design of complex systems and of good project management. However, this fact does not render their application any less important in this instance. Moreover, the requirement that it must be possible to identify those responsible for system failures will be especially demanding if an unmanned weapon system has the capacity to operate in a “fully autonomous” mode, in which case it will be necessary to *assign* responsibility for the outcomes of the actions of the machine in this mode to appropriate parties (Marino and Tamburrini 2006), which may include the commanding officer and/or those who have designed/programmed the UMS (see Sparrow (2007) and Matthias (2004) for further discussion).

Thirdly, the capacity to sustain a chain of responsibility during the operations of UMS is itself an important criteria of good design of these systems. Thus, for instance, “ethical” systems will have robust communications linking them with their operators and will have mechanisms in place to record telemetry data in order that problems with – and responsibility for – the operations of the systems can be identified when necessary.

124.3.3 “Designing Out” War Crimes

The combination of a number of features of UMS may function to lower the psychological, social, and institutional barriers to the commission of war crimes. In particular, the geographic and psychological distance between the operator and the UMS may make it easy for the operator to perform actions that they would not perform if they were physically present in the battlespace (Cummings 2004, 2006; Graham 2006; Ulin 2005). As a result, they may be more likely to attack illegitimate targets or to use a disproportionate amount of force in attacking legitimate targets.

Of course, this possibility exists with any long-range weapon. Modern warfighters already possess a godlike power to call down destruction from the skies upon their enemies. Telescopic sights, night-vision goggles, and other targeting systems already distance those exercising lethal force from the human beings their actions affect. These existing technologies may therefore already serve to lower some of the psychological barriers to illegitimate killing (Dunlap 1999; Shurtleff 2002).

However, the use of UMS is likely to exacerbate this distancing effect while at the same time increasing “contact” with the enemy (Coeckelbergh 2013). In particular, UAVs may make surveillance ubiquitous on the battlefield and also extend it throughout the entire territories of the warring states. The operators of the Predator UAV can watch people going about their daily activities in real time from half a world away. The Predator UAV flies at such a height and produces so little engine noise that those being tracked via this system may have no idea that they are under observation (Fulghum 2003; Kaplan 2006). Watching targeting video taken from the Predator (available via YouTube!) one is struck by the bizarre sense of intimacy this footage generates (Blackmore 2005, p. 202). One description of the Predator UCAV in action recounts how it is possible for the operators to observe individuals in Afghanistan walking outside to defecate and confirm that they have

done so by the infrared traces of the feces they have left behind (Kaplan 2006). Yet the explosions that inevitably follow in footage of drone strikes seem entirely unreal, flickerings on a cathode ray screen made trivial by their similarity to images we have seen a thousand times before in film and on television. By simultaneously increasing the amount of contact with the enemy while distancing warfighters from them, UMS may contribute to weapon operators coming to see enemy combatants and noncombatants as distant annoyances only, to be destroyed on the merest of whims. This in turn may lead to (more) violations of the requirements of *jus in bello*.

It has been suggested to the author that, on the contrary, by reducing the risks to which their operators are exposed, UMS may also lower the levels of anger, fear, and hatred amongst warfighters. The strong emotions that warfighters in combat feel towards their enemy are in part a product of the fact that enemy often poses an immediate physical threat. As the lives of operators of UMS are not at risk, they may be less inclined to experience these passions. Insofar as anger, hatred, or fear are implicated in the commission of war crimes, reducing the level of these emotions amongst warfighters might also be expected to reduce the number of war crimes.

However, whether or not the operators of UMS are likely to develop more or less compassion and respect for their enemy or be more or less motivated by anger, fear, and hatred is, at the very least, an open question. Anecdotal evidence suggests that the operators of UMS become emotionally engaged in and experience strong emotions in response to events in the battlespace regardless of their geographical distance from it. Bender (2005) quotes one operator reporting that

... "the feeling of anger you get is pretty powerful" when American troops are seen or heard taking fire from insurgents. Others speak of the "adrenaline rush" in the room when the Predator destroys an enemy target. (p. A6)

Another report (Shachtman 2005a) quotes a Major Shannon Rogers describing his experience with a UAV:

"We left their truck one big smoking hole", he remembers. "My heart was pumping as we were doing our business. It felt just as real to me, however many thousands of miles away, as if I were sitting right there in that cockpit."

These reports suggest that the operators of UMS *do* experience those emotions implicated in the commission of war crimes. Yet while these systems are capable of sustaining and generating these powerful negative emotions, it is less clear that they are capable of generating the emotions and moral attitudes that might serve to prevent war crimes. Emotions such as compassion, joy, love, or empathy or moral attitudes such as respect are unlikely to develop or be sustained in a context where warfighters are thousands of miles away from their purported objects. Indeed, a likely consequence of increased use of UMS is a decrease in the number of military personnel involved in conflicts who have ever met or spoken with the people who inhabit the territory in which war is being fought. In the absence of any human relations with those who their actions will affect, warfighters may be less inclined to resist impulses arising out of fear, hatred, or anger where they arise.

As Mary Cummings (2004, 2006) has argued, the alienation of the operators from the persons that their actions affect means that building ethics “into” the user interface represents a key challenge in the design of UMS. The interface is the primary means by which the operators gain access to information on the basis of which they must make life-and-death decisions; it is also the mechanism whereby the operators act on the basis of these decisions. The design of the interface can therefore be expected to exercise a significant influence on the actions of operators. This in turn suggests that the designers of the interfaces must take ethical considerations into account when designing them. The interface for a UMS should facilitate killing where it is justified and frustrate it where it is not. Obviously, it will not be possible for designers to make this discrimination at the level of individual actions; nor will it be possible to prohibit deliberate unethical use of UMS by an ill-motivated operator. However, it should be possible to take into account the morally relevant features of the circumstances in which a UMS is designed to be used and also those of its typical use and to design systems that promote ethical usage in these circumstances. In particular, the designers of UMS should work to discourage and counteract the alienation between operator and those whose lives they affect, noted above.

Perhaps the most important feature of systems in relation to this imperative is their sensors and the information that they provide to operators. “Good” sensors and good interfaces will present the operator with as much of the information that is morally relevant to the decisions that they must make as is possible. This might include information relevant to the identity, intentions, and history, of potential targets, as well as their current location and activities. This in turn is likely to require providing operators with access to available “human intelligence” and to any other relevant information available via other networks or systems. This information should help operators distinguish between legitimate and illegitimate targets according to LOAC and also distinguish situations where the killing of (legally, rather than morally) legitimate targets is justified from situations where it may not be. Moreover, the sensors and information systems should facilitate the operators being able not only to reliably identify targets but also to comprehend what happens to them when lethal force is deployed. That is, as much as is possible, the system’s sensors should communicate the moral reality of the consequences of the actions of the operator. It is essential that operators have a vivid awareness of what is at stake when they make decisions, so that they can learn to make them responsibly and well.

It must be acknowledged that these are demanding goals and that there are likely to be significant limits on designers capacity to achieve them, especially given the concerns expressed above about whether remote systems are capable of transmitting and representing the full range of moral and emotional information relevant to combat and also the budgetary and other design constraints the designers of UMS must operate under. Nevertheless, it is important to clarify and state them in this context in order that they may at least provide some direction in relation to ethical design. It is also worth noting that at least some of the imperatives arising out

of a concern for ethical design align with those arising out of a concern with the operational demands on the systems.

Where possible, UMS should possess a range of capacities beyond the firing of deadly weapons. Lethal force should not be the first and only recourse available to operators. Thus, for instance, UGVs for operations in urban environments should have the capacity to communicate with other persons in the battlespace, including noncombatants. Consideration should also be given to equipping such systems with “non” – or, more accurately, “sub” – lethal weapons. Providing operators with a larger range of options will allow them to respond more appropriately – and hopefully, more ethically – to each particular situation.

A possible *policy* response to the geographical and psychological distance between operators and their (potential) targets, with design implications, would be to return the operators of UMS to the theater of operations in which the systems they operate function, so that they have some experience of the local culture and contact with the people whose lives they are affecting. This would have the obvious disadvantage of placing the operators at higher risk by virtue of being closer to the front line and would also involve expenses associated with the transport and supply of these personnel and associated systems. However, it would go some way to addressing the concerns about “remote control” killing surveyed above. Whether this trade-off is sufficient to justify putting the operators closer to the front line will depend on the details of the particular UMS and the roles for which it is intended, as well as the intensity of the particular conflict. Obviously, the range over which systems are intended to be used will have significant design implications. Armed Forces will therefore need to consider these issues early in the design of such systems.

Another important aspect of the project of ethical design will be working to avoid the creation of *other* types of what (Cummings 2004, 2006) describes as “moral buffers” between the operator and their actions. Many UMS have a good deal of automation built into them, into their sensors as well as into the operations of the system itself. Cummings suggests that the operators may come to over-rely on the automation in these systems, to the detriment of the decisions they make. Moreover, Cummings argues, the presence of this automation may form a (further) moral buffer between the users of the system and their actions, allowing them to tell themselves that “the machine” made the decision. This, in turn, may encourage unethical choices by operators who are thereby able to distance themselves morally and emotionally from the consequences of their actions. Good design of UMS will therefore not only (as discussed above) ensure that we can *identify* those responsible for the consequences of the operation of the system, it will also ensure that those who *are* responsible *feel* responsible – and know precisely what they are responsible for.

A final, important, consideration relating to the ethical design of UMS is that because the operators of the UMS are themselves not in any danger while they are in combat, it seems as though they should err on the side of caution when it comes to making decisions about killing. This means that there is some room in designing these systems for checks and balances, such as the gathering of more

information outlined above, which would not be practical for warfighters actually present in the battlespace. Of course, importantly, the lives of *other* friendly forces in the battlespace may well be at stake, which means that many missions will still be time critical, such that it will still be necessary for the UMS to be capable of responding quickly as required. Nevertheless, the fact that the operators of UMS are safe from harm does alter what it is reasonable to expect from them by way of a concern for the requirements of *jus in bello* and therefore the requirements of ethical design of these systems.

The challenge of ethical design is a challenge that, arguably, it is yet to be adequately met. A number of articles on UMS report that the control units for these systems have deliberately been designed around the controls for the PlayStation game console or around a “Gameboy” controller in order to take advantage of potential operators existing familiarity with these controls (Graham 2006; Hambling 2007; Kenyon 2007; Thorton 2005). Unsurprisingly, this has led to reports that there is a tendency for the operators to mistake their activities for playing computer games.

According to Bender (2005),

For the Predator crews in Nevada, however, the main challenge is simply to remember they are not playing a video game when they step out of their air-conditioned office for a Wendy’s hamburger.

“We have to impress upon them that they are not just shooting electrons,” said Major Sam Morgan, a trainer of Predator pilots. “They’re killing people.”

Shachtman (2005b) also cites an analyst saying, of the operation of these systems,

It’s like a video game. It can get a little bloodthirsty. But it’s fucking cool.

Presuming that we do not want warfighters making life-and-death decisions in the subconscious belief that they are playing a video game, these remarks suggest that much work remains to be done in promoting ethical behavior through the design of UMS.

124.4 Conclusion

The development of UMS for military applications poses ethical as well as technical design challenges for roboticists, engineers, computer scientists, and others involved in the design of these systems.

This paper has argued that one set of ethical issues arises out of a concern for the safety of the operators of the system and of those who will work alongside them. While the development of UMS may keep some warfighters safe from harm, there are also circumstances in which it may place others at risk. Responding to this phenomenon will require negotiating a complex set of trade-offs regarding the capacities – and expense – of these systems. The current discussion has also highlighted the possibility that operation of UMS may expose the operators to unique psychological stresses.

There is also another, arguably more difficult, set of issues that arise out of the need for the operations of UMS to meet the requirements of the law of armed conflict. The profound difficulties involved in enabling fully autonomous weapon systems to distinguish between legitimate and illegitimate targets and assess the proportionate use of force suggest that it will be necessary to retain a “human in the loop” for the foreseeable future. A critical requirement for the ethical design and operation of UMS is that those responsible for each aspect of their design and operations can be clearly identified; this may require attributing responsibility if these systems are used in a “fully autonomous” mode. Finally, ethical design of UMS will require paying attention to the ways in which these systems may facilitate unethical behavior by separating the operators from the consequences of their actions and working to overcome this and other “moral buffers” that may arise in the operation of robotic weapons.

Some of these ethical issues can be “designed out” or at least “designed around.” That is to say, with sufficient ingenuity and more sophisticated technology, engineers can avoid them and/or minimize their impacts. For instance, better neural networks, better sensors, and better target recognition algorithms might mitigate some of the difficulties involved in the problem of discrimination and expand the number of roles in which it was appropriate to employ autonomous weapon systems. Sensors which make possible a more vivid appreciation of the battlespace might also reduce the psychological distance between operators and their targets and thus reduce the extent to which the distance between them acts as a “moral buffer.”

However, it is important to note that there are real trade-offs involved in attempting to address some of these issues, such that efforts to address one will intensify another. Thus, for instance, technologies which make possible a larger scope for autonomous operations of robotic weapon systems exacerbate the problem of locating the responsibility for the consequences of the operations of these systems. Systems with sensors that make the battle more “real” for the operators will also increase the risk that they will suffer psychological stress as a result. Controlling UMS over long distances will decrease the risk to the operators but increase the “moral buffer” between them and their actions. Designers of UMS will therefore need to consider the relative priorities of these issues, the relationships between them, and the trade-offs involved in attempts to address them, in the pursuit of “ethical” design.

Unmanned systems are already playing a key role in contemporary conflicts. Given current enthusiasm for UMS and their obvious utility it seems likely that robotic systems will be used much more widely in military roles in the future (Featherstone 2007; Graham 2006; Hanley 2007; Hockmuth 2007; Office of the Secretary of Defense 2006, 2012; Peterson 2005; Scarborough 2005; Singer 2009). It also seems likely that the scope of autonomous action allowed to UMS will increase as the technology improves. Because the communication infrastructure required to keep a “human in the loop” is a weak point in UMS, systems which dispense with a human operator will be more survivable. As the tempo of battle increases as a result of technological developments, including the development of UMS, systems which rely on human input may be at a substantial disadvantage in

combat against fully autonomous systems. There is therefore a substantial incentive for designers of UMS to provide systems with a capacity for autonomous operations (Adams 2001; Blackmore 2005; Excell 2007; Featherstone 2007; Lerner 2006; Szafranski 2005). These trends make the challenges of ethical design of unmanned systems highlighted here all the more urgent.

Acknowledgments The research for this paper was supported by the Australian Research Council, through the award of an ARC Discovery Grant (DP0770545) to Dr Jessica Wolfendale, Professor Tony Coady, and Dr Robert Sparrow. The author would like to thank Neil McKinnon for assistance with locating sources for this paper and with preparing it for publication. The author would also like to thank Jessica Wolfendale, Linda Barclay, Jim Sparrow, John Canning, and Ron Arkin for comments and discussion which have improved this paper.

Abstract

The chapter contains a transcript of testimony presented by the author and Handbook Field Editor to a select ad hoc committee convened by the National Academy of Sciences (USA) in response to a request from the U.S. Defense Advanced Research Projects Agency (DARPA) to evaluate the “Ethical and Societal Implications of Advances in Militarily Significant Technologies that are Rapidly Changing and Increasingly Globally Accessible.” The testimony was delivered at the inaugural meeting of the committee on 31 August 2011 at the NAS Beckman Center, on the campus of the University of California – Irvine.

For the first time this past year (2011), the Air Force recruitment and training pipeline turned out more RPV/UAV operators than it did conventional fighter pilots. This comes as a dual shock to the fighter pilots. First, it was painful to be asked to leave the cockpit and set aside years of education, training, and experience and to sit at a control station thousands of miles removed from the aircraft itself. Pilots resisted this change, until they saw that they were simply leaving themselves out of the fight: better to be flying Predators themselves, they concluded, than to be replaced by teenagers with joysticks! But then came a further blow: the highly skilled fighter pilots were less adapt at learning the ropes and operating Predators than were teenagers with barely a high school education but a lot of video and computer game experience. This is humiliating enough. But one day, one can predict, the Air Force Chief of Staff will be chosen from the ranks of RPV operators. That will provide

the culmination of a cultural sea change among members of the military aviation community. How will that community respond? How will it define and uphold its core values in this new mechanized, automated, “virtual” milieu?

Meanwhile, the U.S. Army has spent millions of dollars to stand up a new “Army Center for the Professional Military Ethic.” No service has worked harder, both to define itself as a community of professionals and to investigate just what the core competencies, skill sets, and core moral values are that define that professional community. But what sense does it make to speak of the Army’s professionalism and professional ethic, if an autonomous and lethally armed ground combat robot can do the same job as well or better? Those are the kinds of questions and challenges that new military technologies are presenting to military services now, and indicative of the transformative effect they will one day doubtless have on civilian communities as well.

With the advent of these exotic new military technologies and the challenges they present, one hears a familiar refrain:

- “Our traditional concepts of warfare and its justification are outmoded.”
- “Existing laws of war and moral constraints regarding conventional combat are useless.”
- “Our conceptions of both must either be cast aside or radically reformulated.”

It can be described as a familiar refrain, because:

- One heard this same complaint earlier, with the wars of genocidal violence and the humanitarian military responses launched in the 1990s.
- One heard this in the aftermath of the terrorist attacks of 9/11 and the subsequent rise of simmering “small wars” of counterinsurgency and other varieties of “irregular” warfare over the past decade (2001–2011).
- And one hears this concern expressed now with the advent of exotic new war-fighting technologies, particular the prospect of lethally armed and autonomous robotics.

There is some rhetorical value to this stratagem. It serves to startle, alarm, and even terrify those who otherwise don’t seem to take the new and very real challenges seriously enough. There is a real danger, however, of threat inflation, exaggeration, and hysteria, as though we are somehow not well equipped to deal with the new challenges, once we have finally awakened to them.

These ethical challenges are very real and complex, but after 2–3 years of sustained reflection, one can predict that the patterns seen here will duplicate the discoveries of the preceding two decades: to wit, conceptions of morally justifiable resort to war, and of the moral and legal constraints on its conduct, are *not* outmoded.

- One still ought not to resort to force, for example, without a very strong moral justification, in terms of either the threat of harm posed or the harm actually inflicted, sufficient to justify the risk and destruction that will inevitably follow.
- Moreover, any such resort to force ought to be undertaken only after reasonable alternatives to a military conflict have been attempted without success.

Likewise, in the conduct of ensuing hostilities, whether carried out with conventional forces or alternatively with robots, cyber weapons, nonlethal weapons or by biologically and/or psychologically enhanced warriors:

- One should *still* not deliberately target noncombatants and civilian infrastructure, and
- One should *still* not deliberately use more force than is necessary to attain legitimate military objectives.

These four points are defined in the long-standing moral discussion of war as “just cause” and “last resort” (with respect to the decision to engage in armed conflict) and “discrimination” and “proportionality” with respect to the conduct of hostilities. All four are basic and widely shared ethical principles long enshrined in moral discourse and reflected for the most part in international law (LOAC).

The problem instead is that the new military technologies show us that *we need to think harder about what these basic concepts mean* and how they translate and apply in these unusual new circumstances.

Here are three examples:

1. First, consider the case of UAV/RPV systems, unmanned, but remotely piloted. Suppose that a given mission in pursuit of insurgents would be permissible under law and morality using conventional manned aircraft. Such a mission would not suddenly be transformed in its legal or moral status, simply by removing the pilot from the cockpit. Either the mission is permissible or it is not. The position of the pilot with respect to the aircraft is not the determining factor in this judgment. Yet many persons think otherwise, presuming that there is something inherently illegal or immoral about such a mission, simply because it is carried out by UAVs. Morality and legality, however, are properties of the mission, not of the particular technology used to carry it out (provided, of course, that the means or weapons technology utilized is not specifically banned by treaty, as causing “superfluous injury or unnecessary suffering”).

But if this point is acknowledged, then it must also follow that the mission’s legal and moral status is likewise not inherently transformed by removing the human pilot from the equation altogether. Providing the autonomous unmanned system has been proven as safe and reliable in its operation (including demonstration of immunity to cyber attack, loss of control, or unpredictable “emergent behaviors”), then the mission in which it is employed is no more or less legal or moral, simply on its account. Yet their “intrinsic” legality or morality is among the most contested issues with respect to the further development and use of unmanned systems. Clearly, everyone involved in evaluating their development and use needs to think harder and more clearly about this issue.

2. Secondly, cyber weapons are, or have been, routinely designed to target civilians and civilian infrastructure (e.g., as unleashed in alleged Russian attacks on Georgia and Estonia or in the alleged CIA “logic bomb” used in the early 1980s to destroy Soviet-era oil pipelines). *That’s not “new,” that’s wrong.* That this deliberate, intentional cyber targeting of civilians and their property has

only recently been highlighted and criticized is again attributable to a cultural anomaly: cyber strategy is largely an extension of espionage, psychological warfare operations, and sabotage of the sort routinely carried out by covert intelligence operatives, rather than combatants. These communities operate according to different rules and assumptions. Their cover actions are always considered domestic crimes within local jurisdictions, rather than acts of war.

The newly promulgated U.S. cyber strategy has been widely summarized in the news media, in the words of an unnamed military expert: “if you launch a cyber attack against our power grid, we may just put a missile down your smokestack.” But *whose* smokestack (given the difficult problem of attribution)? And *how many* missiles down how many smokestacks? And what SORT of smokestacks (defense industries? civilian factories?) Indeed, is a conventional or “kinetic” response of this sort even appropriate as a response to a cyber attack? Would it matter what kind of cyber attack it was: DDOS? Damage to civilian infrastructure? Draining your 401k? And who is a “noncombatant” in a cyber war, during a DDOS, for example, when personal computers of the world over are hijacked in numerous and massive botnets that are collectively carrying out the strike? Clearly, all concerned need likewise to think harder and more clearly about this new technological wrinkle as well.

3. Finally, in quite another context, does the concept of “proportionate use of force” that has always governed the Law of Armed Conflict (LOAC) and specific rules of engagement for combat now dictate that nonlethal weapons should always be used before resorting to lethal weapons? Should militaries use such weapons under existing rules of engagement for lethal weapons (thereby lowering the threat of destruction and damage from mistakes), or should military and security personnel instead expand the regime (or broaden the prevailing norm) permitting the use of force more widely, in light of the presumed “nonlethality” of these alternative weapons? At present, nonlethal weapons threaten to widen the scope of permissible targets, to include civilian noncombatants as well as enemy combatants. *This is not new or revolutionary: this is a mistake*, stemming from failure to think this through. Such an unfortunate widening of the rules of engagement for the use of force has already taken place with disturbing and increasing frequency in domestic law enforcement: the rules governing the engaging of suspects with force has expanded, and so have unintended injuries and deaths stemming from use of nonlethal weapons in situations in which no police officer would have ever drawn his pistol let alone fired it.

These are some of the questions that decidedly challenge *but do not at all “overturn” or obviate* our moral conventions regarding the declaration and conduct of war. To suggest otherwise is extremely unwise and robs us of the resources required to reflect on these (frankly, quite interesting) questions.

Often such extreme declarations about the “end of war and morality as we have known it” are made by those who know little about the moral conventions surrounding war or who secretly thought them specious, nonsensical, or irrelevant

to begin with. Even military personnel, whose underlying professional conduct these moral principles reflect, are sometimes confused by all this or regard such underlying principles as superfluous, irrelevant, externally imposed constraints upon a deadly and dirty business best carried out with ruthless and brutal efficiency by those (like themselves) whom we empower to engage in armed conflict on our behalf.

What goes unrecognized in these attitudes is that military ethics is a *species of professional ethics*. That is, just like communities of physicians and health care professionals, or lawyers, or journalists, members of the military profession can also be portrayed as perpetually immersed in an ongoing dialogue regarding the nature of their practice, including aspirations for best practice, as well as professional probity and rectitude, defining the boundaries of unacceptable practice.

To those who think the “international law of armed conflict” is an external, legal constraint imposed by lawyers wearing fancy neckties in Geneva (who presumably therefore know nothing of the actual experience of war), it is important to emphasize in response that, in essence, the conventions that such lawyers may finally enshrine in some legal regime actually reflect centuries of philosophical reflection upon justified use of force and reflect the views and intuitions that we find warriors themselves discussing, for example, in Plato’s *Republic*, Shakespeare’s *Henry V*, or Sun Tzu’s classic, *The Art of War*. Such works, and the discussions of warriors they embody, attempt to define what a warrior is about and what he, or she, is trying to accomplish; what he or she is willing to do in order to accomplish it; and, perhaps most importantly, what he or she is unwilling to do in pursuit of otherwise legitimate military objectives. This characterization is true, even in a work like Baron Karl von Clausewitz’s *On War*, that seems otherwise to warn us against allowing ethical considerations to influence our judgment about strategy. This is because, at this level, as Michael Walzer observed (1977), ethics is inseparable from strategy: ethics is, ultimately, a mode of strategic thinking about goals and objectives and the best means of attaining them. Military ethics, just war doctrine, and the laws of armed conflict incorporate the consensus of warriors themselves about the nature and limitations of their professional practice.

In the military case, a reasoned, reflective equilibrium of perspectives among people of action has not been easy to come by. And its results are therefore fragile and easily threatened. It is simply not true that warriors cannot discern acceptable from unacceptable conduct, or differentiate justified from unjustifiable and wrong behavior. The consternation reported among many members of the Syrian armed forces over being forced to target fellow citizens during the beginning of their terrible civil strife, or earlier, among the Israeli Defense Forces in Gaza, illustrated this discernment in practice, as do the essays on military ethics written by Georgian, Moldavian, Turkish, Greek, and other allied officers for ethics classes taught at the Naval Postgraduate School. Whatever a soldier is, military students find themselves agreeing that the soldier exists to protect his homeland and fellow citizens, not to turn his weapons upon them. And in protecting both, he does not rain indiscriminate

and disproportionate violence haphazardly on a helpless noncombatant population, not at least without coming eventually to question the moral legitimacy of his undertaking.

Our technological innovations ought not to shatter this fragile consensus, either through their impact on military culture or through their own design and deployment at the hands of those unfamiliar, or unsympathetic, with this way of regarding public security and the rule of law.

Abstract

This chapter attempts to bring closure to the *Handbook of UAVs*. This, by itself, is an extremely challenging and difficult task; it should not be, but it is! After all, the reason is so simple that it was almost entirely ignored and overlooked during the course of preparing the handbook. Unmanned aviation has witnessed

exponential growth, worldwide, amidst controversy and difficulties, with new potential applications regularly surfacing. And although several federal agencies and multiple governments, with perhaps competitive agendas, are involved in accomplishing the common goal of integration of unmanned aviation into civilian airspace, everything seems to move so fast, that when one considers that a specific subject is completed, new changes and modifications are in effect. However, it looks like that 2013 will be “the critical year” for a new jump-start in unmanned aviation, with efforts converging and roadmaps being in place towards the ultimate goal of integration of unmanned aviation into civilian and commercial airspace. This goal remains intact and it has not changed over the years. Therefore, this chapter aims at, simply, summarizing the state of the art, the potential of unmanned aviation, referring to challenges that still need to be resolved and overcome, commenting on economic impact, and highlighting anticipated future developments. At the same time, this epilogue may also be viewed as justification for enhancing the handbook publishing a second edition.

Let's think the unthinkable, let's do the undoable, let's prepare to grapple with the ineffable itself, and see if we may not eff it after all.

Douglas Adams
(Dirk Gently's Holistic Detective Agency, 1987)

126.1 Introduction

The field of unmanned systems (US) and the related US enabling technologies has witnessed a meteoric rise over the recent past. Although “unmanned objects” of the flying or ground variety have been reported from the ancient times on, advances in sensing, communications, computing, controls, and aerospace systems over the past years have provided the impetus for the explosion being experienced in the development and utility of US across multiple domains.

The area of unmanned aviation has seen, for obvious reasons, the largest and most rapid increase in these technologies. The number of fielded systems and the range of missions supported by unmanned aviation, regardless of their acronym (UAVs, UAS, RPA, or RPAS), continue to grow at a dramatic rate. The military unmanned systems market should remain of higher value than the civilian market for the foreseeable future due to higher allocation of funding drawn from national government defense budgets, although tightened spending could have an effect on some programs and procurement. Industry has provided additional funding towards research and development (R&D) costs of national unmanned aviation programs or has developed their own systems with the hope of attracting domestic and international orders.

Although unmanned aviation technologies have expanded rapidly, worldwide, major challenges still remain to be addressed if the ultimate goal is the full utilization of such systems for a wide spectrum of applications, coupled with the

ability for unmanned–manned systems to share commercial airspace. However, in order to justify the statement “full utilization of such systems for a wide spectrum of applications,” one needs to first start by trying to answer the question(s): “*Why UAVs? What do they offer? Why are they useful, if at all?*”

The answers, nowadays, are more than straightforward and obvious. This seems hard to believe since the lack of a human pilot raises eye brows and makes the public suspicious, if not skeptical, against “those things that fly alone in the sky,” to say the least. However, the benefit of the doubt should be credited and granted to the general public. One should not forget what happened in the field of robotics about 60 years ago; it took more than 30 years fighting for survival before robotics was accepted in the USA as a viable, even better, alternative to completing a wide range of applications, which were tedious for humans. Needless to mention that when robotics was accepted in the USA, automakers in Japan had already automated their car assembly lines, and research and development on humanoids had already began. Even European industries used robots before it happened in the USA. The rationale for making the above statement stems from the fact that “those robots” were not pilotless and they did not fly alone. Therefore, it is natural to assume that it will be much more difficult for the public to accept unmanned aviation and their use in civilian applications. However, this is what the future holds, and unmanned aviation is on its way to entering everyday life. Before long, the “*Robots are here to stay*” expression, which already has been on magazine covers, will be accompanied by the “*Unmanned aviation is here to stay*” expression. The economic impact, worldwide, will be major, to say the least.

However, one should not overlook the fact that perhaps the biggest challenges related to full UAV utilization are not only technical. Instead, public acceptance, regulatory and insurance issues, and ethical and legal issues, among others, top the list. A relevant question is how might due process laws governing manned surveillance flights apply to UAS. Privacy advocates fear that UAVs could be used for surveillance of individuals; thus, privacy concerns demand a meaningful framework for discussion. The most controversial domestic use is by law enforcement agencies interested in using such vehicles for surveillance and to fight crime, a prospect that has privacy advocates and other citizens on edge. Ethical issues related to the use of UAVs are also the topic of recent discussions among technologists and social scientists. Data security is also a challenge as a regulation framework must be adapted for protection of data collected by UAS. Controversies surrounding this topic will continue to proliferate in the future as military and security operations impact the lives of noncombatants or result in privacy intrusions and other legal or social concerns.

Regardless, research activities are bound to expand in several directions motivated and supported by government and private industry. The aim will be to improve the autonomy, reliability, and safety of unmanned platforms while reducing life-cycle costs and operator workload. Among other initiatives, the National Robotics Initiative (NRI) is setting the stage for an expanded role of university research in the UAV arena. On August 3, 2013, the Office of Science and Technology Policy announced that the Department of Defense is also supporting the National

Robotics Initiative through the *Defense University Research Instrumentation Program* (DURIP). This \$40 million program, supported by the Army Research Office (ARL), the Office of Naval Research (ONR), the Air Force Office of Scientific Research (AFOSR), and the Office of the Secretary of Defense, strengthens the capability of universities to conduct research and educate scientists and engineers in areas that are important to national defense. Universities worldwide are beginning to introduce academic offerings addressing the design and operation of novel UAV concepts. About ten universities already have formally introduced degree programs in UAVs, while others offer certificates in the UAV field.

126.2 The Future Economic Impact of Unmanned Aviation

The global unmanned aviation market is expanding rapidly with projections falling behind almost on a daily basis. Several forecasts have been published, which project that the U.S. and the global unmanned aviation markets will witness a strong growth during the next 10 years.

As reported in (CRS, 30 January 2013) “A forecast of global UAS demand by the Teal Group shows worldwide annual spending on research, development, testing, and evaluation (RDT&E) and procurement rising from \$6.6 billion in 2013 to \$11.4 billion in 2022. Total spending for the decade is projected to amount to \$89.1 billion.” It is also stated that throughout the forecast period, it is anticipated that the U.S. share of RDT&E will account for 62 % of worldwide spending, while U.S. procurement will amount to 55 % of worldwide spending. According to the Teal Group, “UAS procurement will mirror demand for high-tech arms procurement in the Asia-Pacific region and in Europe.”

In March 2013, the AUVSI (with more than 500 corporate members in 2011 and still growing, representing a significant number of U.S. companies with a stake in UAS manufacturing activities) published its economic impact report (AUVSI, March 2013) documenting the economic benefits to the U.S., once UAS are integrated into the NAS. The report states that from the wide spectrum of potential civilian applications of UAS, precision agriculture and public safety will be the most promising commercial and civil markets, comprising approximately 90 % of the known potential markets for UAS. In further detail, the report concludes that (AUVSI, March 2013):

1. The economic impact of the integration of UAS into the NAS will total more than \$13.6 billion in the first 3 years of integration and will grow sustainably for the foreseeable future, cumulating to more than \$82.1 billion between 2015 and 2025.
2. Integration into the NAS will create more than 34,000 manufacturing jobs and more than 70,000 new jobs in the first 3 years.
3. By 2025, total job creation is estimated at 103,776.
4. The manufacturing jobs created will be high paying and require technical baccalaureate degrees.

5. Tax revenue to the states will total more than \$482 million in the first 11 years following integration (2015–2025).
6. Every year that integration is delayed, the USA loses more than \$10 billion in potential economic impact. This translates to a loss of \$27.6 million per day that UAS are not integrated into the NAS.

According to (CRS, 30 January 2013), in April 2012, the U.S., DOD reported that it had more than 7,100 UAS in its inventory. Further, a June 2011 analysis by the Congressional Budget Office (CBO) examined DOD UAS acquisition costs based on DOD's FY2012 budget request and reported procurement costs for the 2011–2020 period would amount to nearly \$37 billion. U.S. manufacturers with the largest share of the global UAS market include General Atomics (20.4 %), Northrop Grumman (18.9 %), Boeing (1.5 %), and AAI (1.2 %).

Analysts predict that Europe, China, and Japan will also press ahead with significant UAS development programs. Japan, for example, has already addressed safety and airspace regulatory issues, allowing civilian use of unmanned aircraft for certain applications, such as aerial spraying of pesticides. The Teal Group expects that investments by China and Japan could be larger than its forecast suggests, because less is known about those countries' intentions and programs. Forecast International projects that, while Europe will account for almost 15 % of worldwide UAS procurement, European companies will produce only 3.9 % of global production value during the next decade, slightly more than the 3.7 % share that Israel is expected to claim (CRS, 30 January 2013).

In summary, integrating unmanned aviation into the global airspace will have major economic impact, worldwide, as it will create new frontiers to civilian and public domain applications. However, the economic impact due to the growth of civilian market applications is rather long term, as opposed to the economic impact due to military applications, which will continue to be strong.

126.3 Challenges and Issues in UAS Used for Military Applications

The focus on and the perspective of UAS used for military applications will continue to grow, since UAS are preferred over manned aircraft not only because of downsizing risk and increasing confidence in mission success avoiding at the same time the human cost of losing lives if the mission is unsuccessful, but also because unmanned vehicles have better and sustained alertness over humans during dull operations. The statement that UAS are and will be best suited for “dull, dirty, and dangerous” missions has merit and it is supported because:

- Dull operations that require more than 30 or 40 hour missions are best carried out using UAS, since crew members in manned aircraft are used to much shorter duty cycles. Before the 1990s, crews were used to 4 hour sorties and missions. Fatigue and mission duration compromise proficiency and functionality of crew members; thus, the UAS alternative prevails.

Fig. 126.1 Tentative time table trend in unmanned aircraft autonomy – U.S.

- Dirty operations may require that UAS fly into nuclear clouds (as happened in 1946–1948) immediately after bomb detonation, a mission that is clearly dangerous to human crews and threatens human lives.
- Dangerous operations like reconnaissance over enemy territory may result in loss of human lives; thus, UAS are preferred.

All recent U.S. DOD unmanned systems roadmaps envision an Air Force based mostly on unmanned planes. This becomes more evident since future urban warfare, search and rescue, border patrol, homeland security forest fire detection, traffic monitoring, and other applications will utilize an unprecedented level of automation in which human-operated, autonomous, semiautonomous air and ground platforms will be linked through a coordinated control system to perform complex missions.

The main challenge in future operations will relate to networked UAS with adaptable operational procedures, planning and asset deconfliction, and increased situation awareness, coupled with cutting-edge technologies to realize autonomous collaborative operations.

In general, technical challenges will stem from real-time sensing, computing, and communication requirements; environmental and operational uncertainty, hostile threats; and the emerging need for improved UAS and UAS team autonomy and reliability. Significant challenges will also relate to inter-UAS communications, links to command and control, contingency management, etc. The requirement and emerging need for improved UAS autonomy is depicted in Fig. 126.1 that shows

the tentative time table for autonomous control level trends. In essence, Fig. 126.1 tabulates unmanned aircraft sophistication levels from the U.S. DOD perspective, which cover the whole spectrum from the teleoperated and preprogrammed flight of a single aircraft to self-actuating and fully autonomous group vehicle flights.

Challenges increase significantly as one moves up the hierarchy of the chart from single to multi-vehicle coordinated control. Only moderate success has been currently reported in meeting the lower echelon challenges, leaving open the whole field for subsequent developments.

Technically, to meet stated challenges, innovative coordinated planning and control technologies such as distributed artificial intelligence (DAI), multi-agent system (MAS) theory, computational intelligence and soft computing, generalized system theory, as well as game theory and dynamic optimization, coupled with sophisticated hardware and software architectures, will be needed. Even though related approaches and methodologies have been investigated intensively in recent years, most work has been focused on solving particular problems, such as formation control and autonomous search, while less attention has been paid to the overall “system architecture” concept, especially from an implementation and integration point of view.

In addition to all of the above, NATO members, as part of the STANAG 4586, have been working towards “plug and play” capabilities for UAS, attempting to improve the flow of information among shared systems and enhance battlefield efficacy. STANAG 4586 includes the 4586 standard and four volumes of supporting documentation towards establishing interoperability of present and future UAS in a NATO Combined/Joint Service Environment. The STANAG 4586 Annex B is composed of three appendices, which detail Data Link Interface, Command and Control Interface, and Human–Computer Interface requirements.

When focusing on the U.S. DOD *Unmanned Systems Integrated Roadmap FY2011–2036*, the following specific major challenges in UAS technologies need to be addressed and overcome.

126.3.1 Autonomy

The proliferation of unmanned systems and the simultaneous operation of manned and unmanned systems have created a manpower burden. With limited manpower resources to draw upon, the military in the USA are seeking ways to improve the efficiency of operations. The introduction of greater degrees of autonomy promises to enable one operator to control more than one unmanned system, thus, reducing the manpower requirements. The U.S. Army, for example, aims at the “one operator-four UAVs” concept, in essence reversing the currently used “four operators-one UAV.” Additional benefits include the reduction of high bandwidth communication needs and the decrease in decision cycle time.

Improved efficiencies will be gained by automating the tasking, processing, exploitation, and distribution (TPED) of data collected by unmanned systems. Autonomy can help extend vehicle endurance by intelligently responding to the

surrounding environmental conditions (e.g., exploit/avoid currents) and appropriately managing onboard sensors and processing (e.g., turn off sensors when not needed). Increased autonomy will also assist in reducing the detrimental impact of fault/failure modes experienced by UAVs.

However, implementing a higher degree of autonomy faces the following challenges:

- Investment in science and technology (S&T) to enable more capable autonomous operations
- Development of policies and guidelines on what decisions can be safely and ethically delegated to the UAV and under what conditions
- Development of new verification and validation (V&V) and testing and evaluation techniques to enable verifiable systems

126.3.2 Interoperability

To achieve the full potential of unmanned systems, the systems must operate seamlessly across the domains of air, ground, and maritime and also operate seamlessly with manned systems. Robust implementation of interoperability tenets will contribute to this goal while also offering the potential for significant life-cycle cost savings.

126.3.3 Airspace Integration

The unmanned aviation community must continue to work with the Federal Aviation Administration (FAA) to ensure UAS have routine access to the appropriate airspace needed within the National Airspace System (NAS), to meet training and operations requirements. Similar efforts must be leveraged for usage of international airspace.

126.3.4 Communications

Unmanned systems rely on communications for command and control (C2) and dissemination of information. C2 and data transmission require a portion of the electromagnetic spectrum, which is already in very short supply. UAV users must continue to address frequency and bandwidth availability, link security, link ranges, and network infrastructure to ensure availability for operational and mission support of unmanned systems. Planning and budgeting for UAS operations must take into account realistic assessments of projected SATCOM bandwidth, and the community must move towards onboard preprocessing to pass only critical information.

126.3.5 Training

An overall U.S. DOD strategy is needed to ensure continuation, and joint training requirements are in place against which training capabilities can be assessed. Such a strategy will improve basing decisions, training standardization, with the potential to promote common courses resulting in improved training effectiveness and efficiency.

126.3.6 Propulsion and Power

The rapid development and deployment of unmanned systems has resulted in a corresponding increased demand for more efficient and logistically supportable sources for propulsion and power. In addition to improving system effectiveness, these improvements have the potential to significantly reduce life-cycle costs.

126.3.7 Manned–Unmanned (MUM) Teaming

Today's force includes a diverse mix of manned and unmanned systems. To achieve the full potential of unmanned systems, UAV users must continue to implement technologies and evolve tactics, techniques, and procedures (TTP) that improve the teaming of unmanned systems with the manned force.

126.3.8 Human–Machine (UAV) Interface Issues

With the operator in the loop, automated systems for sensing, piloting, targeting, etc., must be designed to provide maximum and reliable information to the operator (sensor, pilot) in the ground control station (GCS). A number of technical and human engineering issues must be addressed if this critical interface will function in an optimum capacity.

Remaining technical challenges also include the following nonexclusive list:

- A significant improvement in response times of single UAVs or UAV swarms.
- A significant improvement in the reliability of such systems, leading to increased trust by humans.
- Improved friend-or-foe capabilities, assessing damage and automatic IED detection.
- Improved and more accurate ability to identify a person in an urban environment from a range of (at least) 200 m.
- Improved self-learning and intelligence gathering capabilities.
- A significant boost to endurance – up to 10 additional hours for large UAVs, 80 h for medium, and 50 h for small UAVs.

- Integrated cyber-attack capabilities, coupled with improved defenses against cyber-attacks.
- Development of aerial robots with biological components.
- Transforming UAVs to perform as “soft robots,” that is, develop systems that could, for example, shrink in order to enter a blocked building through small openings and then expand again.
- Develop a perfectly camouflaged UAV, invisible to human eyes while in the air.
- Develop self-replicating robots.

Several of the above challenges, when overcome, may create transformative technology that may be applicable to civilian UAVs as well.

126.4 Challenges and Issues in UAS Used for Civilian Applications

On December 2, 2013, Amazon CEO Jeff Bezos said on *60 Min* that “Amazon.com is testing delivering packages using drones.” The idea is to use octocopters that will pick up packages in small yellow buckets at Amazon’s fulfillment centers and fly through the air to deliver items to customers after they hit the buy button online at Amazon.com. Although the technology has not yet reached such level of maturity (and despite the claim that it may be available in 4 years), is this *science fiction or reality*? Is such a “futuristic” application going to actually happen, pending “mature technology” and the FAA’s framework for rules and regulations?

As unimaginable as the above statement may sound, and it may be, it is not the first one! A few years ago, AUVSI Board Member Kitty Higgins, during an NTSB 2-day seminar on “UAS in the NAS” in Washington D.C., joked that one day “...our pizzas will be delivered by UAS.” At the same time, Douglas Davis who was at that time the head of the FAA’s Unmanned Aircraft Program Office made it clear that “no one should look to the sky for pizza just yet.” However, and this is very important, the FAA, recognizing that for some special cases UAS may be very useful and effective, did partner with police departments in Miami and Houston to evaluate the use of small UAS for surveillance (Davis 2008a,b). Along the same lines, in AUVSI’s Unmanned Systems Magazine, in a two-part interview with Margaret Gilligan, Associate Administrator for Aviation Safety with the FAA then (Gilligan 2010), she stated that “We are working hard on the rulemaking for small UAS and 2013 continues to be our goal.” However, she also stated that larger systems are more of a challenge, although there are standards. And if UAS meet these standards, then they can fly in the NAS.

A rather interesting but 6-year-old article (Cooney 2008) presents accurately what was going on in 2008 in the U.S., which is also valid today despite progress made. Because of its importance, it is presented in its entirety next:

A ton of work needs to be done by military, federal and civil aviation groups if the rapidly growing unmanned aircraft community is allowed routine access to public airspace. In a wide-ranging report on the impact of unmanned aircraft on the country’s commercial airspace, congressional watchdogs at the Government Accountability Office today called

on Congress to create an overarching body within Federal Aviation Administration to coordinate unmanned aircraft development and integration efforts.

The GAO also called on the FAA to work with the Department of Defense, which has extensive unmanned aircraft experience to issue its program plan. In addition, the Department of Homeland Security (DHS) assesses the security implications of routine unmanned aircraft access to commercial airspace, the GAO said. Even if all issues are addressed, and there are a number of critical problems, unmanned aircraft may not receive routine access to the national airspace system until 2020, the GAO concluded.

But such access is certainly on the minds of the unmanned aircraft community. That's mainly because the market for government and commercial use unmanned aircraft could explode in the coming years. Federal agencies such as the DHS, the Department of Commerce, and NASA alone use unmanned planes in many areas, such as border security, weather research, and forest fire monitoring. Researchers at the Teal Group said in their 2008 market study estimates that UAV spending will more than double over the next decade from current worldwide UAV spending of \$3.4 billion annually to \$7.3 billion, totaling close to \$55 billion in the next ten years. The forecast also indicates that the U.S. could account for 73% of the world's research and development investment unmanned flight in the next decade.

Still, routine unmanned aircraft access to the national airspace system poses technological, regulatory, workload, and coordination challenges, the GAO said. A key technological challenge is providing the capability for unmanned aircraft to meet the safety requirements of the national airspace system. For example, a person operating an aircraft must maintain vigilance so as to see and avoid other aircraft. However, because the airplanes have no person onboard, onboard equipment, radar, or direct human observation must substitute for this capability. No technology has been identified as a suitable substitute for a person on board the aircraft in seeing and avoiding other aircraft, the GAO report stated.

Additionally, the aircraft's communications and control links are vulnerable to unintentional or intentional radio interference that can lead to loss of control of an aircraft and an accident, and, in the future, ground control stations – the unmanned airplane equivalent to a manned aircraft cockpit – may need physical security protection to guard against hostile takeover, the GAO said.

There are other issues as well, the GAO report stated, including Cooney (2008):

- Many unmanned airplanes, particularly smaller models, will likely operate at altitudes below 18,000 ft, sharing airspace with other objects, such as gliders. Sensing and avoiding these other objects represents a particular challenge for unmanned aircraft, since the other objects normally do not transmit an electronic signal to identify themselves and FAA cannot mandate that all aircraft or objects possess this capability so that the aircraft can operate safely. Many small unmanned do not have equipment to detect such signals and, in some cases, are too small to carry such equipment. The Aircraft Owners and Pilots Association, in a 2006 survey of its membership, found that unmanned aircraft's inability to see and avoid manned aircraft is a priority concern.
- The effort to develop the Traffic Alert and Collision and Avoidance System (TCAS), used widely in manned aircraft to help prevent collisions, demonstrates the challenge of developing detect, sense, and avoid capability for unmanned airplanes. Although FAA, airlines, and several private sector companies developed TCAS over a 13-year period, at a cost of more than \$500 million, FAA officials point out that the designers did not intend for TCAS to act as the sole means of avoiding collisions and that the onboard pilot still has the

responsibility for seeing and avoiding other aircraft. FAA officials also point out that TCAS computes collision avoidance solutions based on characteristics of manned aircraft and does not incorporate unmanned aircraft's slower turn and climb rates in developing conflict solutions. Consequently, FAA officials believe that developing detect, sense, and avoid technology that unmanned aircraft would need to operate routinely in the national airspace system poses an even greater challenge than TCAS did. FAA officials believe that an acceptable detect, sense, and avoid system for airplanes could cost up to \$2 billion to complete and is still many years away.

- The lack of protected radio frequency spectrum for unmanned operations heightens the possibility that an operator could lose command and control of the plane. Unlike manned aircraft, which use dedicated, protected radio frequencies, unmanned aircraft currently use unprotected radio spectrum and, like any other wireless technology, remain vulnerable to unintentional or intentional interference. This remains a key security vulnerability for unmanned aircraft, because in contrast to a manned aircraft where the pilot has direct, physical control of the aircraft, interruption of radio frequency, such as by jamming, can sever the plane's only means of control. One of the experts we surveyed listed providing security and protected spectrum among the critical airplane integration technologies.
- Unmanned aircraft have the capability to deliver nuclear, biological, or chemical payloads and can be launched undetected from virtually any site. In response to the events of September 11, 2001, entry doors to passenger airplane cockpits were hardened to prevent unauthorized entry. However, no similar security requirements exist to prevent unauthorized access to unmanned aircraft ground control stations – the unmanned system equivalent of the cockpit. Security is a latent issue that could impede unmanned airplane developments even after all the other challenges have been addressed, according to one study.
- Although U.S. DOD has obtained benefits from its unmanned operations overseas, the agency notes in its Unmanned Systems Roadmap that unmanned aircraft reliability is a key factor in integrating unmanned systems into the national airspace system. Our analysis of information that U.S. DOD provided on 199 military unmanned airplane accidents, of varying degrees of severity, that occurred over 4.5 years during operations Enduring Freedom and Iraqi Freedom, indicates that reliability continues to be a challenge. About 65 % of the accidents resulted from materiel issues, such as failures of aircraft components. FAA officials noted that unmanned aircraft today are at a similar stage as personal computers in their early years before newer, more user-friendly operating systems became standard.
- The variety of ground control station designs across unmanned aircraft is another human factors concern. For example, pilots of the Predator B control the aircraft by using a stick and pedals, similar to the actions of pilots of manned aircraft. In contrast, pilots of the Global Hawk use a keyboard and mouse to control the aircraft. Differences in unmanned system missions could require some variation

among control station designs, but the extent to which regulations should require commonalities across all ground control stations awaits further research.

- Because unmanned aircraft have never routinely operated in the national airspace system, the level of public acceptance is unknown. One researcher observed that as unmanned aircraft expand into the nondefense sector, there will inevitably be public debate over the need for and motives behind such proliferation. One expert we surveyed commented that some individuals may raise privacy concerns about a small aircraft that is “spying” on them, whether operated by law enforcement officials or by private organizations, and raised the question of what federal agency would have the responsibility for addressing these privacy concerns.

Feedback from European agencies was pretty much the same and along the same lines of thought. D. Hughes’ article (2008) stated that “Unmanned aircraft need lots of flying hours to be ‘civilized.’” The article talks about the Eurocontrol plans to develop a roadmap by the end of 2009 outlining how unmanned aircraft will be integrated into the European ATM system. A key issue is harmonization with what the FAA, ICAO, EUROCAE WG-73, and RTCA SC-203 are deciding. According to H. Matthiesen, Senior Specialist in ATM (Hughes 2008), *“What the industry needs is flying hours and experience and lessons [learned] to build confidence in these machines. Airworthiness requires lots of flying hours, especially to support airworthiness on the civil side.”*

Further, M. Bennett (2008) stated that the European Defense Agency (EDA) awarded in January of 2008 a contract to a consortium of defense and aerospace companies to develop a detailed roadmap for integrating UAS into European airspace so that they can fly routinely with other air traffic by 2012 or “the end of 2015 at the latest.”

The previously stated information reveals a very important pattern: The “thought process” in U.S. and European agencies, despite possible differences, has been similar if not identical. Therefore, what appears to be obvious as the aftermath of the same thought process that also includes valid concerns and skepticism is the publication of the roadmaps for integration of UAS into the NAS (Final Report – European RPAS SG, 2013) (Report-FAA, 2013), which lay the foundations for unmanned aviation to be eventually widely used for a multitude of civil and public domain applications.

However, all of the above notwithstanding, there is consensus on a number of challenges that need to be met before UAS fly routinely in civilian airspace. The following are true:

- Safety, safety, and more safety, with all prerequisites and aftermath attached to it. The public will not tolerate accidents; it is as simple as that. For UAS to achieve an equivalent level of safety (ELOS) to that of manned aircraft system, reliability needs to be increased and the probability of midair collisions needs to be reduced. Collision avoidance has been a major area of research since most of the corresponding manned aviation procedures and technology rely primarily on pilots and secondarily on ATC instruction.

- Detect, sense, and avoid technology. The NTSB members have expressed particular interest in the ability of UAS to handle contingencies beyond close encounters in shared airspace. This is perhaps the most important challenge to be overcome, as the FAA states that UAS should function as if there were a pilot onboard. In addition, redundancy is a must, and as such, it is obvious that sense and avoid technology should include both visual and nonvisual sensor components. Such a system should be capable of operating under various weather conditions and situations and, as autonomy increases, with limited operator involvement. The latter is indeed important since different requirements can be expected depending on whether a pilot will be in the decision loop or not. In any case, a successful detect, sense, and avoid (and see and avoid) system will likely entail information fusion from multiple sensors to avoid the “blind spots” of a single sensor. It will also be necessary for the system to interface with ground-based sensors (e.g., radar) for supplementing its own information and with other sensors and onboard systems to be able to make successful decisions for collision avoidance and execute them with precision and timeliness. Based on the principles of fairness and equivalence, it would be reasonable to demand that such systems achieve a performance comparable to that of human pilots. Nevertheless, both research and practice has shown that pilots are not very good at detecting potential collisions. Moreover, currently manned aviation pilots can only monitor a limited part of the airspace around them, mostly in front of the aircraft. As a result, the development of detect, sense, and avoid systems that are capable of exceeding pilot capabilities would be beneficial for the manned aviation sector, as well. In any case, minimum requirements will be mandated that will include minimum detection distances and aircraft separation margins. The “reaction time” of the system should also be at least comparable to that of a pilot, based on the FAA AC 90–48C report. Also, although research has been focused on duplicating pilot vision, efficient deconfliction algorithms will also need to be developed to replace pilot action in the case of a possible collision.
- Sensors development. From a regulation standpoint, sensor capabilities are an issue, since they will determine detect, sense and avoid, and see and avoid performance, which in turn is a major factor affecting safety of operations. Related research has investigated electro-optical, acoustic, and microwave sensors. Acoustic sensors are not very susceptible to problems from the environment and are quite robust but have low resolution and exhibit problems tracking multiple targets. Electro-optical sensors have good resolution and allow multiple target tracking but are more susceptible to environmental interference (sun glare, temperature, vibration). Microwave sensors can give good range estimates but are typically too large, heavy, and expensive especially for smaller UAS, although research is being done on ultra-lightweight radar systems for this class of UAS. When combined, these sensors offer unique characteristics that enable a UAS to detect and in some cases track one or more targets in difficult conditions like fog, glare, or darkness. Besides developing sensors with higher resolutions and improved capabilities, efficient fusion algorithms will also be needed.

Finally sensor miniaturization will play an important role in the integration of small UAS.

- **Bandwidth regulation.** The United Nations International Telecommunications Union (ITU) is working with the International Civil Aviation Organization (ICAO) to provide a safe, global communications infrastructure for UAS operations. One option presented to ITU by the U.S. government – with industry support – is the use of fixed satellite service, which is in abundance and can safely support the projected growth of the UAS market for years to come.
- **Lost link procedures:** In all cases, the UAS must be provided with a means of automatic recovery in the event of a lost link. There are many acceptable approaches to satisfy the requirement. The intent is to ensure airborne operations are predictable in the event of lost link.
- **Flight termination system (FTS):** It is highly desirable that all UAS have system redundancies and independent functionality to ensure the overall safety and predictability of the system. If a UAS is found to be lacking in system redundancies, an independent flight termination system that can be activated manually by the UAS pilot in command may be required to safeguard the public.
- **Autonomous operations:** At first only those UAS that have the capability of pilot intervention, or pilot-in-the-loop, shall be allowed in the NAS outside of restricted, prohibited, or warning areas. UAS that are designed to be completely autonomous, with no capability of pilot intervention, are going to be the last to be authorized for operations in the national airspace system.
- **Technology testing and evaluation.** In parallel with standards and regulations development, other efforts are required to streamline the integration process of UAS in the NAS. Existing regulations severely limit access to airspace so that UAS developers can evaluate their systems. As a result, the FAA announced the establishment of six test sites (December 2013) to evaluate UAS and their subsystems for both R&D as well as certification purposes. Similar centers are planned or have already been built in France, Spain, Canada, Australia, and New Zealand. Such centers can be used to certify UAS hardware and software components as well as provide UAS crew training, as is the goal for the ARCAA in Australia.

In addition, new modeling techniques will be required to capture coupling between individual system/sensor dynamics, communications, etc., with “system of systems” behaviors. Hybrid system approaches will play a key role in capturing complex behaviors and defining the means to represent and manage uncertainty, including spatial–temporal models of distributed sensors to integrate system and motion dependencies, contingency planning, and situation awareness.

Intelligent and hierarchical/distributed control concepts must be developed and expanded to address “system of systems” configurations. Game theoretic approaches and optimization algorithms running in real time to assist in cooperative control and adversarial reasoning will be needed. Comprehensive approaches to control of networks of dynamic agents will be essential to tackle coordination and cooperation issues.

Networking and communications will deviate from traditional communication protocols and standards, requiring novel solutions to overcome jamming. Security metrics will need to be redefined.

Sensors and sensing strategies will need innovative technologies and solutions that will include wireless communications. This will be coupled with building improved, reliable, and cost-effective sensor suites, as well as “smart” sensors, leading to better sensing strategies for massive data processing, data mining, and sensor fusion.

The need for defining new “system of systems” performance and effectiveness metrics for verification, validation, and assessment of networked systems is more than obvious.

126.5 The Road Ahead

During the last almost 20 years, we have witnessed significant advances in the unmanned aircraft and unmanned systems state of the art.

Major research and development projects, sponsored primarily by the military sector, have contributed towards development and deployment of aerial, under-sea, and ground unmanned systems with new designs surfacing at an increasing rate. Common objectives and goals of any such designs are improved autonomy through innovative sensing and control strategies, enhanced reliability and endurance through fault-tolerant control, advanced materials, and high-efficiency power plants.

Yet, new and novel concepts and technologies are required for a more widespread use of such critical assets, not only for military but also for commercial and other applications such as homeland security, rescue operations, forest fire detection, and delivery of goods, to name just a few applications.

Federated systems consisting of multiple unmanned aerial vehicles performing complex missions present new challenges to the control community. UAS must possess attributes of autonomy in order to function effectively in a “system of systems” configuration.

Coordinated and collaborative control of UAS swarms demands new and novel technologies that integrate modeling, control, communications, and computing concerns into a single architecture. Typical application domains include reconnaissance and surveillance missions in an urban environment, target tracking and evasive maneuvers, search and rescue operations, homeland security, etc.

Major technological challenges remain to be addressed for such UAS swarms, or similar federated system of systems configurations to perform efficiently and reliably. Excessive operator load, autonomy issues, and reliability concerns have limited thus far their widespread utility. The systems and controls community is called upon to play a major role in the introduction of breakthrough technologies in this exciting area.
