This chapter presents a distributed architecture for unmanned aircraft systems that provides full integration of both low autonomy and high autonomy. The architecture has been instantiated and used in a rotor-based aerial vehicle, but is not limited to use in particular aircraft systems. Various generic functionalities essential to the integration of both low autonomy and high autonomy in a single system are isolated and described. The architecture has also been extended for use with multi-platform systems. The chapter covers the full spectrum of functionalities required for operation in missions requiring high autonomy. A Control Kernel is presented with diverse flight modes integrated with a navigation subsystem. Specific interfaces and languages are introduced which provide seamless transition between deliberative and reactive capability and reactive and control capability. Hierarchical Concurrent State Machines are introduced as a real-time mechanism for specifying and executing low-level reactive control. Task Specification Trees are introduced as both a declarative and procedural mechanism for specification of high-level tasks. Task planners and motion planners are described which are tightly integrated into the architecture. Generic middleware capability for specifying data and knowledge flow within the architecture based on a stream abstraction is also described. The use of temporal logic is prevalent and is used both as a specification language and as an integral part of an execution monitoring mechanism. Emphasis is placed on the robust integration and interaction between these diverse functionalities using a principled architectural framework. The architecture has been empirically tested in several complex missions, some of which are described in the chapter.

37.1 Introduction

Much of the recent research activity with unmanned aircraft systems (UASs) has focused primarily on the air vehicle (AV) itself, together with the avionics and sensor subsystems. Primary focus has been placed on the navigation subsystem together with low-level control combined with motion planners that allow a UAS to operate

with limited autonomy. The Control Kernel implements diverse control modes such as takeoff, landing, flying to waypoints, and hovering (in the case of rotor-based systems). Sensor payloads are then used to gather data after positioning the AV at salient points of interest.

Development of this type of low-level autonomy has been impressive, resulting in many AV systems that with the help of human operators can autonomously execute missions of moderate complexity. Specification of such missions is often based on the manual or semi-manual construction of a waypoint database, where waypoints may be annotated with sensor tasks to be achieved at each of these points. Such a means of specifying missions is often time consuming and also prone to error due to the low level of abstraction used and to the lack of automation in generating such plans. Additionally, one lacks techniques for the automatic verification of the correctness of a mission.

Although these capabilities provide the basic functionality for autonomous AVs, if one is interested in increasing the complexity of the missions executed and the usefulness of UASs, much more is required. The collection of functionalities and capabilities required to automate both the process of specifying and generating complex missions, instantiating their execution in the AV, monitoring the execution, and repairing mission plans when things go wrong commonly goes under the umbrella term “high autonomy.” Systems with high autonomy require additional architectural support beyond what one commonly uses to support the low-level autonomy. Furthermore, one has to ensure that each of the architectural components that support both low and high autonomy is fully integrated in the resulting system and provides the proper level of quality of service for the relevant tasks.

This chapter describes a distributed software architecture that fully integrates functionality for both low and high autonomy. The architecture has been developed for a number of years and has been both tested and deployed on a number of rotor-based AV systems. The purpose of this chapter is not only to describe the instantiation of the architecture on a particular AV system but also to isolate and describe various generic functionalities essential to the integration of low and high autonomy. These functionalities and their architectural support can be used on any robotic system, be it an aerial, ground, or underwater system. Consequently, this architectural framework should be of interest to anyone developing autonomous systems.

Let us begin by providing a motivating scenario for the use of UASs. On December 26, 2004, a devastating earthquake of high magnitude occurred off the west coast of Sumatra. This resulted in a tsunami which hit the coasts of India, Sri Lanka, Thailand, Indonesia, and many other islands. Both the earthquake and the tsunami caused great devastation. Initially there was a great deal of confusion and chaos in setting into motion rescue operations in such wide geographical areas. The problem was exacerbated by shortage of manpower, supplies, and machinery. The highest priorities in the initial stages of the disaster were searching for survivors in many isolated areas where road systems had become inaccessible and providing relief in the form of delivery of food, water, and medical supplies.

Assume that for a particular geographical area, one had a shortage of trained helicopter and fixed-wing pilots. Assume also that one did have access to a fleet of autonomous unmanned helicopter systems with ground operation facilities and the ability to both scan for salient entities such as injured humans and deliver supplies and resources such as relief packages containing food, water, and medical supplies. These systems could then provide essential assistance to emergency rescue services.

Participating UASs would require functionalities associated with both low and high autonomy operating in tight integration with each other. Additionally, this scenario would involve several UASs, so additional support would be required for collaboration between ground operation and AVs in addition to cooperation between the AVs themselves.

The complex real-world deployment outlined above would have two phases. In the first, one would require the use of as many AVs as were in the area to scan a specific region for injured and to generate a saliency map that could then be used by emergency services or other UASs to provide relief assistance in the form of medical and food supplies. In the second phase, given a particular saliency map, one would have to determine efficient ways to deliver the appropriate supplies to the different regions in an optimal manner. In essence, there are two high-level goals to be achieved:

1. Scan a specific region with available AVs to generate a saliency map consisting of geolocations of injured civilians.
 2. Put together a logistics plan based on the saliency map and available AVs to deliver medical and food supplies to appropriate locations within this region.
- Ideally, one would like to specify a mission at this level of abstraction and have the UASs generate the appropriate plan or plans for the specific AVs involved based on their capabilities, resources, and availability.

This in itself is a highly complex endeavor based on the use of sophisticated automated distributed planning techniques for teams of AVs and human resources in a mixed-initiative context. An essential aspect of the higher-level or high-autonomy functionalities is the ability to clearly and succinctly specify and generate missions to be executed and to coordinate their execution in a distributed manner.

The execution of the tasks associated with such missions in the individual AVs is just as complex. An essential aspect of the lower-level or low-autonomy functionalities involves different forms of compilation and execution mechanisms in (soft) real time that ultimately result in the coordination and use of real-time continuous control modes associated with the individual AVs. Most importantly, the tight integration of processes at these different levels of abstraction is fundamental to the robust operation of AVs in missions which require such high degrees of autonomy.

Later in the chapter, additional detail will be provided as to how the architecture supports the deployment of AVs in missions of this complexity. Before this, there will be an overview of the architecture and the functionalities it includes and a roadmap based on this overview. The remainder of the chapter will provide more detailed descriptions of these functionalities and their integration with each other.

37.1.1 Overview of the HDRC3 Architecture

In recent years, there has been a consolidation of thought regarding essential conceptual components required in software architectures for mobile robots, although there is wide variation in the way these components are implemented in specific robotic systems. One of the clearest presentations of this consolidation of thought is described in Gat (1997). In this article, he traces the history and development of robotic architectures in artificial intelligence and the transition from sense-plan-act architectures to what are now generically known as three-layered architectures. In his own words,

The three-layer architecture arises from the empirical observation that effective algorithms for controlling mobile robots tend to fall into three distinct categories: (1) reactive control algorithms which map sensors directly onto actuators with little or no internal state; (2) algorithms for governing routine sequences of activity which rely extensively on internal state but perform no search; and (3) time-consuming (relative to rate of change of the environment) search-based algorithms such as planners. (Gat 1997, p. 209)

The algorithms associated with each of these categories have distinct temporal latencies in the decision cycles: (1) millisecond range, (2) seconds range, and (3) seconds or even minutes range. Each of these computational abstractions requires interfaces to each other which in essence implement compilational transitions between the layers.

The Hybrid Deliberative/Reactive (HDRC3) architecture presented here is based conceptually on the three-layered approach. It is important to state that this is due not only to the theoretical clarity of the approach but also to empirical necessity. In the development of architectures which support high and low autonomy and their integration for use in complex missions, one naturally gravitates towards such architectures. Although conceptually layered, in practice, the HDRC3 architecture is better described as concentric (as depicted in Fig. 37.1a) in the sense that data and control flow are both vertical and horizontal within and across layers and that the processes evoked by the various algorithms are highly concurrent and distributed.

Figure 37.1b provides a conceptual and functional depiction of the HDRC3 architecture. It also provides a visual depiction of the roadmap for the chapter where a bottom-up approach will be used to describe the architectural components. The HDRC3 architecture consists of three functional layers and a number of interfaces between the layers:

Control Layer This layer provides a library of control modes based on the implementation of continuous control laws such as takeoff, trajectory following, and vision-based landing. Algorithms associated with this layer generally have little or no internal state. Additionally, it provides a real-time environment for accessing hardware and sensors, executing control modes, and switching between them.

Reactive Layer This layer coordinates the execution of high-level plans generated by the deliberative layer and implements a set of robotic behaviors such as **fly-to** and **scan-area** that may be viewed as compiled plans or as reactive procedures.

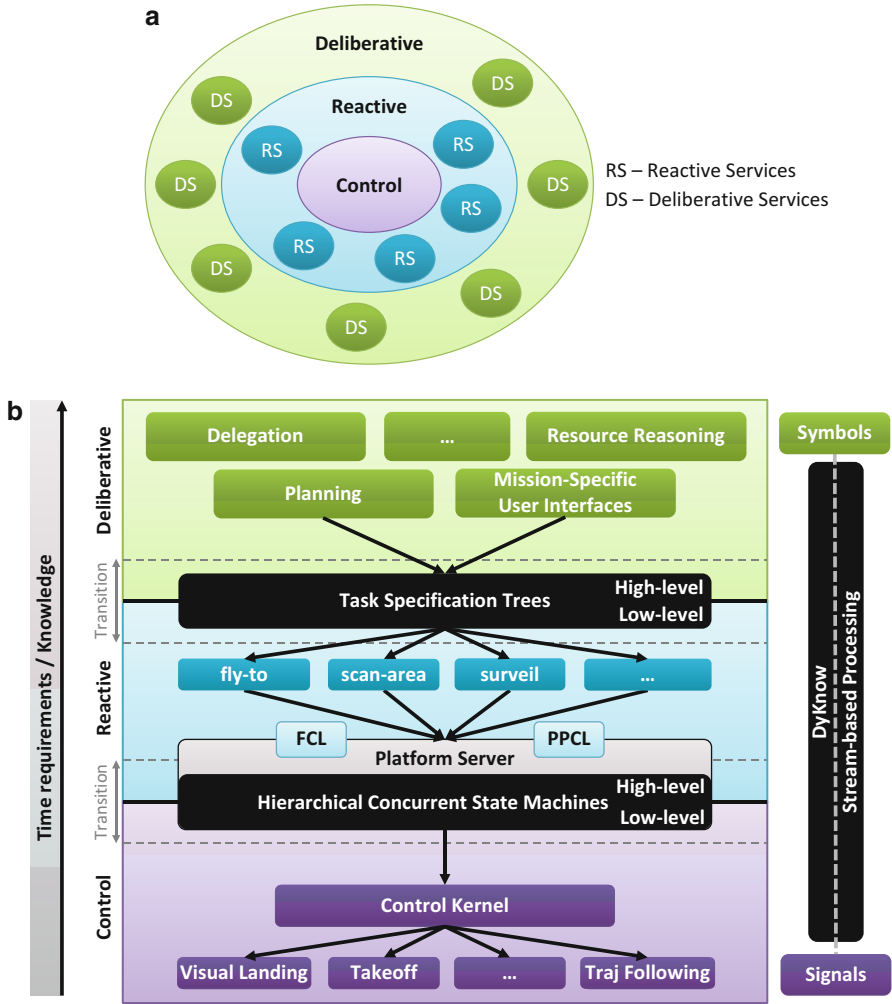

Fig. 37.1 The structure of the Hybrid Deliberative/Reactive (HDRC3) architecture. **(a)** The concentric view. **(b)** The layered view

These are specified as Task Specification Trees (TSTs). The reactive layer also includes a thread-based executor for TSTs. Algorithms associated with this layer do have internal state, but of a postdictive nature generally in terms of previous states of actions.

Deliberative Layer This layer provides a rich set of algorithms commonly associated with deliberation such as automated task planners, motion planners, reasoning and diagnosis mechanisms, and execution monitoring mechanisms.

Algorithms associated with this layer generally have rich internal state of both post- and predictive nature and often include search through large state spaces.

The interfaces used to transition between these layers are central to the success of such architectures. The HDRC3 architecture provides a rich set of interfacing mechanisms:

Interfaces Between the Control Layer and the Reactive Layer A specialized language and implementation is used for interfacing between the control layer and the reactive layer. Hierarchical Concurrent State Machines are used to specify and implement mode switching behaviors at the control layer. Additionally they are used to implement low-level reactive behaviors normally associated with flight control or perception control.

Platform Server Interface Helicopter pilots and ground control personnel often think of controlling unmanned aircraft in terms of a Flight Control Language (FCL) representing various flight modes and a Payload and Perception Control Language (PPCL) representing various modes of perception and sensor control. Because this abstraction is so powerful, an independent server exists which implements this abstraction using two well-defined languages for flight control and perception control, respectively. Any functionality in the system can access the server through these abstract languages.

Interfaces Between the Reactive and Deliberative Layers The notion of robot task specifications and the processes they invoke are central to the achievement of goal-directed behavior. Tasks can be specified in many different ways. HCSMs are one way to specify low-level tasks. At the other end of the spectrum are highly complex tasks which use low-level tasks as primitives. Task Specification Trees (TSTs) are used as a means of not only specifying such high-level tasks declaratively, but also providing procedural correlates executable in the system. TSTs therefore provide both a declarative and procedural means of transitioning between the deliberative and reactive layers. It is often the case, for instance, that TSTs are used to sequentialize commands associated with the FCL and PPCL. Additionally, the output of an automated planner may be viewed as a TST.

37.1.1.1 Middleware Infrastructure

The functionality in the reactive and deliberative layers of the HDRC3 architecture should be viewed as sets of loosely coupled distributed processes that are highly concurrent and often require asynchronous communication with each other. These processes run on multiple onboard (or ground-based) computers, communicating through service calls and transmitting information through a set of distributed communication channels. This requires a rich middleware infrastructure to provide the communication channels between these processes and the ability of each to use other processes when required. An example would be interaction between task planners, path planners, and execution monitors.

In early iterations of the HDRC3 architecture, the underlying middleware infrastructure was based on the use of CORBA (Common Object Request Broker

Architecture). The architecture has recently been transitioned to using ROS, the Robot Operating System. This is a convenient open-source framework for robot software development that provides client libraries and tools for several programming languages (Quigley et al. 2009).

Software written for ROS is organized into *packages* which contain nodes, libraries, and configurations. *Nodes* represent computational processes in the system and are written using the client libraries. For example, many capabilities such as task planning and motion planning are realized as separate ROS nodes. These nodes communicate by passing structured messages on *topics* which can be seen as named buses to which nodes can subscribe and by using request/reply communication through *services*.

Although emphasis in this chapter is placed on a single platform using the HDRC3 architecture, it is also set up for collaborative missions with multiple AV systems. All agents in such a collaborative system currently use a common ROS Master, a standard ROS functionality providing registration and lookup services. For disconnected operation, a federated approach to the ROS Master is used.

Figure 37.2 gives an overview of some of the essential processes and ROS topics that are present in the HDRC3 architecture. These include functionality for use of individual platforms in collaborative scenarios. The functionality associated with the control layer is encapsulated in the Platform Server and accessed by the two languages FCL and PPCL mentioned earlier.

Black arrows indicate calls between processes. Each gray rectangle contains processes and topics that are explicitly associated with a particular agent. Inside this, each rounded rectangle represents a distinct functionality that is currently implemented as one or more related ROS services provided by one or more ROS nodes. Given the fundamental structure of ROS, functionality can easily be moved between nodes without affecting the remainder of the system. Therefore, an exact specification at the node level is not relevant at this level of abstraction.

There is one special functionality associated with the HDRC3 architecture which can be viewed as a shared middleware and interfacing mechanism supporting the creation and management of data flow in the architecture. This middleware is called DyKnow and it is based on the abstraction of streams of data.

One of the highly problematic and open research issues in AI and robotics is the large discrepancy between the quantitative and large amount of raw sensor data input to a robotic system and the requirement for sparse, well-structured, and grounded qualitative data used by the deliberative functionalities in robotic architectures. This is often called the sense-reasoning gap.

DyKnow is a middleware functionality that has been developed in the HDRC3 architecture which provides a principled means of closing this gap both theoretically and pragmatically. DyKnow provides abstractions for the construction, reasoning, processing, and abstraction of data streams within the architecture itself. This middleware is leveraged throughout the architecture and used by many functionalities to great benefit. It is used in a variety of ways at any layer in the HDRC3 architecture and is integrated with ROS.

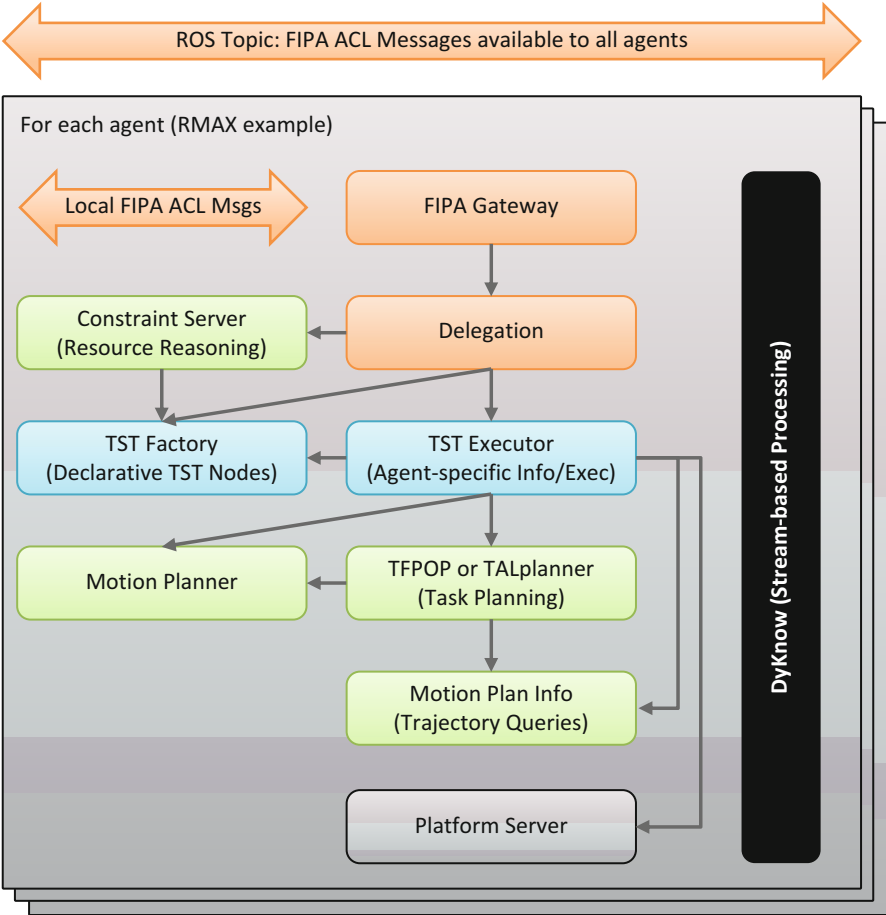

Fig. 37.2 Overview of the ROS-based implementation

37.1.2 Roadmap to the Chapter

Both Figs. 37.1 and 37.2 provide concise visual depictions of the HDRC3 architecture and its essential functionalities. This framework will be used to structure and provide a roadmap for the remainder of the chapter.

Section 37.2 describes the UAS Tech Lab (UASTL) RMAX helicopter system which includes a distributed hardware architecture and a suite of sensors integrated with the base Yamaha RMAX helicopter system.

Section 37.3 describes the Control Layer. This includes a description of the Control Kernel itself with its primary flight modes (Sect. 37.3.2), in addition to two complex compound flight modes: a path-following control mode (Sect. 37.3.3) and a vision based landing mode (Sect. 37.3.4).

Section 37.4 describes the reactive layer. This includes a description of Hierarchical Concurrent State Machines and a real-time HCSM interpreter (Sect. 37.4.1). This is a generic capability that requires instantiation and use in terms of specific HCSMs. Section 37.4.1.1 describes these specific HCSMs used in the UASTL RMAX system. The higher-level ROS-based system shown in Fig. 37.2 interfaces to the real-time control functionalities (Sect. 37.3.2) through the *Platform Server*. This is described in Sect. 37.4.2. Complex tasks and missions are concretely represented as Task Specification Trees using elementary actions such as flying together with a number of task composition constructs such as sequences, concurrent execution, and loops (Sect. 37.4.3). Nodes in such trees, which are general and declarative specifications of tasks to perform, are both created by and stored in a *TST Factory*. The *TST executor* functionality is responsible for generating platform-specific procedural *executors* for any node type that a particular agent supports. Platform-specific constraints on how a certain task can be performed, such as those related to the flight envelope of the RMAX, are also specified here.

Section 37.5 describes the navigation subsystem. This subsystem includes the path and motion planning algorithms (Sect. 37.5.1) in addition to the specific HCSMs used to coordinate these processes (Sect. 37.5.2).

Section 37.6 describes DyKnow, the stream-based processing middleware framework used for managing data and knowledge flow within the HDRC3 architecture. This functionality is used by many other functionalities within the architecture. Connections to DyKnow are omitted in Fig. 37.2 in order to avoid clutter, as information processed by DyKnow can be used by any deliberative or reactive functionality. A traffic monitoring example, where DyKnow plays an essential role, is described in Sect. 37.6.7.

Section 37.7 describes many of the high-level deliberative functionalities in the HDRC3 architecture that can be used by other functionalities in the architecture. One open research issue of great importance is the requirement of formally verifying the behavior of complex deliberative functions which are often dependent on rich world models and also highly nondeterministic in nature. The HDRC3 architecture uses temporal logics not only for specification but for online monitoring purposes. Section 37.7.1 describes Temporal Action Logic (TAL) which is used for formally specifying task plans and Task Specification Trees. Section 37.7.2 describes a *task planner* called TALplanner that is used in the HDRC3 architecture and is highly integrated with motion planners and execution monitoring mechanisms. One of the responsibilities of the task planner is to expand *goal nodes* in a Task Specification Tree into detailed task specifications, which is why it can be called from the TST executor shown in Fig. 37.2. The task planner can also call the motion planner and Motion Plan Info functionalities in order to estimate whether a given flight action is feasible as part of a plan being generated, and if so, at what cost. Section 37.7.3 describes a very sophisticated and efficient execution monitoring functionality based on the use of model-checking temporal logical formulas in real time through use of a progression algorithm. Section 37.7.4 describes an extension to Temporal

Action Logic that allows one to formally specify complex missions. These missions can be compiled into Task Specification Trees and are also useful in specifying collaborative missions.

Section 37.8 briefly discusses collaborative systems consisting of multiple platforms. In a collaborative setting, *delegation* is the key to assigning the responsibility for specific aspects of a mission to specific agent-based unmanned systems. Delegation requests are specified as speech acts in the FIPA Agent Communication Language (ACL) (Foundation for Intelligent Physical Agents 2002) and are sent between agents through a set of communication channels, currently implemented using ROS topics. A *gateway* functionality acts as a clearinghouse for all interagent communication based on such speech acts. Determining whether an agent can accept a delegation request also requires reasoning about whether and how the agent can satisfy the temporal and resource-related constraints associated with a task. This is implemented through a resource reasoning capability that includes a *constraint server*. These particular functionalities are shown in Fig. 37.2.

Section 37.9 provides examples of several highly complex mission scenarios that have been used to empirically test the HDRC3 architecture, its various functionalities, and the tight integration required among the functionalities. UASTL RMAXs have been deployed and used in these scenarios and variations of them on numerous occasions to not only refine the HDRC3 architecture but also to ensure repeatability of missions and robustness of the architecture in real-world environments.

Section 37.10 summarizes and discusses the generic nature of the architecture and many of its functionalities.

37.2 Unmanned Aircraft Platforms

The HDRC3 architecture and variations of it have been used on a number of different research platforms, in particular in the context of research with heterogeneous collaborative systems (Doherty et al. 2013; <http://www.ida.liu.se/divisions/aiics/aiicssite/>). For example, a lightweight version of the architecture has been ported to the LinkQuad, a micro-aerial vehicle platform developed within the UAS Tech Lab (<http://www.uastech.com>). However, this chapter focuses solely on the use of the HDRC3 architecture on a Yamaha RMAX system which has been extended for autonomous use. This platform is called the UAS Tech Lab (UASTL) RMAX (Doherty et al. 2004; Wzorek et al. 2006a; Rudol and Doherty 2008; Conte and Doherty 2009).

37.2.1 The RMAX Helicopter Platform

The UASTL RMAX platform is a modified Yamaha RMAX helicopter (Fig. 37.3). The Yamaha RMAX helicopter is a radio-operated commercial system marketed in

Fig. 37.3 The UASTL RMAX helicopter

Japan by Yamaha Motor Co. Ltd. Two of these were acquired and used as a basis for developing fully autonomous systems. The HDRC3 architecture is integrated on both systems.

The RMAX is approximately 2.7×0.7 m with a total length of 3.6 m including the rotor. It uses a 21 HP two-stroke engine and has an empty weight of 61 kg and a maximum takeoff weight of 95 kg.

37.2.2 Computational Aspects

The computer systems used onboard the UASTL RMAX need to work reliably in harsh environmental conditions characterized by high vibrations, limited space, and a high range of operating temperatures. The PC104 is an industrial-grade embedded computer standard that is especially suited for such applications. The onboard system developed for the UASTL RMAX contains three such PC104 embedded computers. These embedded computers physically reside in a specially designed box which is integrated with the RMAX and is shown in Fig. 37.3. Figure 37.4 provides a hardware schematic of the integrated system.

- The Primary Flight Computer (PFC, 1.06 GHz Intel Celeron M) handles core flight functionalities and control modes. This computer is directly connected to a GPS receiver and several additional sensors including a barometric

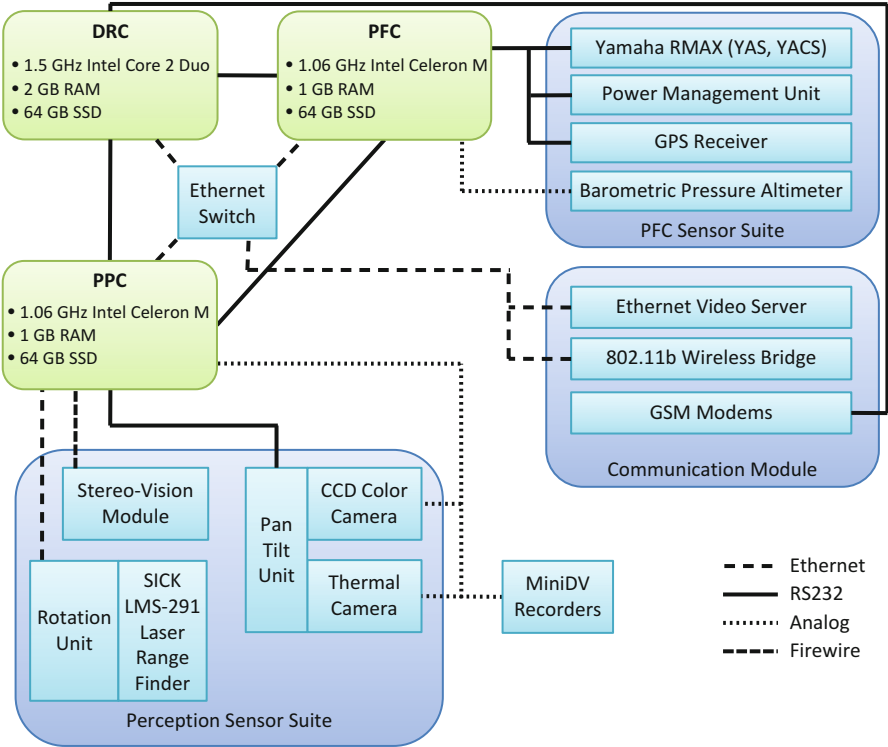

Fig. 37.4 Onboard hardware schematic

altitude sensor. The PFC is also connected to the UASTL RMAX helicopter through the standard Yamaha Attitude Sensor (YAS) and Yamaha Attitude Control System (YACS) interfaces.

- The Deliberative/Reactive Computer (DRC, 1.5 GHz Intel Core 2 Duo) executes all high-level autonomous functionalities such as path planning (Sect. 37.5.1), stream-based reasoning (Sect. 37.6), and mission planning (Sect. 37.7.2).
- The Primary Perception Computer (PPC, 1.06 GHz Intel Celeron M) runs software related to the use of cameras, range finders, and similar equipment. This includes image processing and sensor fusion.

Due to the high degree of vibration onboard the UASTL RMAX, in its current configuration it is not possible to use standard hard drives for storage. Instead all computers use Solid State Disk (SSD) technology.

Network communication between the onboard computers is realized with serial lines (RS232C) as well as Ethernet. The serial lines are used to implement a robust real-time communication channel between each of the onboard computers.

Fig. 37.5 Cameras used on the UASTL RMAX. (a) CCD Block Camera on PTU. (b) Infrared Camera

37.2.3 Communications, Sensors, and Other Hardware

A wireless Ethernet bridge as well as a GSM modem is available for communication with ground control stations. GSM provides a mature, commercially available communication infrastructure that permits the operation of AVs at large distances, out of sight from the ground operator. It also provides a redundant alternative in the case where other communication frequencies are jammed. In order to test the feasibility of GSM technology for interfacing purposes, a multimodal graphical user interface has been designed, constructed, and implemented on a mobile telephone (Wzorek et al. 2006b). This has been used as a mobile ground operator control system where mission plans can be specified, uploaded, and monitored through the mobile telephone.

A camera platform is suspended under the AV fuselage, vibration-isolated by a system of springs. The platform consists of a Sony FCB-780P CCD block camera (Fig. 37.5a) and a ThermalEye-3600AS miniature infrared camera (Fig. 37.5b) mounted rigidly on a pan-tilt unit (PTU). Section 37.9.1.1 presents a method for using both cameras in an algorithm for finding human bodies and building saliency maps. The video footage from both cameras is recorded at full frame rate by two miniDV recorders to allow processing after a mission.

A modified SICK LMS-291 laser range finder has also been integrated with the UASTL RMAX using a rotation mechanism developed in-house. It is mounted on the front as shown in Fig. 37.3. This system provides the ability to generate high-accuracy 3D models of the environment in which the aircraft is operating, without the need for reflectors, markers or scene illumination (Sect. 37.9.2).

A software-controlled power management unit provides information about voltage levels and current consumption. It also allows for remote power control where all devices can be switched on or off through software. The unit controls all three PC104 computers, all sensors, and the wireless Ethernet bridge.

The HDRC3 architecture is distributed on this hardware platform. The control layer of this architecture, which in many ways operates close to the hardware, will now be described.

37.3 The Control Layer

The control layer implements basic continuous control modes used by the UASTL RMAX. These control modes are implemented using continuous control laws as a basis. Already at this level, the algorithms used are quite complex. For instance, two essential modes described in this section, path-following (Sect. 37.3.3) and vision-based landing (Sect. 37.3.4), require tight integration with the architecture and involve discrete event control capability (Sect. 37.4.1). This section describes both these modes in addition to the Control Kernel (Sect. 37.3.2) and its real-time demands (Sect. 37.3.1).

37.3.1 Real-Time Aspects

Certain functionality, such as control laws in the Control Kernel, requires support for real-time processing with latency guarantees. Since the current implementation of the HDRC3 architecture runs on a Linux-based operating system, the Real-Time Application Interface (RTAI, Mantegazza et al. 2000) is used for this purpose.

RTAI is a hard real-time extension to the standard Linux kernel and provides industrial-grade real-time operating system functionality. RTAI allows for the creation of a kernel module that takes full control over the CPU and can suspend itself in order to let user-space applications run. Such a module is used to implement real-time functionalities in the HDRC3 architecture. The standard Linux distribution running on the same CPU is viewed as a separate task with lower (non-real-time) priority, running preemptively so that it can be interrupted by real-time processes at any time. Real-time and non-real-time processes can then communicate through shared memory.

All computers in the UASTL RMAX platform (Fig. 37.4) have both hard and soft real-time components, but the processor time is assigned to them in different proportions. On one extreme, the PFC runs mostly hard real-time tasks with only a minimal number of non-real-time user-space applications (e.g., an SSH daemon for remote login). On the other extreme, the DRC uses the real-time part only for device drivers and real-time communication, while the majority of its time is spent on running deliberative services.

37.3.2 The Control Kernel

The Control Kernel (CK) encapsulates all core control functionalities, including a set of continuous control laws implementing the basic flight and payload control modes as well as control over the perception capabilities that can be used by the

reactive and deliberative layers. It is also responsible for switching between control modes through the use of Hierarchical Concurrent State Machines (Sect. 37.4.1).

The kernel is distributed on two onboard computers (PFC and PPC) and also coordinates real-time communication between these computers as well as between CKs of other robotic systems when collaborative missions are involved. However, the kernel itself is self-contained, and only the part running on the PFC computer is necessary for maintaining flight capabilities. This enhances the safety of the operation of the UASTL RMAX platform.

The following flight control modes have been implemented on the UASTL RMAX platform:

- *Hovering*: Keep the helicopter in the desired position, heading, and altitude given current sensor readings. The mode is implemented using a set of PID loops.
- *Takeoff*: Bring the helicopter from the ground to a specified altitude.
- *Path-following*: Fly along a specified segmented path (Sect. 37.3.3).
- *Vision-based landing*: Land the AV on an artificial pattern. This mode does not require a GPS signal, instead it relies on a more accurate relative state estimation performed onboard (Sect. 37.3.4).
- *Reactive car following*: Maintain a specified distance to a moving car. The car position estimation is performed onboard the AV and is based on color tracking using camera images.

Additionally, a set of control modes for payloads has been developed:

- *Camera pan-tilt absolute/relative control*: Maintain the absolute/relative angles of the pan-tilt mechanism.
- *Camera pan-tilt visual servoing control*: Keep a tracked object in the center of the camera image. The position of the object is provided by image processing functionalities such as vision-based color object tracking.
- *Camera pan-tilt look at GPS coordinate control*: Keep a geographical location in the center of the camera image.
- *Camera (color, IR) parameter control*: Actively control camera parameters such as shutter, zoom, and iris. Among other things, this allows for adjusting to the current lighting conditions.
- *Laser range finder rotational mechanism control*: Actively control parameters of the rotational mechanism, such as rotational speed. Among other things, this allows for adjusting the trade-off between speed and accuracy when building a 3D map.
- *Laser range finder parameter control*: Actively control parameters of the laser range finder, such as its measurement distance resolution and angular resolution. Among other things, this allows for adjusting the trade-off between speed and accuracy when building a 3D map.

Perception functionalities accessible in the Control Kernel include:

- *Vision-based state estimation*: Provides a very accurate pose estimate in relation to a specifically designed pattern. This functionality is used for the autonomous vision-based landing mode.
- *Vision-based object tracking*: Provides an estimate of the relative position to a moving object based on the color and/or thermal image streams. This is used in the reactive car-following control mode.

- *Vision-based human body identification*: Identifies human body positions in a stream of color and thermal images (Sect. 37.9.1.1).
 - *Laser range finder 3D map building*: Provides a 3D elevation map of the environment based on laser range finder data. The map can be used for various applications such as navigation where it is used as input to a path planner (Sect. 37.9.2).
 - *Localization based on reference images*: Provides an absolute position estimate in GPS-denied environments based on geo-referenced imagery (Conte 2009).
- Two complex flight control modes will now be considered in more detail.

37.3.3 Path-Following Control Mode

One of the control modes executed and coordinated by the Control Kernel is the path-following control mode (PFCM (Conte et al. 2004; Conte 2009), bottom part of Fig. 37.17 on p. 33) which executes paths consisting of a set of segments. Figure 37.7 presents an example path consisting of three segments.

Given a specific robotic platform, a classical problem in control theory is to find a trajectory compatible with its kinematic and dynamic constraints. A trajectory is the evolution of the state of a robot. The robot state is a vector composed of a set of time-dependent variables describing its kinematic and dynamic status. In this specific case, the most relevant components of the state vector are the three-dimensional position, velocity and acceleration, the attitude angles (pitch, roll, yaw), and the attitude rates. In general, the problem of finding a trajectory compatible with the platform dynamic constraints is a very difficult problem. In the context of a robotic helicopter flying in a cluttered environment, the problem becomes even harder since the platform dynamics is unstable. In addition, the flight path must not collide with the obstacles in the environment. The methodology used here to deal with this complexity is to decompose the problem as follows:

- *Decoupling the path-planning problem from the platform dynamics*, by first searching for a collisionfree path and then adapting this path to the dynamics of the AV platform. This yields a dramatic dimensionality reduction in the search space. In the HDRC3 architecture, the task of finding a collision-free path is solved by a path planner.
- *Dividing the control problem into fast and slow dynamics*. This is usually achieved using an *inner* feedback loop which has the task of stabilizing the attitude dynamics. The inner loop is usually implemented at a relatively high frequency (around 200 Hz). An *outer* feedback loop is then used to stabilize the platform position and velocity at a lower frequency (around 20 Hz). Dividing the problem in this way facilitates analyzing and solving the platform control task. In other words, the inner loop takes care of stabilizing and controlling the rotational dynamics, while the outer loop takes care of stabilizing and controlling the translational dynamics. They are implemented at different frequencies because the platform rotational and translational dynamics have different time constants. The rotational dynamics is usually faster than the translational dynamics.

Fig. 37.6 Control point on the reference path

This section deals with the problem of finding a *guidance* algorithm which enables the helicopter to follow a geometric path generated by a path planner. The distinction between path and trajectory must be emphasized here. As previously mentioned, a trajectory is the evolution of the state of the vehicle in the state space. The trajectory is usually time dependent. The path is a geometric description of the flight course and it is time independent. The problem addressed here is referred to in the literature as the *path-following* problem. The approach is suitable when a geometrical description of the path is provided in a parameterized polynomial form. In this case the so-called virtual leader approach (Egerstedt et al. 2001) can be applied.

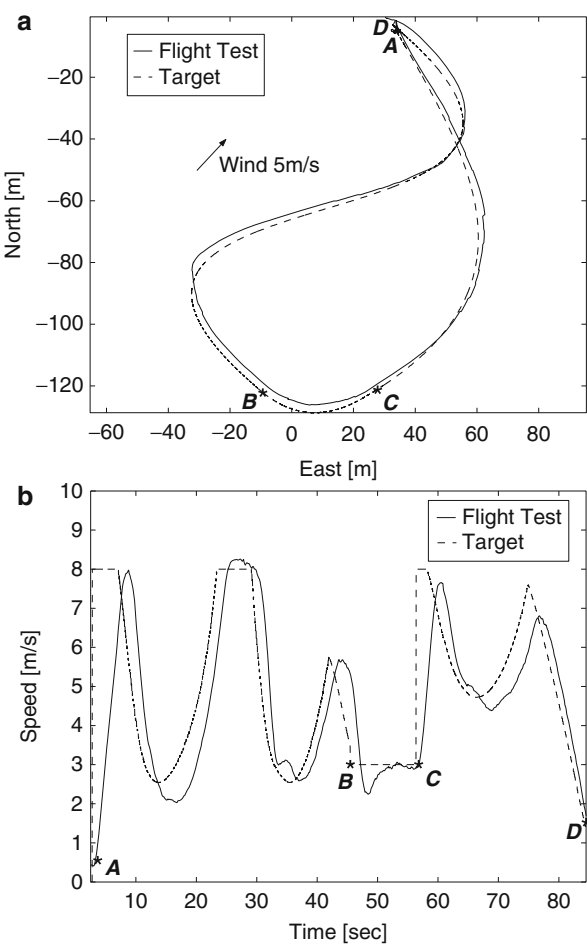

By using the path-following method, the helicopter is forced to fly close to the geometric path with a specified forward speed. In other words, following the path is always prioritized over following other trajectory parameters as, for instance, the desired speed. This is a requirement for robots that, for example, have to follow roads and avoid collisions with buildings. The PFCM method developed is weakly model dependent and computationally efficient.

The approach adopted here uses a guidance algorithm similar to the one described in Egerstedt et al. (2001) which is also known as virtual leader. In this case the motion of the control point on the desired path is governed by a differential equation containing error feedback which gives great robustness to the guidance method. The control point (Fig. 37.6) is basically the closest point on the path relative to the current platform position.

A path is composed of several consecutive segments. Each segment is mathematically described by the equation $\vec{p}(s) = \mathbf{A}s^3 + \mathbf{B}s^2 + \mathbf{C}s + \mathbf{D}$, where \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} are 3D vectors calculated from the boundary conditions of the segment. s is the segment parameter and assumes values between 0 (start of the path) and 1 (end of the path). The control point is found using a feedback method. Details of the algorithm can be found in Conte (2009) and Conte et al. (2004). Once the control point is found, from the path equation it is possible to compute all the geometric parameters which are then used for control purposes. The parameters are the 3D position, 3D path tangent, and 3D path curvature.

Path segments are generated in the deliberative layer of the HDRC3 architecture by the path-planner functionality (Sect. 37.5). The segments in a path are passed sequentially to the PFCM for execution. Together with the path parameters, the path planner provides a desired target velocity to the PFCM. During execution,

Fig. 37.7 Flight test of a multi-segment path. (a) Target and executed path. (b) Velocity profile

the PFCM performs a compatibility check between the desired target velocity and the maximum allowable velocity at that precise point on the path. The maximum allowable velocity profile for a path is calculated using the path curvature R and the maximum helicopter roll angle ϕ_{\max} : $V = \sqrt{|\phi_{\max} g R|}$, where g is the gravity constant. In addition, the path curvature is used as a feed-forward term in the outer control loop in order to reduce the tracking error. Besides the basic control task, the PFCM returns a set of status flags which are used to coordinate the path segment switching mechanism.

A safety braking procedure is activated in case the next segment is not provided by the navigation subsystem (e.g., due to communication failure) before a specific point in time. This timepoint is calculated using the minimum distance necessary to safely stop the helicopter at the end of the current segment.

Figure 37.7 shows a multi-segment path and the relative velocity profile during a real flight test using the UASTL RMAX helicopter. The segments AB, BC, and CD have the desired target velocity set at 8, 3, and 8 m/s, respectively. One can observe how the PFCM adjusts the target speed, slowing down the helicopter in order to meet the compatibility requirements discussed above.

37.3.4 Vision-Based Landing Mode

Many autonomous landing systems for AVs are based on GPS and a dedicated close range sensor for accurate altitude measurement (radar altimeter, sonar, infrared, or theodolites). However, in urban environments, buildings and other obstacles disturb the GPS signal and can even cause loss of signal (multipath effects, EM noise due to active emitters). Once the GPS signal is lost, the dead reckoning capability of affordable onboard inertial navigation systems does not allow precision navigation for more than a few seconds.

In contrast, the vision-based landing mode discussed here is self-contained and not jammable (Merz et al. 2004). In the current implementation, it provides a position measurement one order of magnitude more accurate than standard GPS (cm accuracy or better). Additionally, it does not require a complex infrastructure, only a pattern placed on the designated landing area (Fig. 37.8). To improve robustness, readings from an inertial measurement unit are fused with the position sensed by the vision system.

The landing system includes three main components: (a) a vision system that allows robust pose estimation from a suitable distance at a sufficient rate with low latency, using a landing pad of minimal size; (b) an algorithm to fuse vision data with inertial measurements; and (c) a matching control strategy.

Vision System. The vision system consists of a monocular camera mounted on a pan/tilt unit (PTU) and a landing pad (a foldable rectangular plate) with a reference pattern on its surface (Fig. 37.8). The reference pattern is designed specifically for fast recognition, accurate pose estimation for close and distant range, minimum size, and minimal asymmetry. The choice of black circles on a white background allows for fast detection and provides accurate image features. From the projection of three circles lying on the corner points of an equilateral triangle, the pose of an object is uniquely determined assuming all intrinsic camera parameters are known. Circles are projected as ellipses, described by the center point, the semimajor axis, the semiminor axis, and the semimajor axis angle. The pose of the landing pad with respect to the camera coordinate system is estimated by minimizing the reprojection error of the extracted center points and semi-axes of the three ellipses. Five circle triplets of different size are used (radius, 2–32 cm; distance, 8–128 cm) with a common center point to achieve a wide range of possible camera positions. Each triplet is uniquely determined by a combination of differently sized inner circles.

Fig. 37.8 Landing pad with reference pattern seen from the onboard camera

The output of the image processing unit is the camera pose relative to the pattern. The pose parameters are converted to helicopter position and attitude using angles from the PTU and known frame offsets and rotations.

Sensor Fusion. The position and attitude estimates provided by the vision system cannot be fed directly into the controller due to their intrinsic lack of robustness: The field of view can be temporarily occluded (e.g., by the landing gear), and the illumination conditions can change dramatically just by moving a few meters (sun reflections, shades, etc.). On the other hand, vision readings are very accurate, when available.

Hence, a navigation filter based on a Kalman filter (KF) has been developed, fusing highly accurate 3D position estimates from the vision system with inertial data provided by the onboard accelerometers and angular rate gyros. Besides filtering out a large part of the noise and outliers, the filter provides an adequate dead reckoning capability, sufficient to complete the landing even when the vision system is “blind” due to occlusions between the camera and the pattern (landing gears) or due to sun reflections.

Control Strategy. The requirements set on the flight control system during landing are the following:

1. It should be possible to engage the landing mode from any point where the landing pad is visible, meaning approximately within a 20 m radius hemisphere centered on the pattern.
2. Once the landing mode is engaged, the helicopter state should be compatible with the proper functionality of the vision system until touchdown. Thus, during the approach phase the following should be considered: (a) The helicopter's position and attitude should not cause physical occlusion of the visual field; (b) the regions where the accuracy of the vision system is worst should be avoided, if possible; (c) the helicopter velocity and angular rates should not saturate the

pan/tilt unit's capability for compensation – too high angular rates of the visual beam may result in blurred images; and (d) the position of the dominant light source (sun) should be considered, to avoid full reflections.

3. The wind direction has to be taken into account: Tailwind landings should be avoided.
4. The control system should be dimensioned for wind levels up to 10 m/s.
5. The engine should be shut down autonomously once touchdown is detected. Detection should be timely: Early detections cause high touchdown loads and late detections can cause ground resonance.
6. The vertical velocity at touchdown should be of the same order of magnitude as for a manual landing.

Experimental Results. Numerous autonomous landings were conducted from different relative positions to the landing pad within the specified envelope, on grass and snow fields, with different wind and illumination conditions. The vertical velocity at touchdown ranged between 18 and 35 cm/s, corresponding to load factors of about 1.4 g on grass fields. The horizontal velocity was in the order of magnitude of 15 cm/s. The average touchdown point precision was about 42 cm (13 % of the rotor diameter).

This section has isolated and described the essential aspects of the Control Kernel and two complex control modes. In order to put these to use, though, they have to be integrated and interfaced with many different parts of the HDRC3 architecture. These details are described in Sects. 37.4 and 37.5.

37.4 The Reactive Layer

The functionality associated with the reactive layer is an essential part of the HDRC3 architecture since it provides transitional capability between functionality in the deliberative layer and functionality in the control layer. The tasks associated with this layer range from very low-level state machine-based processes which provide discrete control capability for the control layer to much higher-level procedural mechanisms which provide discrete control capability for complex functionalities in the deliberative layer. In fact, the abstractions and language interfaces used for these transitions are what make such architectures so unique and useful. Specification and design of these mechanisms involve more than just engineering skills.

There is an independent generic flavor to the mechanisms required for combining both discrete and continuous control capabilities and managing the processes evoked by task descriptions at many different levels of abstraction with required temporal latencies to guarantee quality of service and robustness.

This section will describe three generic interfacing capabilities associated with the HDRC3 architecture in addition to several task execution mechanisms for tasks defined at different levels of abstraction. Section 37.4.1 considers the specification of complex combinations of state machines using Hierarchical Concurrent State Machines as a specification language. Additionally, an algorithm for executing

HCSMs in real time using an online interpreter is described. Section 37.4.2 describes the two abstract languages FCL and PPCL and a Platform Server which relates these languages to combinations of low-level control modes. This mechanism provides a high-level abstraction for any functionality in the system to access the control layer and combinations of control modes in an efficient and declarative manner. Section 37.4.3 describes Task Specification Trees. TSTs provide both a declarative means of specifying complex tasks and an execution mechanism which allows for distributed execution of TSTs.

37.4.1 Hierarchical Concurrent State Machines

Missions generally involve multiple control modes used in sequence or in some cases in parallel. For example, in building surveillance one would use takeoff, hovering, path-following, camera control, landing, and possibly other control modes. Even if only a sequence of control modes is needed, execution is non-trivial as it requires a smooth handover between the control mode that is terminated and the one that is started, leading to what is often called the *mode switching problem*.

The conditions for being able to switch to a new control mode vary depending on the particular mode transition. For example, in the case of switching between hovering and path-following modes, one must verify that the current helicopter heading is aligned with the path to be flown. If the heading difference is too large, an additional yaw maneuver is necessary before the transition to the path-following mode. Otherwise, the execution of the path could result in a maneuver that potentially leads to a crash.

Solutions to the mode switching problem are often based on Finite State Machines (FSMs) (Harel 1987; Koo et al. 1998), a mathematical abstraction used to create a behavior model of a system. FSMs are composed of a finite number of states, state transitions that can be guarded by conditions, and actions. For example, a condition can depend on the evaluation of a sensor value. The input to a state machine is a sequence of symbols, events, or commands. Standard FSMs such as Moore (1956) and Mealy (1955) machines have been successfully used in the past for modeling systems for various purposes. However, several extensions are necessary to make them useful for modeling complex real-time systems.

One major problem related to FSMs is their flat single-level structure, which provides no easy way to partition a problem into subproblems that can be dealt with separately. Each state has to be modeled explicitly, leading in the worst case to a combinatorial explosion in the number of states. This results in large and unmanageable models even for moderately complex systems.

It would be much easier to define a system gradually with different levels of granularity or with the help of various levels of abstraction. An obvious additional advantage would be the reusability of existing modeled parts of the system in different contexts. A novel modeling and development framework for hybrid control systems called *Hierarchical Concurrent State Machines* (HCSMs, Merz 2004; Wzorek 2011) has been developed. HCSMs are based on a combination of Moore

and Mealy machines with several extensions which include support for hierarchy and concurrency. This allows all low-level components to be efficiently modeled and contributes to a solution to the mode switching problem in the HDRC3 architecture. It permits all *functional units* of the control system to be coordinated ranging from the lowest level (such as device drivers), through the use of control laws (such as hovering and dynamic path-following) and communication, to high-level deliberative components. The system has proven to be robust, reliable, and easy to extend and has been used in a number of autonomous missions during a period of several years.

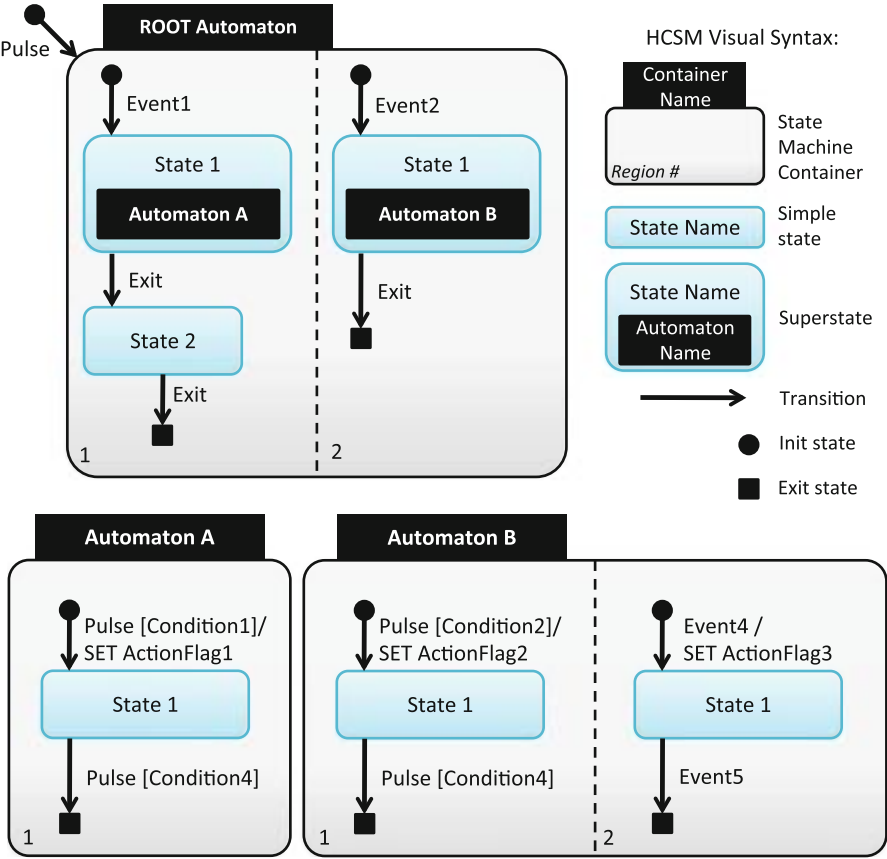

The HCSM specification language and computation model are to an extent influenced by the Statecharts formalism (Harel 1987) which has certain similarities to MATLAB Stateflow. However, the HCSM language and model have several differences intended to support a clean visual syntax, a clear semantics, and a highly efficient implementation providing strong real-time guarantees. HCSMs can also be interpreted as opposed to being compiled. This facilitates reconfiguring the system at runtime.

State Machines, Hierarchy, and Concurrency. A *state machine* consists of states and transitions. A state represents any activity of a system at any level of abstraction. Two main types of states are defined: *simple states* and *superstates*. A superstate represents a nested state machine, allowing a hierarchy of state machines to be created. Two special types of simple states are defined: *init* (the starting state) and *exit* (which terminates execution). Figure 37.9 presents a visual syntax for HCSMs and provides an example of a simple state and a superstate: *State 2* and *State 1* of the root automaton, respectively. In the remainder of this chapter, the terms *state machine* and *automaton* will be used interchangeably and will refer to HCSMs.

A *state machine container* is a collection of one or more concurrent (child) state machines. Each of these machines is contained in a *region*. Regions are ordered by a consecutive number (RegionNumber) and are separated by a dashed line in the visual syntax. For example, *Automaton B* contains two regions in Fig. 37.9.

Hierarchies provide a powerful mechanism for encapsulating specific behaviors. The framework permits reuse of state machine containers, providing all the necessary means to execute multiple instances of a state machine. Such encapsulation also provides a practical way of aborting a particular behavior. *Concurrency* prevents combinatorial explosion of states, which would occur in FSMs, and permits easy handling of asynchronous state machines. In the HCSM visual language, a *hierarchy* is modeled by vertical state machine decomposition and *concurrency* by horizontal decomposition (Fig. 37.9).

An example where one can take advantage of concurrency and hierarchy is when modeling complex behaviors such as vision-based landing (Sect. 37.3.4). The landing mode consists of several lower-level behaviors controlled by the main superstate of the landing mode. For instance, it includes control laws steering the helicopter, and it coordinates the camera system and image processing functionalities. When the landing behavior is activated, several state machines modeling the necessary activities are executed. These include searching for a predefined pattern with the

Syntax of a transition in EBNF notation:
Transition = EventID ["[" Guard "]"] ["/" ActionList]
ActionList = Action { "," Action }
Action = SET FlagID | UNSET FlagID | GET MemorySlotID | PUT MemorySlotID |
SEND EventID MemorySlotID DestinationID
Guard = ["-"] FlagID | Guard Op Guard | "(" Guard ")"
Op = "&" | "V"
(* all ID symbols are ANSI C id-tokens *)
(* all Name symbols are sequences of ASCII characters *)

Fig. 37.9 HCSM visual syntax with an example of three state machines

camera system and inputting the image processing results to a Kalman filter which fuses them with inertial measurements. Once the pattern is found, another state machine controls the camera in order to keep the pattern in the center of the image. This increases the robustness of image processing when the helicopter is close to the ground or in the presence of strong wind gusts.

State Transitions, Events, and Guards. A transition between two states is triggered by an *event*. Events in the HCSM framework can be generated internally by the state machine itself or externally. Both asynchronous (or sporadic) and periodic events are supported.

There are two types of special events. A *pulse* event is a periodic event generated before each iteration of the HCSM algorithm, similar to a clock pulse (discussed later). For example, this can be used to trigger a transition without a specific asynchronous event. An *exit* event is created when a state machine is in its exit state and it is only sent to the parent superstate informing it that a child automaton has finished its execution.

State transitions can optionally be guarded by *conditions* in the form of Boolean expressions. If an event for a particular state transition has been generated and the condition guarding the transition is TRUE, then the state transition takes place.

Activities vs. Actions. As in Harel (1987), a distinction is made between actions and activities. Actions have no duration (zero-time assumption) and are executed in transitions (as in a Mealy machine), while activities take time and are associated with states (as in a Moore machine).

During each transition, a possibly empty set of *actions* can be executed. Supported actions include setting binary flags (SET *flag-name*), sending events (SEND *event-name data target-computer*), retrieving (GET *source*), and storing (PUT *dest*) data. Data is transmitted using a predefined memory bank with labeled slots. Data from received events is automatically stored in the *cache* memory slot. A GET action copies data from a source slot to the cache slot. A PUT action copies data from the cache slot to a destination slot.

Activities are defined in terms of regularly executed functions. They are coordinated by a set of binary flags which are changed by actions. Functions are executed outside the state machine algorithm, and their execution is discussed in the next section.

HCSM Design and Execution. As illustrated in Fig. 37.10, the design of a system in the HCSM framework starts either by generating a visual description of state machines using a graphical tool or (in simpler cases) by directly describing state machines in a text-based language. In either case, tables describing transitions can be derived and passed to the system and are then interpreted by HCSM Interpreters at runtime on the robotic platform. Due to its compact and efficient implementation, the interpreter can run in the real-time part of the system as a periodic task with high execution rate.

The HCSM supports AND/OR/NOT operators in condition statements directly in the visual description and HCSM text files. However, the atomic conditions and the activities used are implemented procedurally. A library of such conditions and activities is generally written in an early development phase, after which the modeling of the system behavior itself can take full advantage of the flexibility of the interpreted state machine language with no need for recompilation.

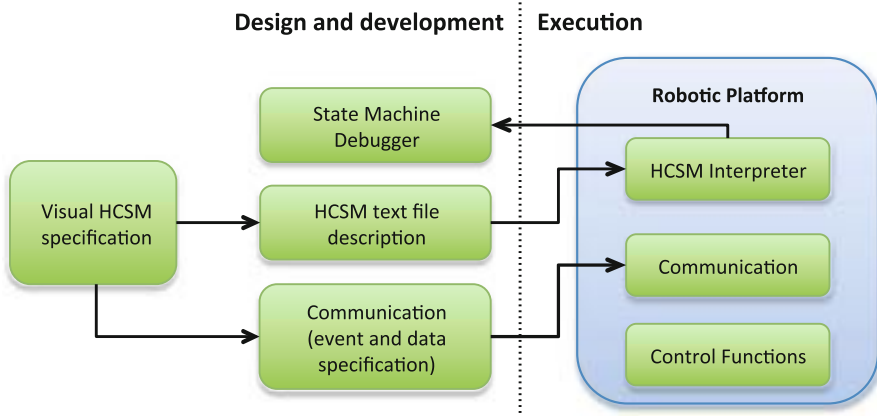

Fig. 37.10 Overview of the HCSM design process and execution

Three forms of communication are supported: (1) between states of the HCSM language processed by the same interpreter, (2) between computer systems of the same robot, and (3) between different robots or robots and operators. The first form is realized by an *internal event queue*, while the remaining two are realized by transmitting external events in packets with predefined sizes. Received external events are put in an *external event queue*. The framework directly supports real-time transmissions with built-in integrity checking given that the network satisfies real-time properties, and it automatically generates the required communication code during the design process (Fig. 37.10).

Abstractly, HCSM execution proceeds as shown in Algorithm 1 (see Sect. 37.4.1.1 for concrete examples). The automatically generated communication functions are called in the *Communicate* function. Events received by the system are parsed, checked for integrity and put in the external event queue. The HCSM is then executed (*ExecuteStateMachine*). Binary flags set by the state machine transitions (using actions) coordinate the execution of the control functions (*RunControlFunctions*) which are defined by the user.

Details are shown in Algorithm 2. Transitions in HCSMs are divided into *macro steps* and *micro steps*, where external events are considered in the macro step and internal events in the micro step. A macro step (*ExecuteStateMachine* lines 5–9) begins by processing the first event from an external event queue. Events are processed in the order they were received. An event can trigger one or more transitions. These transitions may generate both internal and external events which in turn trigger more transitions. The macro step is finished when the external event queue is empty and no more transitions are made. Micro steps are steps within a macro step (*ExecuteStateMachine* lines 7–8).

In case the external event queue is empty, only the micro steps are executed, which results in all of the internal events being processed (at the beginning one pulse event is in the internal event queue).

Algorithm 1 Skeleton of a procedure for execution of a HCSM-based system on a single computer

– *Main Execution Loop*

```

5:     else
6:       append Event to internal event queue
7:     end if
8:   else
9:     execute action
10:  end if
11: end for

```

The system assumes the “synchrony hypothesis”: During a macro step, inputs do not change and external events are not received. In practice, external events are not processed as soon as they arrive, but they are buffered until the state machine interpreter is called.

On the UASTL RMAX, the state machine interpreter is called periodically every 20 ms in the real-time environment. The duration of one *macro step* is set to 200 μ s which corresponds to the worst-case execution time. This time depends on the complexity of the state machine being executed, which is expressed in terms of the number of regions and the maximum number of *micro steps* (generated events). The periodic update time and the duration are user configurable and were empirically chosen for the UASTL RMAX system.

Related Work. Many specification languages, software frameworks, and design tools are used in control or embedded system design, including Ptolemy II (Eker et al. 2003), Esterel (Berry 1992), Statecharts (Harel 1987), Stateflow (<http://en.wikipedia.org/wiki/Stateflow>), Simulink (<http://en.wikipedia.org/wiki/Simulink>), and UML 2 (Booch et al. 2005), but none of these are optimized for building control systems for autonomous robots.

HCSMs are primarily influenced by Harel’s Statecharts formalism. State machine-based approaches have already been used successfully in many robotic systems. Brooks (1989), for instance, uses state machines to build reactive systems, and Kleinhagenbrock et al. (2004) include them in a deliberative/reactive system. Albus and Proctor (1996) propose an architecture for intelligent hybrid control systems which has some similarities with the HCSM framework. It also includes state machines, defines a hierarchy of functional modules, and includes a communication system, but it lacks some of the features mentioned above. The HCSM framework supports the component-based design methodology. In Brooks et al. (2005), a component-based framework is proposed which aims for similar goals, but it also does not provide some of the features mentioned above (such as real-time aspects). Cremer et al. (1995) propose a framework for modeling reactive system behavior in virtual environment applications. Although some similarities in the modeling formalism exist, it lacks some of the fundamental features required for use in robotics applications such as strong real-time execution guarantees and a clear definition of the visual syntax necessary in the design of complex control systems.

37.4.1.1 Using HCSMs on the UAS Tech Lab RMAX

HCSMs are used on the UASTL RMAX platform as a low-level real-time mechanism for modeling system behavior and are executed on all three of its onboard computers. This is illustrated in Fig. 37.11 which also shows the Platform Server that will be discussed in Sect. 37.4.2.1. HCSMs are used on the PFC computer for modeling and executing the control system. HCSMs control a set of sensors and available perception functionalities on the PPC computer. On the DRC computer, HCSMs provide an interface to flight control modes, payload, and perception functionalities in the Control Kernel (Sect. 37.3) accessible to the high-level deliberative and reactive algorithms. Because the HCSMs running on different

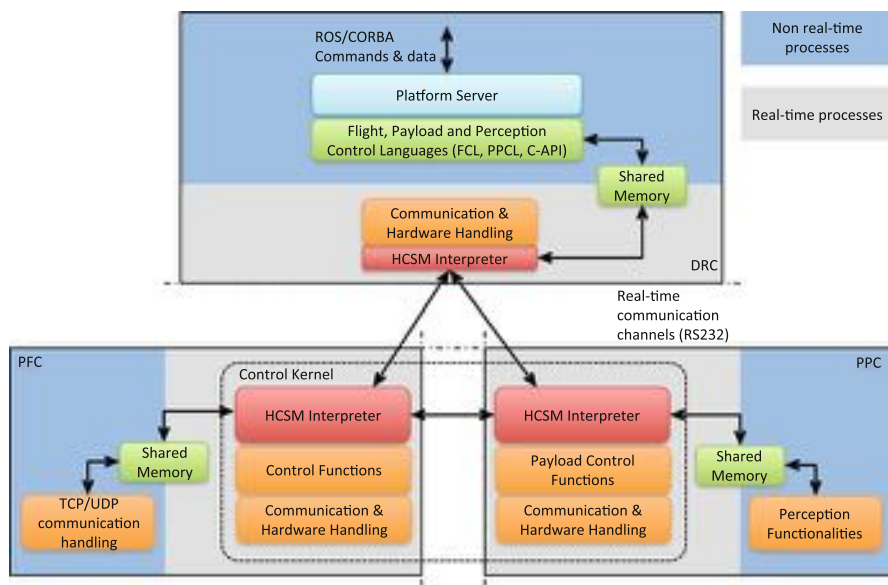

Fig. 37.11 HCSMs and the control kernel

computers communicate with each other, all of the individual events used in the system have globally unique IDs.

Several non-real-time processes also run on each of the computers and communicate with the real-time HCSMs through shared memory. Specifically:

- **PFC:** The TCP/UCP communication handling necessary for sending HCSMs status data used for state machine debugging interfaces (see Fig. 37.10)
- **DRC:** The *Platform Server*, which provides the deliberative and reactive services with an interface to the Control Kernel through the FCL and PPCL languages (Sects. 37.4.2.1–37.4.2.3)
- **PPC:** The perception functionalities available in the Control Kernel

The remainder of the section presents an example using HCSMs running on the PFC computer. An overview of all HCSMs running on the PFC system is given, followed by a description of two state machines involved in control mode switching. A more detailed example of the use of HCSMs in the context of the path-following control mode (PFCM) is presented in Sect. 37.5.2.

Overview of the PFC HCSMs. Figure 37.12 presents a hierarchical view of all of the 15 automata that run on the PFC computer. The whole UASTL RMAX system uses 207 events in total. Note that the HCSMs presented in this section are examples from the deployed system. Various extensions and different ways of modeling to achieve the same functionality of the system are of course possible.

The software-controlled power system (Sect. 37.2.3) is managed by the PFC computer. This allows all devices except the PFC itself to be switched on and off

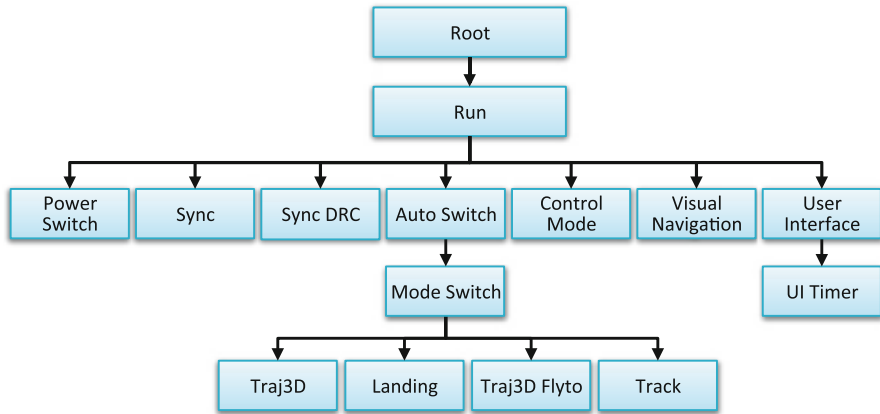

Fig. 37.12 A hierarchical view of the HCSM automata running on the PFC computer

through software coordinated by the *Power Switch* automaton. At system start-up, the *Root* automaton makes sure that at least the DRC computer is switched on (in case it has not been manually switched on by the user). The *Root* automaton also contains a superstate for the *Run* automaton, which in turn contains only one superstate for the following automata: *Power Switch*, *Sync*, *Sync DRC*, *Auto Switch*, *Control Mode*, *Visual Navigation*, and *User Interface*.

The *Sync* and *Sync DRC* automata are responsible for achieving a common state among the different computers through synchronization. For example, the common state includes the local computer time and the ground position and altitude reference. The *Sync DRC* automaton handles the synchronization between the PPC and DRC computers. The *Sync* automaton is responsible for sending the common state from the PFC to the PPC and DRC computers.

The *User Interface* automaton handles commands received from a ground control user interface (UI), while the *UI Timer* automaton implements timeouts for accepting commands by the *User Interface* state machine when using a miniaturized external keyboard.

The *Visual Navigation* automaton coordinates the execution of a localization algorithm that runs on the PPC and is based on reference images (Conte 2009). The *Auto Switch* automaton handles helicopter platform initialization and operational modes, including the following aspects:

- Initializing the UASTL RMAX helicopter system before it is ready to accept commands. This includes monitoring the engine-on status and the RC radio transmitter status.
- Monitoring sensor data and initializing a Kalman filter used for the state estimation of the helicopter.
- Handling the simulation mode of a hardware-in-the-loop simulator that uses a dynamic helicopter model (Duranti and Conte 2007; Conte 2007) and runs all of

the software components used during a real flight onboard the AV. This allows newly developed functionalities to be tested before a real flight is performed.

- Handling the RC radio transmitter switch that selects manual or autonomous flight mode.

The *Auto Switch* automaton starts up the execution of the *Mode Switch* state machine after a successful initialization of the system when the autonomous flight mode switch is selected. The *Mode Switch* and *Control Mode* automata in turn handle the switching between flight control modes. This includes initializing, running, and handling error conditions for particular control functions.

Certain control modes are also associated with their own mode-specific state machines: *Traj3D* for the path-following control mode (Conte et al. 2004), *Landing* for the vision-based landing control mode (Merz et al. 2004), *Traj3D Flyto* for a simplified path-following mode which only uses straight line paths, and *Track* for a reactive car tracking mode. Other control modes such as takeoff and hovering do not require multiple states and are therefore modeled directly by the *Mode Switch* and *Control Mode* automata without any additional state machines.

Periodic Execution. The *Main Execution Loop* in Algorithm 1 executes periodically at a rate of 50 Hz. In each iteration data packets can be sent and received, and HCSMs are executed (Algorithm 2) and can update a set of action flags using SET. The active control mode is then updated based on the current values of these flags, after which the flags are automatically unset. Thus, action flags should essentially be seen as triggers that switch control modes. Finally, the currently selected control mode is executed.

Examples. Figure 37.13 presents two state machines that handle the execution of control modes and implement a mode switching mechanism for the UASTL RMAX. For clarity the following notation is used:

- For fast identification, each automaton has a letter label and all state transitions are numbered.
- Names of states end with “-ST,” while names of events end with “-EV.”
- Names of conditions end with “-CO.”
- Names of SET action flags end with “-AC.”
- Names of labeled memory slots (data offsets) end with “-DO.”

Each control function follows a predefined template with at least three internal states (*initializing*, *running*, and *stopping*) and two internal flags: an input flag used to switch between the internal states and a status flag used for error handling (e.g., when the initialization of the function fails). Both flags are used by the *Control Mode* automaton which models the internal states of the function (Ctrl-Init-ST, Ctrl-Run-ST, and Ctrl-Stop-ST). The additional states present in the automaton (Ctrl-Off-ST and Ctrl-Error-ST) are used to make sure the previous function has been properly stopped and no other functions are initialized.

The *Control Mode* automaton (Fig. 37.13) sets the appropriate input flag and keeps track of the control function status. Because each control function follows the

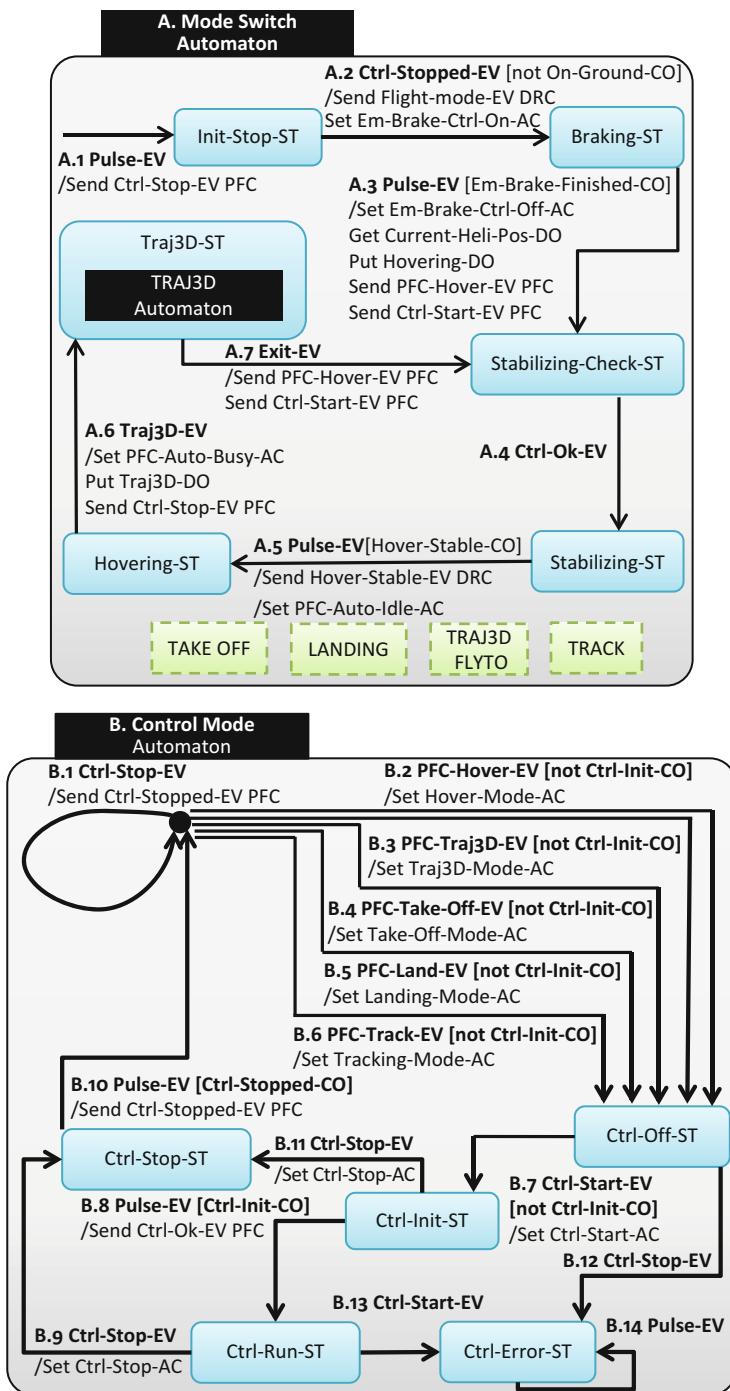

Fig. 37.13 The Mode Switch and Control Mode automata

predefined template, the *Control Mode* state machine handles all modes transparently, and there is no mode-specific state. When a particular control function should be executed, a state machine (such as *Mode Switch*) sends a mode-specific start event (such as PFC-Hover-EV) to the *Control Mode* automaton. This triggers one of the transitions B.2, B.3, B.4, B.5, or B.6 during which appropriate internal flags are set by executing SET actions (e.g., SET Hover-Mode-AC). In the next iteration of the *Main Execution Loop*, the control function starts its execution passing through the initialization state (Ctrl-Init-ST). If the initialization is successful, the *Control Mode* automaton switches its state to Ctrl-Run-ST, and the control function is executed periodically in each iteration.

Control Mode mainly interacts with the *Mode Switch* state machine which implements flight mode switching, including sequentialization and coordination of control function execution. For example, it ensures that after the execution of the path-following control mode, a default hovering mode is switched on.

The *Mode Switch* state machine, additionally, generates events that are sent to the high-level system (DRC), for example, in the A.2 transition. It also reacts to events sent from the DRC, such as A.6.

Use Case: Example of Control Mode Switching. The following example relates to a simple use case where a backup pilot performs a manual takeoff procedure. When the maneuver is finished, the AV control is switched to autonomous mode by using the auto switch button on the RC radio transmitter. A default hovering function should then be engaged as described below.

Figure 37.14 shows the interaction between the *Control Mode* and *Mode Switch* automata for this example. The time line shows state transitions and events exchanged between the two state machines. The execution starts with an exchange of two events, Ctrl-Stop-EV (A.1) and Ctrl-Stopped-EV (B.1), to make sure no other control function is active. The *Mode Switch* automaton executes a braking procedure (Braking-ST). This procedure, also called emergency braking, is designed to stop the helicopter before the default hovering mode is engaged. The procedure uses the path-following control mode with a predefined straight line path and a zero target velocity value as an input.

When braking has finished, the current helicopter position is saved to be used for the hovering function (in the Hovering-DO memory slot). Two events are also sent to the *Control Mode* automaton. The first event (PFC-Hover-EV, A.3) makes *Control Mode* select the hovering function for execution (SET Hover-Mode-AC). The second one (Ctrl-Start-EV, A.3) starts the initialization of the hovering control function.

After a successful initialization, Ctrl-Ok-EV (B.8) is generated and *Mode Switch* changes its state to Stabilizing-ST. The automaton remains in this state until a Hover-Stable-CO condition is satisfied. The condition checks if the position, altitude, heading, and velocity are within hovering tolerance bounds. The tolerances used in the UASTL RMAX system are set to 5 m for position, 2 m for altitude, 5° for heading, and 1 m/s for vertical and horizontal velocities.

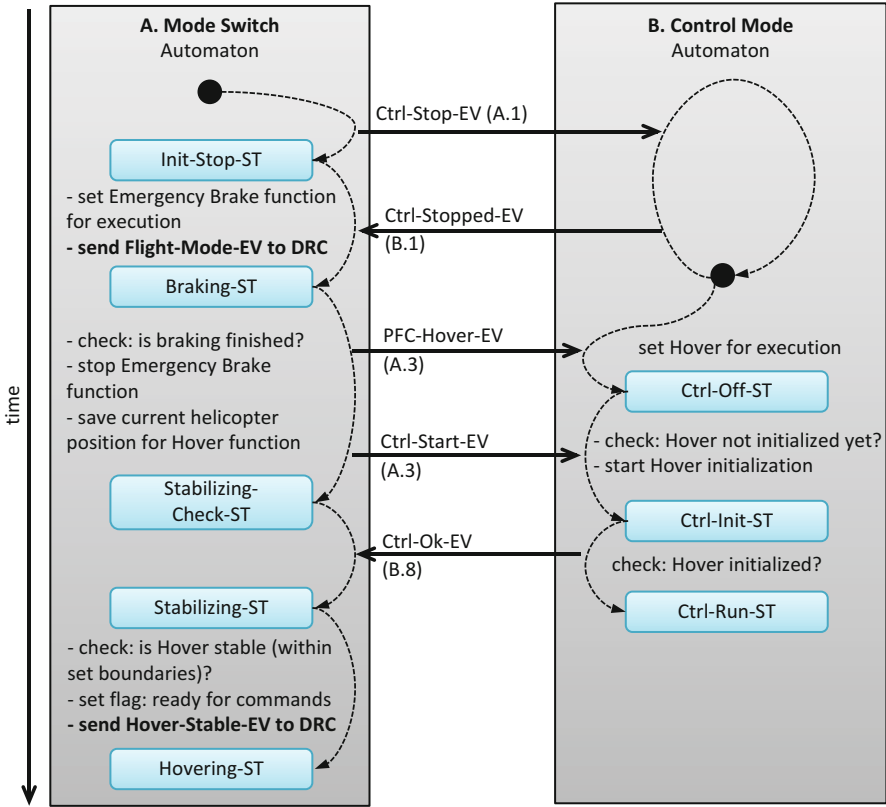

Fig. 37.14 Execution trace: The interaction between the Control Mode and Mode Switch automata

When the Hover-Stable-CO condition is satisfied, a Hover-Stable-EV event is sent to the DRC computer, and an internal system flag is set to indicate that the system is in the autonomous mode and ready to accept new commands (SET PFC-Auto-Idle-AC). The Mode Switch automaton changes its state to Hovering-ST.

Extended State Machines. The HCSM framework has been further developed, resulting in Extended State Machines (ESMs) (Merz et al. 2006). The new framework adds several useful modeling features. The main changes include explicit modeling of task states, data flow, control and system flags, an event filtering mechanism, and no explicit external events. It also includes a visual tool for designing and debugging state machines, facilitating the development of new and existing systems.

ESMs use three types of states: *simple states*, *superstates* (as in the HCSMs), and *task states*. Control and other functions are modeled explicitly in the task states. A schedule for function execution is provided by a scheduler included in

the framework. The data used as input/output to the task state functions (data flow) is also explicitly modeled in the ESM formalism by *Data paths*. Asynchronous external events are modeled by a combination of *pulse event* and guard conditions. Thus, only one internal event queue is used in the ESM. Additionally the ESM introduces an event filtering mechanism which limits the scope of internal events. The full details are available in Merz et al. (2006).

37.4.2 Interfacing Between the Control Kernel and Higher Layers

37.4.2.1 The Platform Server

The *Platform Server* (Fig. 37.11 on p. 22) encapsulates the functionality of the Control Kernel to provide a higher-level control and sensing interface for use by any of the functionalities in the reactive and deliberative layers. These functionalities interface to the Platform Server through two languages, the Flight Control Language (FCL) and Payload and Perception Control Language (PPCL), described in the following subsections. The former provides high-level parameterized commands which actuate the helicopter itself, while the latter provides commands which actuate sensor payloads and call perception-based functionality. Many of these commands provide feedback to their callers in the form of events which are communicated through a shared memory resource. Each command is essentially associated with one or more HCSMs.

From one perspective, the commands associated with FCL and PPCL provide the primitive or basic actions provided by the UASTL RMAX system. Specification of more complex tasks used by different functionality in the reactive and deliberative layers uses these basic actions as part of their definition. The intent is that most if not all use of the functionality in the control layer is accessed through the Platform Server interface.

This is a design decision that encapsulates the use of the control and sensor system in the UASTL RMAX through one common language interface. This makes the Control Kernel extensible in a straightforward manner. Any new control modes or addition of sensors is added to the system by implementing appropriate HCSMs to deal with real-time properties and temporal latencies near the hardware. The FCL and/or PPCL is then extended with an appropriate command interface.

Since the functionalities in the reactive and deliberative layers are only committed to soft real-time behavior while the HCSMs encapsulate real-time constraints, the Platform Server serves as an intermediary between these different temporal latencies. The distributed nature of the HCSM framework allows different functionalities to run on different computers. Each of the onboard computers therefore executes its own HCSM interpreter, and peer-to-peer RS232 serial lines are used to implement real-time communication channels between these. This allows the Platform Server to run on the DRC computer despite the fact that it must communicate with HCSMs associated with flight control modes and payload control which rely on timely execution and run in the real-time part of the system on the PFC and PPC computers.

Calling the Platform Server. The Platform Server runs on the DRC computer and provides a ROS-based interface to the commands available in the FCL and PPCL languages. When the server is asked to execute a specific command, it internally forwards the command through a lower-level programming interface based on the FCL and PPCL (“C-API” in Fig. 37.11). This API in turn uses shared memory to forward the command to an HCSM executing in the real-time part of the DRC.

The HCSM on the DRC generates one or more events that are sent through the real-time communication channel to an HCSM on either the PFC or the PPC, depending on the command. The events generated on those computers, as well as any associated sensor data generated in the CK, are passed back to the Platform Server in the same manner.

FCL and PPCL commands are executed sequentially without an internal command queue for buffering commands. If a command has been accepted for execution, a success flag (FCL_OK or PPCL_OK) is returned. In case the system was already executing another command, a busy flag (FCL_BUSY) is returned. In case a new command has to be started immediately, the caller can first abort any currently running activity by sending a Cancel command.

Data Interface. An additional task of the Platform Server is to provide a Data Interface (DI) to the state of the UASTL RMAX system. The data periodically published through this interface contains the AV’s state information (position, attitude, velocities), status information (such as the current engine RPM), payload information (such as the current position of the pan-tilt unit), and the results of perception-based functionalities (such as the color tracker). The Data Interface provides a common interface accessible by all deliberative and reactive functionalities. For example, the information obtained through the DI is used by the DyKnow system (Sect. 37.6) and by execution monitoring (Sect. 37.7.3).

37.4.2.2 FCL: Flight Control Language

The Flight Control Language (FCL) consists of a set of commands that are based on the control modes available in the Control Kernel and their parameterization. The reactive and deliberative services use the FCL commands for mission execution as it provides the interface to the available control functionalities in the CK.

The following are the most important commands currently available on the UASTL RMAX platform. The list is not exhaustive: Certain housekeeping commands, parameters, and return values are omitted here.

- *Takeoff*: `fcl.takeoff()` takes off to a predefined altitude (using the takeoff control mode). Returns:
 - FCL_BUSY: Another command is being executed.
 - FCL_NOT_ACCEPTED: Takeoff can only be commanded when the AV is on the ground.
 - FCL_FINISHED.
- *Land*: `fcl.land(heading)` performs a vision-based landing (using the landing control mode). The parameter specifies the desired heading for landing. This heading

should take into account the current position of the sun in order to avoid having the shadow of the AV fall on the landing pattern. Returns:

- FCL.BUSY: Another command is being executed.
- FCL.NOT_ACCEPTED: This command can only be issued if the AV is hovering.
- FCL.FINISHED.
- *Yaw*: `fcl.yaw(heading)` changes the heading to a specific value (using the hovering control mode with a specified heading).
Returns: The same values as for the `fcl.land()` command above.
- *Climb*: `fcl.climb(altitude)` climbs or descends to the given altitude (using the path-following control mode with a predefined vertical path).
Returns: The same values as for the `fcl.land()` command above.
- *Traj3d fly-to*: `fcl.traj3d.flyto(longitude, latitude, altitude, velocity)` flies to a position in a straight line (using the path-following control mode with a single straight line segment). The parameters specify the world position to fly to and the desired cruising velocity.
Returns: The same values as for the `fcl.land()` command above.
- *Traj3d*: `fcl.traj3d(spline_description, velocity, end.velocity)` flies between two way-points following a spline specification (using the path-following control mode). The parameters specify the beginning, ending, and direction vectors of the spline path and the cruise/final segment velocities (Sect. 37.3.3).
Returns: The same values as for the `fcl.land()` command above.
- *Track*: `fcl.track()` engages the object-following control mode (uses the path-following control mode, camera pan-tilt visual servoing control and vision-based color object tracking).
Returns: The same values as for the `fcl.land()` command above.
- *Emergency brake*: `fcl.emergency.brake()` engages the emergency brake mode (path-following and hovering control modes). This immediately aborts all flight control modes and engages the hovering control mode.
Returns: FCL_OK.
- *Cancel*: `fcl.cancel()` cancels the execution of the current FCL command.
Returns: FCL_OK.

For example, to scan an area in a given environment where the AV starts on the ground, the FCL commands used would include a *takeoff*, a sequence of *fly-to* commands, and a *land* command.

37.4.2.3 PPCL: Payload and Perception Control Language

Similarly to the FCL, the Payload and Perception Control Language (PPCL) consists of a set of commands that are based on the modes available in the CK and their parameterization. The commands in this group relate to the use of payload control modes and perception functionalities.

The following are the most important PPCL commands currently available on the UASTL RMAX platform. The list is not exhaustive: Certain housekeeping commands, parameters, and return values are omitted here.

- *Request PTU, camera, laser range finder, and perception functionality control*: Requests exclusive control and ownership for these functionalities. For example,

the control over the pan-tilt unit and camera parameters cannot be granted during a vision-based landing. The landing control mode handles these parameters.

- `ppcl.request_ptu_control()`: request control over the pan-tilt unit.
- `ppcl.request_cam_control()`: request control over the camera parameters.
- `ppcl.request_ip_control()`: request control over the image processing algorithms.
- `ppcl.request_laser_control()`: request control over the laser range finder.

Returns:

- `PPCL_CONTROL_DENIED`
- `PPCL_OK`

- *Release PTU, camera, laser range finder, and perception functionality control:*

Releases the control over these functionalities.

- `ppcl.release_ptu_control()`: release control over the pan-tilt unit.
- `ppcl.release_cam_control()`: release control over the camera parameters.
- `ppcl.release_ip_control()`: release control over the image processing algorithms.
- `ppcl.release_laser_control()`: release control over the laser range finder.

Returns:

- `PPCL_OK`

- *Pan-tilt unit control:* engages one of the pan-tilt control modes.

- `ppcl.look_at(longitude, latitude, altitude)`: world coordinates of a position at which the camera should be pointed.
- `ppcl.turn_to(pan_angle, tilt_angle)`: values of the pan-tilt unit axis to set.
- `ppcl.ptu_abort()`: abort the current control mode.

- *Perception control:* engages one of the perception functionalities.

- `ppcl.ip_color_tracker(x, y)`: coordinates of a center of a object to track.
- `ppcl.ip_state_estimation()`: engages the vision-based state estimation algorithm.
- `ppcl.ip_abort()`: abort the current command.

- *Camera parameters control:* sets the required camera parameters.

- `ppcl.zoom(value)`: the value of the camera zoom from 0 (full zoom out) to 1 (full zoom in).
- `ppcl.exposure(auto)`: specifies whether automatic or manual exposure should be used.
- `ppcl.iris(value)`: the value of the camera iris to set.
- `ppcl.shutter(value)`: the value of the camera shutter to set.

- *Laser parameters control:* sets the required laser range finder parameters.

- `ppcl.laser_angular_resolution(value)`: the angular resolution of the laser sensor (1, 0.5, 0.25°).
- `ppcl.laser_distance_resolution(value)`: the distance resolution of the laser sensor (1 mm, 1 cm).
- `ppcl.laser_rotation_speed(value)`: the speed and direction of the laser rotation mechanism.
- `ppcl.laser_rotation_angle(value)`: the angle of the laser rotation mechanism to set.

- *Laser control*: engages one of the laser perception functionalities.
 - `ppcl.laser_start_data_collection()`: starts collection of the laser range finder data.
 - `ppcl.laser_stop_data_collection()`: stops collection of the laser range finder data.
- *Pan-tilt activity info*: returns which pan-tilt control mode is currently active.
 - `ppcl.ptu_activity_info()`.
 Returns:
 - `PPCL_LOOK_AT_POINT`
 - `PPCL_TURNTO`
 - `PPCL_IDLE`
- *Camera parameters*: returns parameters of a specific camera.
 - `ppcl.get_camera_info(index)`: index of the camera (color or thermal)
 Returns: Intrinsic camera parameters.
- *Pan-tilt parameters*: returns parameters of the pan-tilt mechanism.
 - `ppcl.min_pan_value()`, `ppcl.max_pan_value()`, `ppcl.min_tilt_value()`, `ppcl.max_tilt_value()`:
 Returns: Ranges of pan-tilt unit angles which can be set.

In the case of scanning an area in a given environment, the required PPCL command sequence would include *request control: pan-tilt*, *request control: camera*, *pan-tilt control: tilt 90°*, *camera control: set specific zoom*, *release control: pan-tilt*, and *release control: camera*.

37.4.2.4 DI: Data Interface

Along with the FCL and PPCL languages, the Control Kernel also provides information about the state of the UASTL RMAX platform. This data is made available to the higher layers periodically at the rate of 25 Hz. It is currently distributed in the system in the form of ROS topics. The two most commonly used data collections provided by this interface are:

- *Helicopter state*:
 - altitude, latitude, longitude: current position.
 - velocity_north, velocity_east, velocity_up: current velocity in the given direction.
 - pitch, roll, heading: current pitch angle, roll angle, and heading.
 - rpm: engine revolutions per minute.
 - on_ground_flag: true if the AV is on the ground.
 - auto_flag: true if the AV is in autonomous flight mode.
 - drc_minus_pfc_time, ppc_minus_pfc_time: time differences between computers.
 - power_status: indicates which onboard devices are switched on.
 - pfc_time: data timestamp.
- *Camera state*:
 - id: id of the camera (color or thermal).
 - pan, tilt: current position of the PTU's pan and tilt axis, respectively.
 - zoom: current zoom factor of the camera.
 - ipc_time: timestamp.

37.4.3 Task Specification Trees

The concept of a *task* has many different interpretations in the literature and has been instantiated in many different ways in architectures proposed for mobile robots. One way to specify a particular type of task that has strict real-time requirements is using HCSMs. This type of task is often called a *behavior* in the robotics literature (Arkin 1998; Konolige et al. 1997), and different ways are proposed for combining such behaviors. At the other end of the spectrum, a task is often interpreted as an action or combination of actions (composite action) that are combined using standard control structures such as sequentialization, concurrency, and conditional branching. In fact, there have been several proposals to simply implement robot behaviors and tasks using a subset of a conventional programming language such as C (Konolige 1997). Firby's Reactive Action Package (Firby 1987) is one example where tasks are specified using a specialized language which combine actions with control. RAPs are often interpreted as *compiled plans*. Automated planners themselves combine actions specified as plan operators. The output of any planner can be interpreted as a composite action or task. The transition from plans to executable tasks is an essential part of any intelligent system.

The choice and construction of a task specification language which covers much of the spectrum of interpretations above has to be chosen with generality in mind in order to be used as a common interface to many diverse functionalities, but at the same time, the actual tasks have to be efficiently executable. The choice is further complicated by the fact that when specifying collaborative mission scenarios, tasks are often shared and must be distributable. An additional factor is that in the context of heterogeneous robotic systems, the specification of tasks should include context. For example, the **fly-to** action of a fixed-wing platform and the **fly-to** action of a rotor-based platform have much in common but also much that is different.

Task Specification Trees (TSTs) have been proposed as a general task specification language which meets many of the requirements stated above. Each node in such a tree is a specification of an elementary action such as a ROS call to an FCL command; a control structure such as sequential, concurrent, branching, or loop execution; or a goal for which a plan must be generated and executed (Sect. 37.7.2). In the latter case, the tree is *dynamically expandable* as a plan is generated. Goal nodes are therefore allowed to add children to themselves, after which they act as sequence or concurrency nodes. TSTs also allow for the statement of context in the form of constraints which can then be checked for consistency with a constraint solver. Additionally, these constraints are often temporal and spatial in nature and implicitly combine both a reasoning and procedural execution mechanism for tasks.

A TST is in itself purely declarative, defining what should be achieved and providing parameters and constraints for tasks. For example, a sequence node declaratively specifies that its children should be sequentially executed while a **fly-to** node would specify that an aircraft should fly to a specific location, usually with associated parameters such as the intended speed and altitude, possibly constrained by context.

At the same time there is a close integration with execution aspects of actions and action composition constructs through the coupling of *executors* to specific types of TST nodes. Each executor is an executable procedure specifying *how* a task of the given type should be performed. In many cases, the interface provided by the Platform Server is used to issue commands in the Flight Command Language and Payload and Perception Control Language (Sect. 37.4.2). The implementation of the executor can be platform specific, allowing the exact mode of execution for a particular task to be platform dependent as is often necessary when heterogeneous platforms are used. Thus, the use of executors provides a clear separation between task specifications and platform-specific execution details.

In the case of the UASTL RMAX system, nodes for actions such as takeoff, vision-based landing, hovering, or path-following are generally associated with executors calling the Platform Server to initiate the corresponding autonomous flight modes. Through this interface TST nodes can also control the payload and sensors of the UAS platform and receive associated information including image processing results. Note that executors are required even for *control nodes* or *structural nodes*, though such executors may be identical across platforms. For example, a sequential node requires an executor that procedurally ensures its children are executed in sequential order, possibly with additional timing constraints.

TSTs have been applied and tested successfully in a number of deployed UAS systems (Doherty et al. 2010, 2013; Landén et al. 2010).

Example 37.1. Consider a small scenario similar to the first goal in the example described in the introduction. The mission is that two AVs should concurrently scan the areas Area_A and Area_B , after which the first AV should fly to Dest_4 (Fig. 37.15a). The corresponding TST (Fig. 37.15b) uses three *elementary action nodes* (marked E), corresponding to two elementary actions of type **scan-area** and one of type **fly-to**. Furthermore, it requires a *concurrent node* (marked C) specifying that the **scan-area** actions can be performed concurrently, as well as a *sequential node* (marked S). Further explanations will be given below.

37.4.3.1 Task Specification Tree Structure

Task Specification Trees are implemented as a distributed data structure where nodes can reside on any platform, linked to their parents and children on the same or another platform. Each platform involved in a mission has a TST manager accessible through ROS-based service calls, allowing communication and synchronization between nodes when necessary.

As illustrated in Fig. 37.15b, each *type* of node is associated with a set of *node parameters*. Together, these parameters are called the *node interface*. The interface always contains a platform (agent) assignment parameter, usually denoted by P_i , which identifies the agent responsible for executing the task. There are also always two parameters for the start and end times of the task, usually denoted by T_{Si} and T_{Ei} , respectively. Tasks often have additional type-specific parameters, such as a speed parameter and an area parameter for a **scan-area** action node.

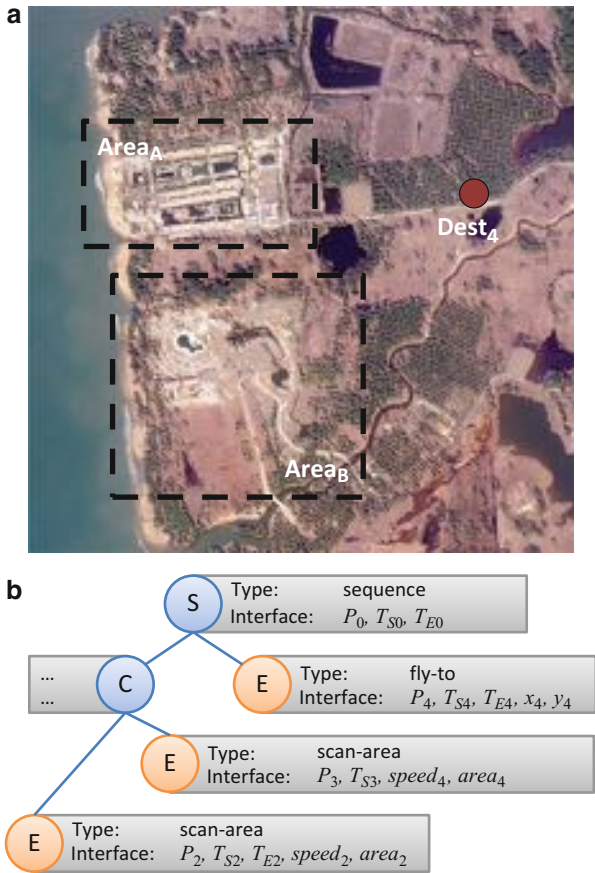

Fig. 37.15 Example mission. (a) Map of the mission area. (b) Example Task Specification Tree

When a concrete TST is specified, some node parameters may be given actual values through arguments. In the example, one may specify that the areas to scan are Area_A and Area_B (not shown in the figure). Other parameters may be left open. Concrete values may then be chosen by the executing agent, subject to a set of *constraints* associated with each node. These constraints can be used to constrain permitted values for the parameters of the same node as well as all parameters of ancestor nodes in the tree. By constraining temporal parameters, one can also express precedence relations and organizational relations between the nodes in the TST that are not implicitly captured by the use of specific control nodes. Together the constraints form a constraint network where the node parameters function as constraint variables.

Note that constraining node parameters implicitly constrains the degree of autonomy of an agent, as it reduces the space of possibilities that the agent can choose from. Also, both human and robotic agents may take the initiative and set

```

TST      ::= NAME '(' VARS ') ' '=' (with VARS)? TASK (where CONS)?
TSTS     ::= TST | TST ';' TSTS
TASK     ::= ACTION | GOAL | call NAME '(' ARGS ') ' | sequence TSTS | concurrent TSTS |
           if [VAR] COND then TST else TST | while [VAR] COND TST |
           foreach VARS where [VAR] COND do conc TST
VAR      ::= <variable name>
VARS     ::= VAR | VAR ',' VARS
ARG      ::= VAR | VALUE
ARGS     ::= ARG | ARG ',' ARGS
CONS     ::= <constraint> | <constraint> and CONS
VALUE    ::= <value>
NAME     ::= <node name>
COND     ::= <FIPA ACL query message requesting the value of a boolean expression>
GOAL     ::= <goal statement name( $\bar{x}$ )>
ACTION   ::= <elementary action call name( $\bar{x}$ )>

```

Fig. 37.16 Task Specification Tree language

the values of the parameters in a TST before or during execution. This provides support for one form of mixed-initiative interaction.

37.4.3.2 Task Specification Tree Language

For convenience, a text-based language for representing Task Specification Trees has also been defined (Fig. 37.16). The TST construct corresponds to a specific parameterized node and introduces the main recursive pattern. All such nodes must be explicitly named in order to allow name-based references. The parameters provided after the name specify the node interface which can be accessed from the outside. These can be constrained relative to each other using constraints in a **where** clause.

The formal semantics of a TST is specified through a translation from this language into composite actions in Temporal Action Logic (Doherty and Kvarnström 2008; Doherty et al. 2012). This provides a means of formally verifying the behavior of tasks and is also useful as a debugging tool.

Example 37.2. Consider again the TST depicted in Fig. 37.15b. This TST contains two composite actions, *sequence* (here named τ_0) and *concurrent* (τ_1), and two elementary actions, *scan* (τ_2 , τ_3) and *flyto* (τ_4).

Nodes in this TST have the task names τ_0 – τ_4 associated with them.

```

 $\tau_0(T_{S_0}, T_{E_0}) = \text{with } T_{S_1}, T_{E_1}, T_{S_4}, T_{E_4} \text{ sequence }$ 
 $\tau_1(T_{S_1}, T_{E_1}) = \text{with } T_{S_2}, T_{E_2}, T_{S_3}, T_{E_3} \text{ concurrent }$ 
 $\tau_2(T_{S_2}, T_{E_2}) = \text{scan-area}(T_{S_2}, T_{E_2}, \text{Speed}_2, \text{Area}_A);$ 
 $\tau_3(T_{S_3}, T_{E_3}) = \text{scan-area}(T_{S_3}, T_{E_3}, \text{Speed}_3, \text{Area}_B)$ 
where  $\text{cons}_{\tau_1};$ 
 $\tau_4(T_{S_4}, T_{E_4}) = \text{fly-to}(T_{S_4}, T_{E_4}, \text{Speed}_4, \text{Dest}_4)$ 
where  $\text{cons}_{\tau_0}$ 

```

$$\begin{aligned} cons_{\tau_0} &= T_{S_0} \leq T_{S_1} \wedge T_{S_1} < T_{E_1} \wedge T_{E_1} \leq T_{S_4} \wedge T_{S_4} < T_{E_4} \wedge T_{E_4} \leq T_{E_0} \\ cons_{\tau_1} &= T_{S_1} \leq T_{S_2} \wedge T_{S_2} < T_{E_2} \wedge T_{E_2} \leq T_{E_1} \wedge T_{S_1} \leq T_{S_3} \wedge T_{S_3} < T_{E_3} \wedge T_{E_3} \leq T_{E_1} \end{aligned}$$

The use of TSTs which call path planners is described in the next section. Additional features of TSTs and their relation to Temporal Action Logic and high-level mission specifications are described in Sect. 37.7.4.

37.5 The Navigation Subsystem

Many of the missions where AVs are deployed require sophisticated path-planning capability. One might need to fly directly to a particular waypoint, or in more complex scenarios, one might require the generation of a segmented path which is guaranteed to be collision-free. Many of the TSTs used in actual missions are required to call a motion planner which then outputs such segmented paths. The TST is then expanded with this output and executed. The navigation subsystem is responsible for this complex combination of processes which begin with a call to a motion planner at the deliberative layer. The output of the motion planner and its execution involve numerous calls to the Platform Server through use of FCL commands which in turn initiate execution of appropriate HCSMs. These in turn use the continuous control modes implemented in the Control Kernel.

This section provides a detailed description of the processes involved in the generation and execution of motion plans on the UASTL RMAX system. Additionally, it describes two path-planning algorithms integrated in the HDRC3 architecture based on extensions (Pettersson 2006; Pettersson and Doherty 2006) to two sample-based planning methods: Probabilistic RoadMaps (PRM, Kavraki et al. 1996) and Rapidly Exploring Random Trees (RRT, Kuffner and LaValle 2000).

Navigation Scheme. The standard navigation scheme in the HDRC3 architecture, assuming static operational environments, is depicted in Fig. 37.17. The task of flying is represented through an action node in a TST. For example, the task of flying to a specific waypoint can be represented declaratively as an elementary action node of type **fly-to**. The executor for nodes of this type calls a path planner (step 1 in the figure) that takes a map of static and dynamic obstacles together with the initial position, goal position, desired velocity, and possibly a set of additional constraints. The path planner then generates a segmented path (see Sect. 37.5.1) which is represented as a sequence of cubic polynomial curves. The generated path is collision free relative to the world model provided by a *geographical information system* (GIS Service). Each segment of the path is defined by start and end points, start and end directions, target velocity, and end velocity. If successful, this segmented path is returned to the TST node executor (step 2).

Once a segmented path is returned, the TST node executor requires a suitable interface to the low-level path-following control mode (PFCM). The PFCM implements continuous control laws which place certain real-time requirements on the way they are used, and the mode execution is therefore coordinated by HCSM state

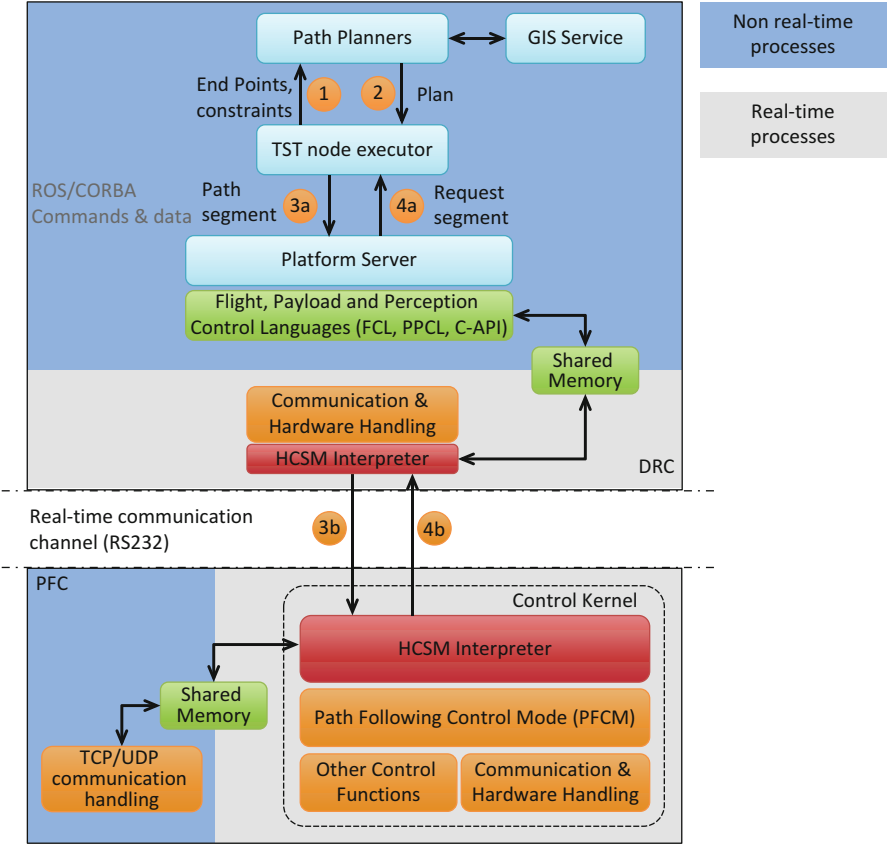

Fig. 37.17 Navigation subsystem and main software components

machines. The TST node executor therefore sends the first segment of the path via the Platform Server (step 3) and waits for a *Request Segment* event to be returned. This event is generated by the HCSM responsible for the path execution as soon as the PFCM controller receives a path segment as input. Details will be discussed in Sect. 37.5.2.

When a *Request Segment* event arrives (step 4), the TST node executor sends the description of the next segment to the HCSM that coordinates path execution at the control level. This procedure is repeated (steps 3–4) until the last segment is executed. However, because the high-level system is not implemented in hard real time, it may happen that the next segment does not arrive at the Control Kernel on time. In this case, the controller has a timeout limit after which it goes into safety braking mode in order to stop and hover at the end of the current segment. The timeout is determined by a velocity profile dynamically generated for the path segment together with the current position and current velocity.

Fig. 37.18 Execution time line for a path consisting of two segments

Figure 37.18 depicts a timeline plot of the execution of a 2-segment trajectory. At time t_0 , a TST node executor sends the first segment of the path to the PFCM controller and waits for a *Request Segment* event which arrives immediately (t_1) after the helicopter starts to fly (t_{start1}). Typical time values for receiving a *Request Segment* event ($t_1 - t_0$) are well below 200 ms. Time t_{o1} is the timeout for the first segment which means that the TST node executor has a $\Delta t_{1timeout}$ time window to send the next segment to the PFCM controller before it initiates a safety braking procedure. If the segment is sent after t_{o1} , the helicopter will start braking. In practice, the $\Delta t_{1timeout}$ time window is large enough to replan the path using the standard path planner (Sect. 37.5.1). The updated segments are then sent to the PFCM controller transparently.

The path execution mechanism described here allows for dynamic replacement of path segments if necessary. This is an important part of the architecture due to the fact that it is assumed that higher-level deliberative components are continually planning, executing, and monitoring missions which are likely to change due to contingencies. This architectural solution supports a certain type of any-time behavior in the system which takes into account resource constraints when reconfiguring plans (Wzorek 2011).

37.5.1 Path and Motion Planning

Path-planning and motion planning algorithms deal with the problem of generating collision-free paths for a robot in order to navigate or move in an physical space, called the *workspace* \mathcal{W} . The workspace is most often modeled as \mathcal{R}^3 but can be restricted to \mathcal{R}^2 for robots navigating in a single plane. This type of representation is particularly well suited for collision checking since the robot and the obstacles are represented in the same space. However, in many practical applications, the workspace is not sufficient to describe the planning problem, and a more expressive representation is required.

The *configuration space* (C or C -space) is defined as a vector space or manifold of configurations q , where a configuration is a set of parameters that uniquely defines the location of all points of the robot in the workspace \mathcal{W} . For a rigid-body robot such as an AV platform, this would include not only its position but also its orientation. Additionally, not all robot configurations are attainable due to obstacle constraints. The *free space* denoted by C_{free} is a subset of the C -space that is free from collisions with obstacles.

When dealing with robotic systems in motion, the configuration of the robot is insufficient to describe the problem: The dynamic state of a robot (its velocity) also has to be accounted for. The *state-space* representation extends the configuration space by adding first-order derivatives \dot{q} of the robot configuration q . Thus, for a robot configuration $q = (q_0, \dots, q_n)$, the state x is defined by $x = \langle q, \dot{q} \rangle$ where $\dot{q} = (\dot{q}_0, \dots, \dot{q}_n)^T$.

Constraints. In addition to the requirement of avoiding collisions, plans must also satisfy *kinematic* and *dynamic* constraints. Kinematic constraints include only first-order derivatives of the configuration parameters, while second-order derivatives such as acceleration are allowed in the dynamic constraints. The algorithms presented below handle the kinematic and dynamic constraints of the UASTL RMAX platforms.

Both of these types of constraints belong to a class of nonholonomic constraints (also called motion constraints) and are common for many types of robots. A robot is nonholonomic if it has fewer controllable degrees of freedom than total degrees of freedom. A car is nonholonomic since it can only drive forward or backward, not sideways. So is a helicopter: Though it can move freely in any direction, its freedom of movement depends on its speed. When a helicopter is hovering or flying slowly, it could be considered to be holonomic, but this would constrain its usage.

Path Planning. The path-planning problem is defined as finding a path in C_{free} that connects the start (q_0) and the goal (q_g) configuration. For high-dimensional configuration spaces, this problem is intractable in general which has led to the development of sample-based methods such as PRMs (Kavraki et al. 1996) and RRTs (Kuffner and LaValle 2000). These use an approximation of the C_{free} continuous space (in configuration space or state space) in order to deal with

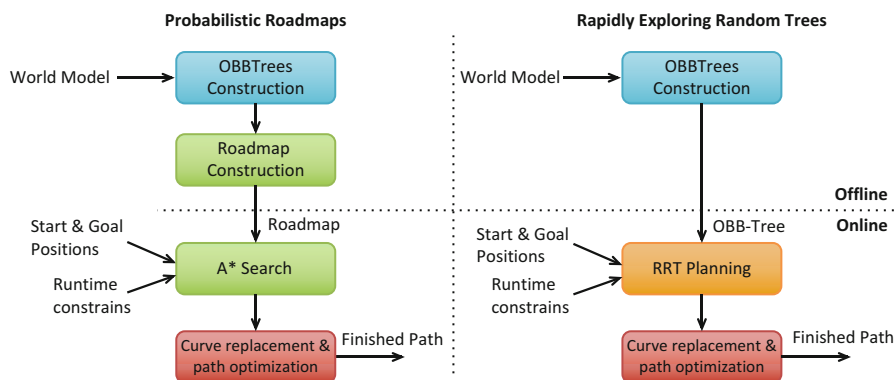

Fig. 37.19 PRM and RRT path-plan generation

the complexity of high-dimensional problems. The discrete representation of the original continuous space (typically represented in the form of a graph) sacrifices strict completeness for a weaker definition such as *resolution completeness* or *probabilistic completeness* (LaValle 2004).

37.5.1.1 Probabilistic Roadmaps and Rapidly Exploring Random Trees

The standard probabilistic roadmap (PRM) algorithm (Kavraki et al. 1996) works in two phases, one offline and the other online. In the offline phase, a discrete roadmap representing the free configuration space is generated using a 3D world model. First, it randomly generates a number of configurations and checks for collisions with the world model. A local path planner is then used to connect collision-free configurations taking into account kinematic and dynamic constraints of the helicopter. Paths between two configurations are also checked for collisions. This results in a roadmap approximating the configuration free space. In the online or querying phase, start and goal configurations are provided, and an attempt is made to connect each configuration to the previously generated roadmap using a local path planner. Finally, a graph search algorithm is used to find a path from the start configuration to the goal configuration in the augmented roadmap.

Figure 37.19 provides a schema of the PRM path planner that is used. The planner uses an Oriented Bounding Box Trees (OBBTrees) algorithm (Gottschalk et al. 1996) for collision checking and an A* algorithm for graph search. Here one can optimize for various criteria such as shortest path and minimal fuel usage.

The mean planning time in the current implementation for a selected set of flight test environments is below 1,000 ms, and the use of runtime constraints (discussed below) does not noticeably influence the mean. See Pettersson (2006) and Pettersson and Doherty (2006) for a detailed description of the modified PRM planner.

Rapidly exploring random trees (RRT, Kuffner and LaValle 2000) provide an efficient motion planning algorithm that constructs a roadmap online rather than offline (Fig. 37.19). The RRT algorithm generates two trees rooted in the start and goal configurations by exploring the configuration space randomly in both directions. While the trees are being generated, an attempt is made at specific intervals to connect them to create one roadmap. After the roadmap is created, the remaining steps in the algorithm are the same as with PRMs. The mean planning time with RRT is also below 1,000 ms, but the success rate is considerably lower, and the generated plans may sometimes cause anomalous detours (Pettersson 2006). The UASTL RMAX system uses both the PRM and RRT planners individually and in combination.

37.5.1.2 Path-Planner Extensions

The standard PRM and RRT algorithms are formulated for fully controllable systems only. This assumption is true for a helicopter flying at low speed with the capability to stop and hover at each waypoint. However, when the speed is increased, the helicopter is no longer able to negotiate turns of a smaller radius. This in turn imposes demands on the planner similar to nonholonomic constraints for car-like robots.

The most straightforward way of handling dynamic constraints in the PRM and RRT algorithms is to complement the configurations with their derivatives and record the complete state at each node in the graph. This enables the local path planner to adapt the path between two nodes to their associated derivatives, which is necessary to respect the dynamic constraints at boundary points between adjacent edges in the solution path. The drawback of this approach is that the dimensionality of the space in which the roadmap/tree is situated is doubled thus increasing the complexity of the problem. An alternative approach to nonholonomic planning is to postpone the nonholonomic constraints to the runtime phase. The following extensions have therefore been made with respect to the standard version of the PRM and RRT algorithms.

Multilevel Roadmap/Tree Planning. Inspired by a multilevel planner proposed by Sekhavat et al. (1996), new planners for AV applications have been developed (Pettersson 2006; Pettersson and Doherty 2006). In this approach, linear paths are first used to connect configurations in the graph/tree, and at a later stage, these are replaced with cubic curves when possible (Fig. 37.20). These are required for smooth high-speed flight. If it is not possible to replace a linear path segment with a cubic curve, then the helicopter has to slow down and switch to hovering mode at the connecting waypoint before continuing. This rarely happens in practice.

The random sampling nature of these planners and the limited density of the sampled nodes make the PRM and RRT algorithms produce paths that are often jagged and irregular with occasional detours. In order to improve the quality of the paths, a smoothing step is usually added. For the implemented path planners, the following smoothing steps are performed:

Fig. 37.20 Transformation from linear to cubic path segments for smooth flight

Fig. 37.21 Alignment of nodes for improved path quality. (a) Alignment halfway. (b) Full alignment

- **Node Alignment:** For each node n along the path, two attempts are made to move it to a point that straightens out the path (Fig. 37.21). The point m in the middle between the two neighbors is located. First, an attempt is made to move n halfway to m (Fig. 37.21a), if this is possible given known obstacles. Then an attempt is made to move it all the way to m (Fig. 37.21b).
- **Node Elimination:** For each node along the path, an attempt is made to eliminate it by connecting the two adjacent nodes directly. If the connection satisfies all constraints, the middle node is eliminated.

The curve replacement step described above is performed between the alignment and the elimination step.

Runtime Constraint Handling. Some constraints are not available during roadmap or tree construction but are added at runtime, when a final plan is requested. The motion planner currently handles the following types of runtime constraints during the A* search phase:

- **Maximum and minimum altitude** – verified through an intersection test between the configuration or curve and a horizontal plane.
- **Forbidden regions (no-fly zones)** – regions created by a set of horizontal polygons covering an area which the AV must not enter. The satisfaction test for configurations involves checking if the AV's position, projected in the X/Y plane, is within the polygon. The test for curves includes checking if the curve intersects any of the planes bounding the polygon in the 3D-space.
- **Limits on the ascent and descent rate.**

Adding constraints to a path-planning problem may break the connectivity of the PRM roadmap. In this case a combination of the PRM and RRT algorithms is used to mitigate the problem. An optional reconnection attempt using the RRT planner is made during the query phase of the PRM planner in order to reconnect the broken roadmap. Both planners (PRM and RRT) and their combination with the presented extensions are accessible to the deliberative and reactive services in the HDRC3 architecture.

37.5.2 HCSMs for Path Execution

The use case described in this section assumes the UASTL RMAX system is already in autonomous flight mode and the default hovering function is active (e.g., after executing the use case presented in Sect. 37.4.1). The description focuses on the execution of the path at the lowest control level running on the PFC computer after a TST node executor has received a path plan (a segmented cubic polynomial curve) from the path planner as described at the beginning of previous section. For better understanding of the interactions between the HCSM automata, the focus will be on the execution of one path segment.

As previously stated, the TST node executor sends the first segment (step 3 in Fig. 37.17, Traj3D-EV) of the trajectory via the *Platform Server* and waits for a Request-Segment-EV event that is generated by the controller. At the control level, the path is executed using the path-following control mode (PFCM, described in Sect. 37.3.2). When a Request-Segment-EV event arrives (step 4), the TST node executor sends the next segment. This procedure (steps 3–4) is repeated until the last segment is sent. However, because the high-level system is not implemented in hard real time, it may happen that the next segment does not arrive at the Control Kernel on time. In this case, the controller has a timeout limit after which it goes into safety braking mode in order to stop and hover at the end of the current segment.

As described in Sect. 37.4.1, the implementation of the PFCM function follows a predefined design template. The function itself is executed by setting an appropriate internal flag using a SET action (SET Traj3D-Mode-AC, B.3) by the *Control Mode* automaton. *Mode Switch* makes sure the default hovering function is properly terminated before the PFCM function can be activated. Additionally, when path execution is finished, it engages the default hovering function, in a manner similar to the example shown previously.

The role of the *Traj3D* automaton (Fig. 37.22) is to coordinate an exchange of events with other services (such as TST node executors) and to ensure that the appropriate segment data is available to the PFCM control function when needed. An example time line for a path execution showing the interaction between the three automata is presented in Fig. 37.23. The example focuses on the execution of a single segment.

The *Mode Switch* automaton starts in the Hovering-ST state. After receiving a Traj3D-EV event from the DRC computer, the data describing a segment for

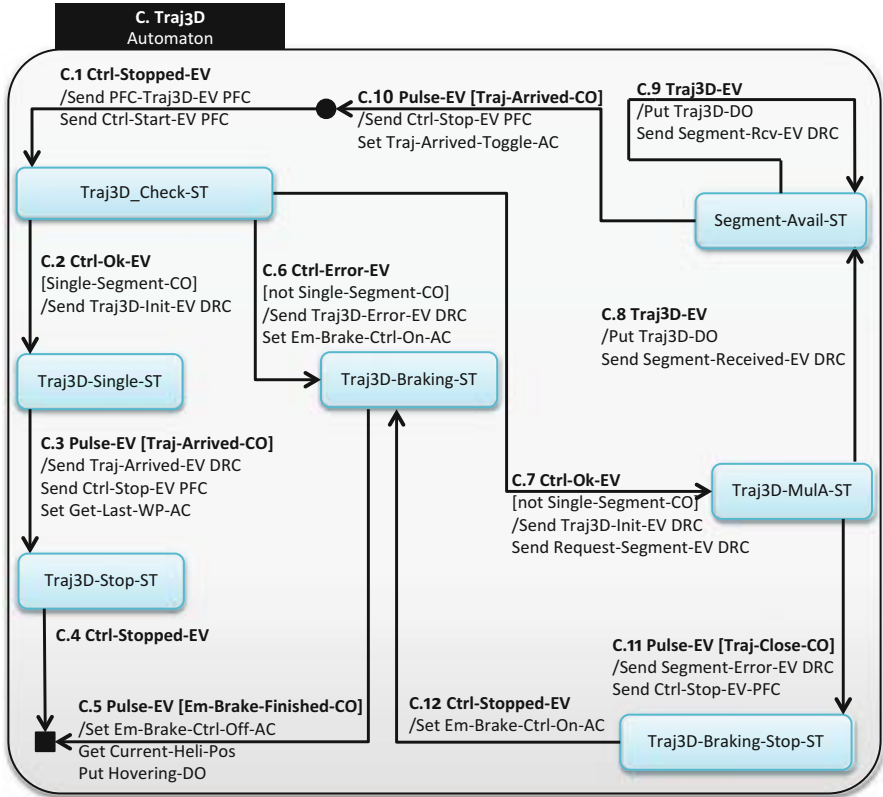

Fig. 37.22 The *Traj3D* automaton

execution is saved in the memory slot used by the PFCM function (Traj3D-DO). Additionally, the Ctrl-Stop-EV event (A.6) is sent to the *Control Mode* automaton in order to stop the execution of the default hovering function. At this time, *Mode Switch* transitions to the Traj3D-ST state (Fig. 37.22), thereby starting the *Traj3D* automaton in its *init* state. *Mode Switch* remains in Traj3D-ST until the PFCM execution is finished and then switches to the default hovering mode.

When *Traj3D* starts, it waits for confirmation from *Control Mode* that the hovering function has been terminated (Ctrl-Stopped-EV, B.10) and sends two events back to initialize and start the execution of the PFCM control function (PFC-Traj3D-EV (C.1) and Ctrl-Start-EV (C.1)). It transitions to the Traj3D-Check-ST state waiting for confirmation that the PFCM function has been initialized (Ctrl-Ok-EV, B.8). When the event arrives, the HCSM checks whether a single segment has been received (Single-Segment-CO, C.3). A single segment is defined by the path parameters with the end velocity for the segment set to zero. If the condition is satisfied, the event informing the DRC computer that the segment has been accepted for execution is sent.

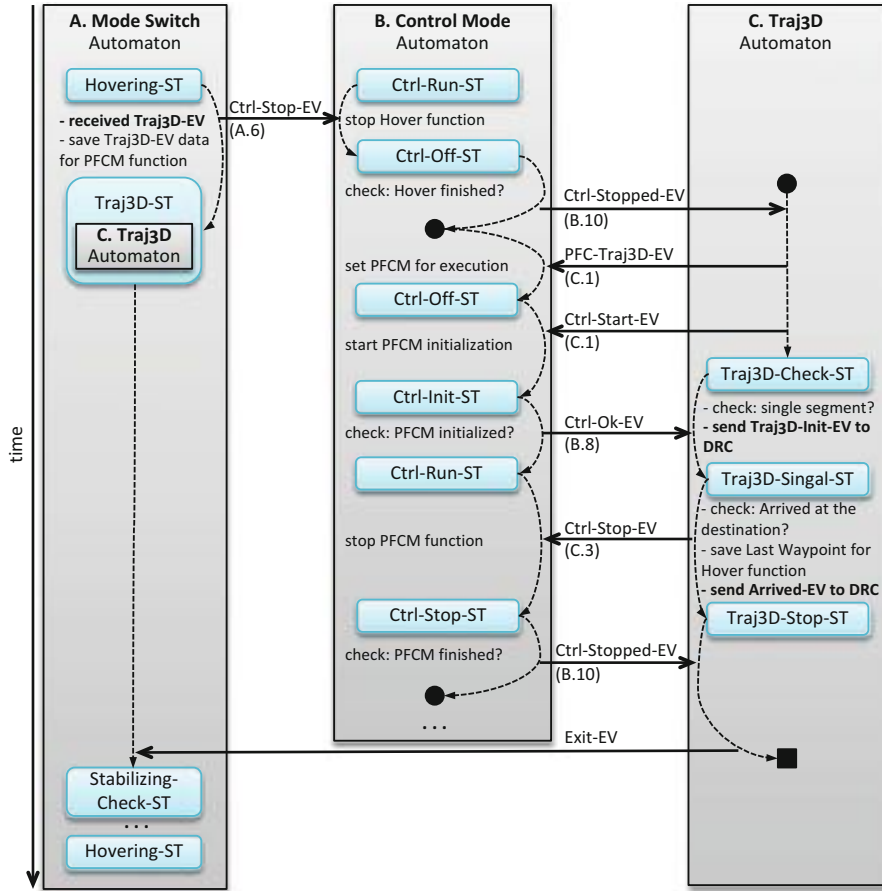

Fig. 37.23 Execution trace: The interaction between *Control Mode*, *Mode Switch*, and *Traj3D*

At this time the PFCM starts the execution of the segment. The *Traj3D* automaton is in the *Traj3D-Single-ST* state and remains there until the *Traj-Arrived-CO* condition is not satisfied. On the UASTL RMAX, the segment has been successfully executed when the distance to the final waypoint is less than 3 m. At that point, the last waypoint of the path is saved for the hovering function, and the *Traj-Arrived-EV* event is sent to the DRC computer informing it that the path execution is finished. Additionally, the *Traj3D* automaton stops the execution of the PFCM function by sending the *Ctrl-Stop-EV* event (C.3) to the *Control Mode* state machine. When the termination of the execution is confirmed by receiving the *Ctrl-Stopped-EV* event (B.10), the *Traj3D* automaton transitions to its exit state, and the *Mode Switch* state machine takes care of engaging the default hover mode, in a manner similar to the example described previously (Sect. 37.4.1.1).

37.6 DyKnow: Stream-Based Reasoning Middleware

For autonomous unmanned aerial systems to successfully perform complex missions, a great deal of embedded reasoning is required. For this reasoning to be grounded in the environment, it must be firmly based on information gathered through available sensors. However, there is a wide gap in abstraction levels between the noisy numerical data directly generated by most sensors and the crisp symbolic information that many reasoning functionalities assume to be available. This is commonly called the *sense-reasoning gap*.

Bridging this gap is a prerequisite for deliberative reasoning functionalities such as planning, execution monitoring, and diagnosis to be able to reason about the current development of dynamic and incompletely known environments using representations grounded through sensing. For example, when monitoring the execution of a plan, it is necessary to continually collect information from the environment to reason about whether the plan has the intended effects as specified in a symbolic high-level description.

Creating a suitable bridge is a challenging problem. It requires constructing representations of information incrementally extracted from the environment. This information must continuously be processed to generate information at increasing levels of abstraction while maintaining the necessary correlation between the generated information and the environment itself. The construction typically requires a combination of a wide variety of methods, including standard functionalities such as signal and image processing, state estimation, and information fusion.

These and other forms of reasoning about information and knowledge have traditionally taken place in tightly coupled architectures on single computers. The current trend towards more heterogeneous, loosely coupled, and distributed systems necessitates new methods for connecting sensors, databases, components responsible for fusing and refining information, and components that reason about the system and the environment. This trend makes it less practical to statically predefine exactly how the information processing should be configured. Instead it is necessary to configure the way in which information and knowledge is processed and reasoned about in a context-dependent manner relative to high-level goals while globally optimizing the use of resources and the quality of the results.

To address these issues, the stream-based reasoning middleware DyKnow (Heintz and Doherty 2004; Heintz 2009; Heintz et al. 2010) has been developed. This is a central part of the HDRC3 architecture as shown in Fig. 37.1.

37.6.1 DyKnow

The main purpose of DyKnow is to provide generic and well-structured software support for the processes involved in generating state, object, and event abstractions about the environments of complex systems. The generation is done

at many levels of abstraction beginning with low-level quantitative sensor data and resulting in qualitative data structures which are grounded in the world and can be interpreted as knowledge by the system. To produce these structures, DyKnow supports operations on streams at many different levels of abstraction. For the result to be useful, the processing must be done in a timely manner so that a UAS can react in time to changes in the environment. The resulting structures are used by various functionalities in the HDRC3 architecture for situation awareness and assessment (Heintz et al. 2007), planning to achieve mission goals (Sect. 37.7.2), and monitoring (Sect. 37.7.3). DyKnow provides a declarative language for specifying the structures needed by the different subsystems. Based on this specification, it creates representations of the external world and the internal state of an AV based on observations and a priori knowledge, such as facts stored in databases.

DyKnow helps organize the many levels of information and knowledge processing in a distributed robotic system as a coherent network of processes connected by streams. The streams contain time-stamped information and may be viewed as representations of time-series data which may start as continuous streams from sensors or sequences of queries to databases. Eventually, they will contribute to more refined, composite, knowledge structures. Knowledge producing processes combine streams by applying functions, synchronization, filtering, aggregation, and approximation as they move to higher levels of abstraction. In this sense, DyKnow supports conventional data fusion processes, but also less conventional qualitative processing techniques common in the area of artificial intelligence. In Heintz and Doherty (2006), it is argued that DyKnow supports all the functional abstraction levels in the JDL Data Fusion Model (White 1988).

A knowledge process has different quality of service properties such as maximum delay, trade-off between quality and delay, and how to calculate missing values, which together define the semantics of the knowledge derived by the process. It is important to realize that knowledge is not static, but is a continually evolving collection of structures which are updated as new information becomes available from sensors and other sources. Therefore, the emphasis is on the continuous and ongoing knowledge derivation process, which can be monitored and influenced at runtime. The same streams of data may be processed differently by different parts of the architecture by tailoring the knowledge processes relative to the needs and constraints associated with the tasks at hand. This allows DyKnow to support easy integration of existing sensors, databases, reasoning engines, and other knowledge producing services.

A knowledge processing application in DyKnow consists of a set of *knowledge processes* (Fig. 37.24) connected by *streams* satisfying *policies*. A policy is a declarative specification of the desired properties of a stream. Each knowledge process is an instantiation of a *source* or a *computational unit* providing *stream generators* that produce streams. A source makes external information, such as the data provided by the Data Interface in the Platform Server (Sect. 37.4.2.1), available in the form of streams while a computational unit refines and processes streams.

Fig. 37.24 A prototypical knowledge process

37.6.2 Streams and Policies

Knowledge processing for a physical agent is fundamentally incremental in nature. Each part and functionality in the system, from sensing to deliberation, needs to receive relevant information about the environment with minimal delay and send processed information to interested parties as quickly as possible. Rather than using polling, explicit requests, or similar techniques, the strategy is to model and implement the required flow of data, information, and knowledge in terms of *streams* while computations are modeled as active and sustained *knowledge processes* ranging in complexity from simple adaptation of raw sensor data to complex reactive and deliberative processes.

Streams lend themselves easily to a *publish/subscribe* architecture. Information generated by a knowledge process is published using one or more *stream generators* each of which has a (possibly structured) *label* serving as an identifier within a knowledge processing application. Knowledge processes interested in a particular stream of information can subscribe to it using the label of the associated stream generator which creates a new stream without the need for explicit knowledge of which process hosts the generator. Information produced by a process is immediately provided to the stream generator, which asynchronously delivers it to all subscribers, leaving the knowledge process free to continue its work. Using an asynchronous publish/subscribe pattern of communication decouples knowledge processes in time, space, and synchronization, providing a solid foundation for distributed knowledge processing applications.

Each stream is associated with a declarative *policy*, a set of requirements on its contents. Such requirements may include the fact that elements must arrive ordered by valid time, that each value must constitute a significant change relative to the previous value, that updates should be sent with a specific sample frequency, or that there is a maximum permitted delay. Policies can also give advice on how these requirements should be satisfied, for example, by indicating how to handle missing or excessively delayed values.

37.6.3 Objects, Features, and Fluent Streams

For modeling purposes, the environment of an AV is viewed as consisting of physical and nonphysical *objects*, *properties* associated with these objects, and

relations between these objects. The properties and relations associated with objects are called *features*. Due to the potentially dynamic nature of a feature, that is, its ability to change values through time, a total function from time to value called a *fluent* is associated with each feature. It is this fluent, representing the value over time of a feature, which is being modeled. Example objects are *the AV*, *car37*, and *the entity observed by the camera*. Some examples of features are the *velocity* of an object, the *road segment* of a vehicle, and the *distance between* two car objects.

A *fluent stream* is a partial representation of a fluent, where a stream of *samples* of the value of the feature at specific timepoints is seen as an approximation of the fluent. Due to inherent limitations in sensing and processing, an agent cannot always expect access to the actual value of a feature over time. A sample can either come from an observation of the feature or a computation which results in an estimation of the value at the particular timepoint, called the *valid time*. The timepoint when a sample is made available or added to a fluent stream is called the *available time*. A fluent stream has certain properties such as start and end time, sample period, and maximum delay. These properties are specified by a declarative policy which describes constraints on the fluent stream.

For example, the position of a car can be modeled as a feature. The true position of the car at each timepoint during its existence would be its fluent and a particular sequence of observations or estimations of its position would be a fluent stream. There can be many fluent streams all approximating the same fluent.

37.6.4 State Generation

One important functionality in DyKnow is state generation. Many functionalities require access to a consistent “state of the world,” but sensor readings take time to propagate through a distributed system which may consist of multiple AVs together with ground stations and associated hardware and software. DyKnow therefore provides services for data synchronization, generating a best approximation of the state at a given point in time using the information that has propagated through the distributed system so far.

For example, if a car has both a speed and a position, then there are two features: “speed of car” and “position of car.” But this could also be represented by a single fluent stream containing *tuples* (in this case pairs) of values, called *states*, containing both the speed and the position.

37.6.5 Semantic Integration of Symbolic Reasoning

One important use of DyKnow is to support the integration of symbolic reasoning in a UAS. To do symbolic reasoning, it is necessary to map symbols to streams available in a UAS, which provides them with the intended meaning for the particular UAS.

For example, a temporal logic formula consists of symbols representing variables, sorts, objects, features, and predicates besides the symbols which are part of the logic. Consider $\forall x \in AV : x \neq av1 \rightarrow \Box XYDist[x, av1] > 10$, which has the intended meaning that all AVs, except *av1*, should always be more than 10m away from *av1*. This formula contains the variable *x*, the sort AV, the object *av1*, the feature XYDist, the predicates \neq and $>$, and the constant value 10, besides the logical symbols. To evaluate such a formula (see Sect. 37.7.3 for details), an interpretation of its symbols must be given. Normally, their meanings are predefined. However, in the case of reasoning over streams, the meaning of features cannot be predefined since information about them becomes incrementally available. Instead their meaning has to be determined at runtime. To evaluate the truth value of a formula, it is therefore necessary to map feature symbols to streams, synchronize these streams, and extract a state sequence where each state assigns a value to each feature.

In a system consisting of streams, a natural approach is to syntactically map each feature to a single stream. This is called *syntactic integration*. This works well when there is a stream for each feature and the person writing the formula is aware of the meaning of each stream in the system. However, when systems become more complex and when the set of streams or their meaning changes over time, it is much harder for a designer to explicitly state and maintain this mapping. Therefore, automatic support for mapping features in a formula to streams in a system based on their semantics is needed. This is called *semantic integration*. The purpose of this matching is for each feature to find one or more streams whose content matches the intended meaning of the feature. This is a form of semantic matching between features and contents of streams. The process of matching features to streams in a system requires that the meaning of the content of the streams is represented and that this representation can be used for matching the intended meaning of features with the actual content of streams.

The same approach can be used for symbols referring to objects and sorts. It is important to note that the semantics of the logic requires the set of objects to be fixed. This means that the meaning of an object or a sort must be determined for a formula before it is evaluated and then may not change. It is still possible to have different instances of the same formula with different interpretations of the sorts and objects.

The goal is to automate the process of matching the intended meaning of features, objects, and sorts to content of streams in a system. Therefore, the representation of the semantics of streams needs to be machine readable. This allows the system to reason about which stream content corresponds to which symbol in a logical formula. The knowledge about the meaning of the content of streams needs to be specified by a user, even though it could be possible to automatically determine this in the future. By assigning meaning to stream content, the streams do not have to use predetermined names, hard-coded in the system. This also makes the system domain independent, which implies that it could be used to solve different problems in a variety of domains without reprogramming.

The approach to semantic integration in DyKnow uses semantic web technologies to define and reason about ontologies. Ontologies provide suitable support for creating machine readable domain models (Horrocks 2008). Ontologies also provide reasoning support and support for semantic mapping which is necessary for the integration of streams from multiple UASs.

The Web Ontology Language (OWL) (Smith et al. 2004) is used to represent ontologies. Features, objects, and sorts are represented in an ontology with two different class hierarchies: one for objects and one for features.

To represent the semantic content of streams in terms of features, objects, and sorts, a semantic specification language called SSL_T has been defined (Heintz and Dragisic 2012). This is used to annotate the semantic content of streams.

Finally, a semantic matching algorithm has been developed which finds all streams which contain information relevant to a concept from the ontology, such as a feature. This makes it possible to automatically find all the streams that are relevant for evaluating a temporal logical formula. These streams can then be collected, fused, and synchronized into a single stream of states over which the truth value of the formula is incrementally evaluated. By introducing semantic mapping between ontologies from different UASs and reasoning over multiple related ontologies, it is even possible to find relevant streams distributed among multiple UASs (Heintz and Dragisic 2012).

37.6.6 ROS-Based Implementation

The ROS-based implementation of DyKnow consists of three main parts: a stream processing part, a stream reasoning part, and a semantic integration part. Each part consists of a set of components. There are three types of components: engines, managers, and coordinators. An *engine* takes a specification and carries out the processing as specified. A *manager* keeps track of related items and provides an interface to these. A *coordinator* provides a high-level functionality by coordinating or orchestrating other functionalities. An overview of the parts and the components is shown in Fig. 37.25. This diagram corresponds to the DyKnow component in Fig. 37.2. The design is very modular as almost every component can be used independently.

The *stream processing* part is responsible for generating streams by, for example, importing, merging, and transforming streams. The *Stream Manager* keeps track of all the streams in the system. Streams can either be generated by a stream processing engine or by some external program. A *stream processing engine* takes a stream specification and generates one or more streams according to the specification.

The *semantic integration* part is responsible for finding streams based on their semantics relative to a common ontology. The *Stream Semantics Manager* keeps track of semantically annotated streams, where an annotation describes the semantic content of a stream. The *Ontology Manager* keeps track of the ontology which provides a common vocabulary. The *Semantic Matching Engine* finds all streams whose semantic annotation matches a particular ontological concept. The semantic

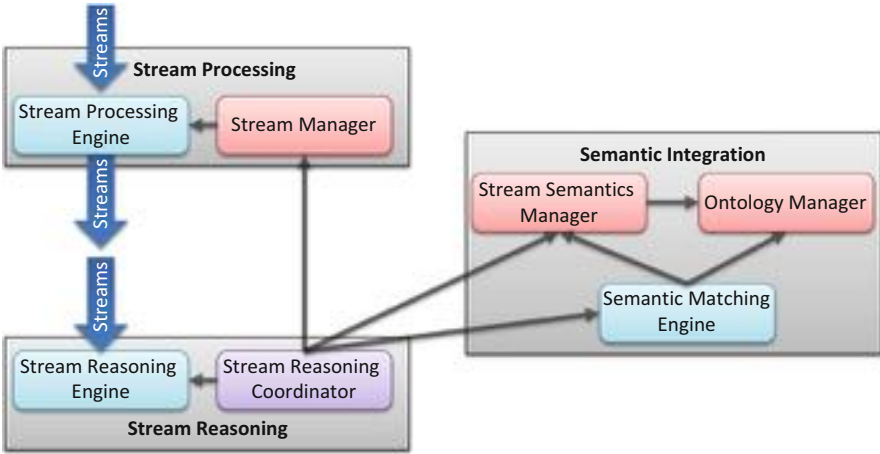

Fig. 37.25 The components of DyKnow

integration part is used by the stream reasoning part to find the relevant streams in order to evaluate a logical formula.

The *stream reasoning* part is responsible for evaluating temporal logical formulas over streams as described in Sect. 37.7.3. A *stream reasoning engine* takes a logical formula and a stream of states and evaluates the formula over this stream. A *Stream Reasoning Coordinator* takes a logical formula, finds all the relevant streams needed to evaluate the formula, creates a stream specification for generating a single stream of states from all the relevant streams, and instructs the stream reasoning engine to evaluate the formula over the stream as it is generated by a stream processing engine.

37.6.7 A Traffic Monitoring Example

As a concrete example of the use of DyKnow, Fig. 37.26 provides an overview of how part of the incremental processing required for a traffic surveillance task can be organized as a set of DyKnow knowledge processes.

At the lowest level, a *helicopter state estimation component* uses data from an *inertial measurement unit* (IMU) and a *global positioning system* (GPS) to determine the current position and attitude of the UASTL RMAX. A *camera state estimation component* uses this information, together with the current state of the *pan-tilt unit* on which the cameras are mounted, to generate information about the current camera state. The *image processing component* uses the camera state to determine where the camera is currently pointing. Video streams from the *color* and *thermal cameras* can then be analyzed in order to generate *vision percepts* representing hypotheses about moving and stationary physical entities, including their approximate positions and velocities. The data originating from the PFC and the PPC is provided by the Data Interface through the Platform Server (Sect. 37.4.2.1).

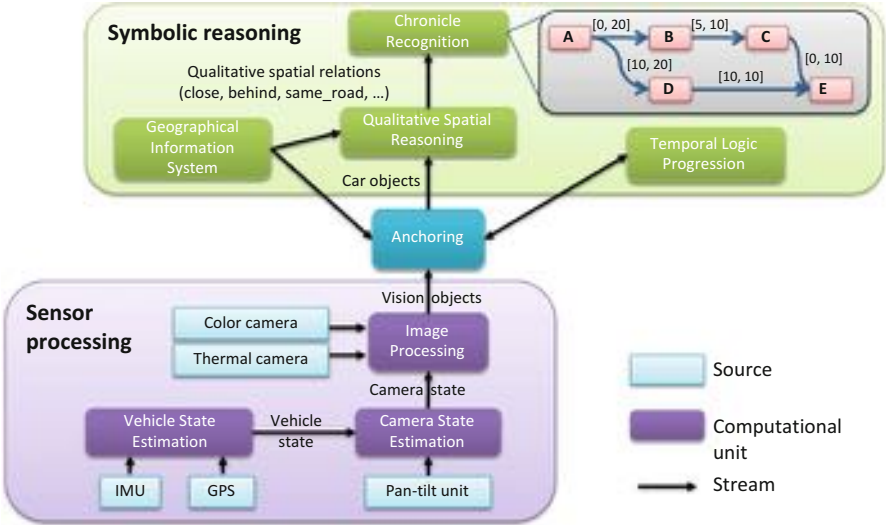

Fig. 37.26 Potential organization of the incremental processing required for a traffic surveillance task

Symbolic formalisms such as chronicle recognition (Ghallab 1996) require a consistent assignment of symbols, or identities, to the physical objects being reasoned about and the sensor data received about those objects. Image analysis may provide a partial solution, with vision percepts having symbolic identities that persist over short intervals of time. However, changing visual conditions or objects temporarily being out of view lead to problems that image analysis cannot (and should not) handle. This is the task of the *anchoring* system, which uses *progression* of formulas in a metric temporal logic to incrementally evaluate potential hypotheses about the observed objects (Heintz et al. 2013). The anchoring system also assists in object classification and in the extraction of higher-level attributes of an object. For example, a *geographical information system* can be used to determine whether an object is currently on a road or in a crossing. Such attributes can in turn be used to derive relations *between* objects, including *qualitative spatial relations* such as *beside*(*car*₁, *car*₂) and *close*(*car*₁, *car*₂). Concrete events corresponding to changes in such attributes and predicates finally provide sufficient information for the *chronicle recognition system* to determine when higher-level events such as reckless overtakes occur.

37.7 The Deliberative Layer

Conceptually, the deliberative layer includes all high-autonomy functionalities normally associated with rich world models and deep reasoning capabilities. Functionalities commonly associated with the deliberative layer are automated task

planners, motion planners, execution monitoring systems, diagnosis systems, and knowledge bases with inference engines, among others. The temporal latencies associated with the decision cycles for these functionalities are often far slower than for functionalities which exist in the reactive and control layers. The decision cycles for the different layers are necessarily asynchronous where each of the sets of functionalities run concurrently. The interfaces between the deliberative layer and the reactive and control layers are essential for transitioning output from deliberative functionality into useful processes at the lower layers of the architecture. In some sense, much of what happens is a form of dynamic compilation which results in transforming qualitative goal-directed assertions into actual actuation commands associated with the control layer of the architecture which contribute to the achievement of these goals.

A deliberative functionality, motion planning, and the dynamic compilation of its output have already been described in Sect. 37.5. This section will describe two additional deliberative functionalities central to high autonomy in the HDRC3 architecture. Section 37.7.2 describes an automated task-based planner, TALplanner, and its integration in the HDRC3 architecture. Section 37.7.3 describes a novel execution monitoring system based on specifying monitoring queries in terms of temporal logical formulas and evaluating these formulas online in real time. Due to the complex nature of these functionalities, an open research issue is how one might provide verification and validation techniques for the use and integration of these functionalities, in addition to the formal specification of high-level missions. The section therefore begins with a brief presentation of a Temporal Action Logic (TAL) which provides a formal basis for specifying the semantics of TSTs, TALplanner, and the execution monitor (Sect. 37.7.1). Additionally, in Sect. 37.7.4, it is shown that high-level missions can in fact be specified in terms of TSTs. Consequently, high-level missions are not only provided with a formal semantics, but due to the relation between these specifications and TSTs, there is a natural means of coupling declarative specification of missions with their procedural execution.

37.7.1 Temporal Action Logic

Temporal Action Logic, TAL, is a well-established non-monotonic logic for representing and reasoning about actions (Doherty et al. 1998; Doherty and Kvarnström 2008). This logic provides both clear intuitions and a formal semantics for a highly expressive class of action specifications which supports temporal aspects, concurrent execution, and incomplete knowledge about the environment and the effects of an action. Therefore it is a highly suitable basis for describing and reasoning the elementary actions used in realistic mission specifications. Here a limited subset of TAL is described, and the reader is referred to Doherty and Kvarnström (2008) for further details.

TAL provides an extensible macro language, $\mathcal{L}(\text{ND})$, that supports the knowledge engineer and allows reasoning problems to be specified at a higher abstraction level than plain logical formulas. The basic ontology includes parameterized features

$f(\bar{x})$ that have values v at specific timepoints t , denoted by $[t]f(\bar{x}) \hat{=} v$, or over intervals, $[t, t']f(\bar{x}) \hat{=} v$. Incomplete information can be specified using disjunctions of such facts. Parameterized actions can occur at specific intervals of time, denoted by $[t_1, t_2]A(\bar{x})$. To reassign a feature to a new value, an action uses the expression $R([t]f(\bar{x}) \hat{=} v)$. Again, disjunction can be used inside $R()$ to specify incomplete knowledge about the resulting value of a feature. The value of a feature at a timepoint is denoted by $value(t, f)$.

The logic is based on scenario specifications represented as *narratives* in $\mathcal{L}(\text{ND})$. Each narrative consists of a set of statements of specific types, including *action-type specifications* defining named actions with preconditions and effects. The basic structure, which can be elaborated considerably (Doherty and Kvarnström 2008), is as follows:

$$[t_1, t_2]A(\bar{v}) \rightsquigarrow (\Gamma_{pre}(t_1, \bar{v}) \implies \Gamma_{post}(t_1, t_2, \bar{v})) \wedge \Gamma_{cons}(t_1, t_2, \bar{v})$$

stating that if the action $A(\bar{v})$ is executed during the interval $[t_1, t_2]$, then given that its preconditions $\Gamma_{pre}(t_1, \bar{v})$ are satisfied, its effects, $\Gamma_{post}(t_1, t_2, \bar{v})$, will take place. Additionally, $\Gamma_{cons}(t_1, t_2, \bar{v})$ can be used to specify logical constraints associated with the action. For example, the following defines the elementary action **fly-to**: If a AV should fly to a new position (x', y') within the temporal interval $[t, t']$, it must initially have sufficient fuel. At the next timepoint $t + 1$, the AV will not be hovering, and in the interval between the start and the end of the action, the AV will arrive and its fuel level will decrease. Finally, there are two logical constraints bounding the possible duration of the flight action.

$$[t, t']\text{fly-to}(av, x', y') \rightsquigarrow$$

$$\begin{aligned} & [t] \text{fuel}(av) \geq \text{fuel-usage}(av, x(av), y(av), x', y') \rightarrow \\ & R([t + 1] \text{hovering}(av) \hat{=} \text{False}) \wedge \\ & R((t, t'] x(av) \hat{=} x') \wedge R((t, t'] y(av) \hat{=} y') \wedge \\ & R((t, t'] \text{fuel}(av) \hat{=} value(t, \text{fuel}(av) - \text{fuel-usage}(av, x(av), y(av), x', y'))) \wedge \\ & t' - t \geq value(t, \text{min-flight-time}(av, x(av), y(av), x', y')) \wedge \\ & t' - t \leq value(t, \text{max-flight-time}(av, x(av), y(av), x', y')) \end{aligned}$$

The translation function $Trans()$ translates $\mathcal{L}(\text{ND})$ expressions into $\mathcal{L}(\text{FL})$, a first-order logical language (Doherty and Kvarnström 2008). This provides a well-defined formal semantics for narratives in $\mathcal{L}(\text{ND})$. This separation between the macro language and the base logic makes TAL highly extensible. When adding new constructs to the formalism, new expression types are defined in $\mathcal{L}(\text{ND})$, and $Trans()$ is extended accordingly, generally with no extension required in the base language $\mathcal{L}(\text{FL})$.

The $\mathcal{L}(\text{FL})$ language is order-sorted, supporting both types and subtypes for features and values. This is also reflected in $\mathcal{L}(\text{ND})$, where one often assumes variable types are correlated to variable names – for example, av_3 implicitly ranges over AVs. There are a number of sorts for values \mathcal{V}_i , including the Boolean sort \mathcal{B} with the constants $\{\text{true}, \text{false}\}$. \mathcal{V} is a superset of all value sorts. There are a number of sorts for features \mathcal{F}_i , each one associated with a value sort

$dom(\mathcal{F}_i) = \mathcal{V}_j$ for some j . The sort \mathcal{F} is a superset of all fluent sorts. There is also an action sort \mathcal{A} and a temporal sort \mathcal{T} . Generally, t, t' will denote temporal variables, while $\tau, \tau', \tau_1, \dots$ are temporal terms. $\mathcal{L}(\text{FL})$ currently uses the following predicates, from which formulas can be defined inductively using standard rules, connectives, and quantifiers of first-order logic:

- *Holds*: $\mathcal{T} \times \mathcal{F} \times \mathcal{V}$, where *Holds*(t, f, v) expresses that a feature f has a value v at a timepoint t , corresponding to $[t] f \hat{=} v$ in $\mathcal{L}(\text{ND})$.
- *Occlude*: $\mathcal{T} \times \mathcal{F}$, where *Occlude*(t, f) expresses that a feature f is permitted to change values at time t . This is implicit in reassignment, $R([t] f \hat{=} v)$, in $\mathcal{L}(\text{ND})$.
- *Occurs*: $\mathcal{T} \times \mathcal{T} \times \mathcal{A}$, where *Occurs*(t_s, t_e, A) expresses that a certain action A occurs during the interval $[t_s, t_e]$. This corresponds to $[t_s, t_e]A$ in $\mathcal{L}(\text{ND})$.

When a narrative is translated, *Trans*() first generates the appropriate $\mathcal{L}(\text{FL})$ formulas corresponding to each $\mathcal{L}(\text{ND})$ statement. Foundational axioms such as unique names and domain closure axioms are appended when required. Logical entailment then allows the reasoner to determine when actions must occur, but the fact that they *cannot* occur at other times than explicitly stated is not logically entailed by the translation. This problem is handled in a general manner through filtered circumscription, which also ensures that fluents can change values only when explicitly affected by an action or dependency constraint (Doherty and Kvarnström 2008).

The structure of $\mathcal{L}(\text{ND})$ statements ensures that the second-order circumscription axioms are reducible to equivalent first-order formulas, a reduction that can often be performed through predicate completion. Therefore, classical first-order theorem proving techniques can be used for reasoning about TAL narratives (Doherty and Kvarnström 2008). For unmanned systems, however, the logic will primarily be used to ensure a correct semantics for planners, execution monitors, and mission specification languages and correlate this semantics closely to the implementation. Using TAL does not require theorem proving onboard.

37.7.2 Task Planning Using TALplanner

When developing the architecture for a system capable of autonomous action execution and goal achievement, one can envision a spectrum of possibilities ranging from each behavior and task being explicitly coded into the system, regardless of complexity, up to the other extreme where the system itself generates complex solutions composed from a set of very primitive low-level actions. With the former end of the spectrum generally leading to more computationally efficient solutions and the latter end generally being far more flexible in the event of new and potentially unexpected tasks being tackled, the proper choice is usually somewhere between the two extremes. In fact, several different points along the spectrum might be appropriate for use in different parts of a complex system. This is also the case in the HDRC3 architecture: Elementary action nodes in TSTs provide a set of high-level actions such as “takeoff” and “fly-to point A,” but one also makes use

Fig. 37.27 Task planning called by TST executors for goal nodes

of automated planning techniques to *compose* such actions into plans satisfying a set of declaratively specified goals. The goals themselves will vary depending on the nature of a mission. For example, they could involve having acquired images of certain buildings or having delivered crates of emergency supplies to certain locations after a natural disaster.

Support for planning is closely integrated in the HDRC3 architecture through the use of *goal nodes* in Task Specification Trees (Sect. 37.4.3). Any given TST can contain multiple goal nodes, each of which describes a simple or complex goal to be achieved at that particular point in the corresponding mission. When a goal node is assigned to a specific agent, the executor for that goal node can call DyKnow (Sect. 37.6) or use any other means at its disposal to acquire essential information about the current state of the world and the AV's own internal state (Fig. 37.27). The node is then *expanded* by that agent through a call to an onboard task planner, which in turn can call the motion planner and Motion Plan Info functionalities discussed earlier (Sect. 37.5.1). The resulting concurrent plan is converted to a new “plan subtree” attached under the goal node. Since TST structures are inherently distributable, the entire plan can then be distributed to the participating agents. This is the principal means of invoking a task planning functionality.

Note that the resulting TST directly represents a plan using sequence and concurrency nodes together with elementary action nodes corresponding to plan actions. Therefore, a plan can be executed at the appropriate time in the standard manner using TST executors. This obviates the need for a separate plan execution system and results in an integrated means of executing a mission, regardless of the techniques or combination of techniques that was used to generate it.

The planner that is used to expand a goal node can be changed freely, and in a heterogeneous system different platforms may use different planners. Currently the planners most commonly used in the HDRC3 architecture are TALplanner (Doherty and Kvarnström 2001; Kvarnström 2005) and TFPOP (Kvarnström 2011), two domain-independent concurrent temporal planners that were developed explicitly for use in this architecture. These planners are similar in certain respects: Both have a semantics based on Temporal Action Logic (Sect. 37.7.1), and both use *domain-specific control formulas* in this logic to guide the search for a solution, leading to very rapid plan generation. However, they use different search spaces and plan

structures, and they differ in the expressivity of the temporal constraints they permit. TALplanner will be described here, while the reader is referred to Kvarnström (2011) for further information about TFPOP.

TALplanner. TALplanner (Doherty and Kvarnström 1999; Kvarnström and Doherty 2000; Kvarnström 2005) is a forward-chaining temporal concurrent planner where planning domains and problem instances are specified as *goal narratives* in a version of TAL extended with new macros and statement types for plan operators, resource constraints, goal specifications, and other types of information specific to the task of plan generation. These macros serve to simplify planning domain specifications, but retain a basis in standard TAL through an extended translation function. For example, plan operators are converted into standard TAL action-type specifications, and actions in a plan are represented as standard timed action occurrences of the form $[t_1, t_2] A(\bar{v})$.

Control Formulas. In addition to providing a declarative first-order semantics for planning domains, TAL is also used to specify a set of domain-specific temporal *control formulas* acting as constraints on the set of valid solutions: A plan is a *solution* only if its final state satisfies the goal *and* all control formulas are satisfied in the complete state sequence that would result from executing the plan, which can be viewed as a logical model.

The use of control formulas serves two separate purposes. First, it allows the specification of complex temporally extended goals such as safety conditions that must be upheld throughout the (predicted) execution of a plan. Second, the additional constraints on the final solution often allow the planner to prune entire branches of the search tree – whenever it can be proven that every search node on the branch corresponds to a state sequence that violates at least one control rule. Formulas can then be written to guide the planner towards those parts of the search space that are more likely to contain plans of high quality, in terms of time usage or other quality measures.

As an example, consider three simple control rules that could be used in an airplane-based logistics domain. First, a package should only be loaded onto a plane if a plane is required to move it: if the goal requires it to be at a location in another city. Regardless of which operator is used to load a package, one can detect this through the fact that it is in a plane at time $t + 1$, but was *not* in the same plane at time t .

$$\begin{aligned} &\forall t, obj, plane, loc. \\ &[t] \neg in(obj, plane) \wedge at(obj, loc) \wedge [t+1] in(obj, plane) \rightarrow \\ &\exists loc' [goal(at(obj, loc')) \wedge [t] city_of(loc) \neq city_of(loc')] \end{aligned}$$

Second, if a package has been unloaded from a plane, there must be a valid reason for this: It must be the case that the package should be in the city where the plane has landed.

$$\begin{aligned}
& \forall t, obj, plane, loc. \\
& [t] \text{in}(obj, plane) \wedge \text{at}(plane, loc) \wedge [t+1] \neg \text{in}(obj, plane) \rightarrow \\
& \exists loc' [\text{goal}(\text{at}(obj, loc')) \wedge [t] \text{city_of}(loc) \doteq \text{city_of}(loc')]
\end{aligned}$$

Third, if a package is at its destination, it should not be moved.

$$\begin{aligned}
& \forall t, obj, loc. \\
& [t] \text{at}(obj, loc) \wedge \text{goal}(\text{at}(obj, loc)) \rightarrow [t+1] \text{at}(obj, loc)
\end{aligned}$$

Surprisingly, such simple hints to an automated planner can often improve planning performance by orders of magnitude given that the planner has the capability to make use of the hints.

Concurrent Plan Structure. Forward-chaining planning is most often used for sequential plans, where each new action is added immediately after the previous one in the plan. TALplanner uses a similar technique for concurrent plan generation, with a relaxed constraint on where a new action occurrence is placed.

Definition 37.1. (Concurrent Plan). A *concurrent plan* for a goal narrative \mathcal{G} is a tuple of ground fluent-free action occurrences with the following constraints. First, the empty tuple is a concurrent plan for \mathcal{G} . Second, given a concurrent plan $p = \langle [\tau_1, \tau'_1] o_1(\bar{c}_1), \dots, [\tau_n, \tau'_n] o_n(\bar{c}_n) \rangle$ for \mathcal{G} , its successors are the sequences that add one new action occurrence $[\tau_{n+1}, \tau'_{n+1}] o_{n+1}(\bar{c}_{n+1})$ and satisfy the following constraints:

1. Let $\mathcal{G}' = \mathcal{G} \cup \{[\tau_1, \tau'_1] o_1(\bar{c}_1), \dots, [\tau_n, \tau'_n] o_n(\bar{c}_n)\}$ be the original goal narrative \mathcal{G} combined with the existing plan. Then, the new action $o_{n+1}(\bar{c}_{n+1})$ must be applicable over the interval $[\tau_{n+1}, \tau'_{n+1}]$ in \mathcal{G}' . This implies that its preconditions are satisfied, that its effects are not internally inconsistent and do not contradict the effects of the operator instances already present in the sequence, and that the duration $\tau'_{n+1} - \tau_{n+1}$ is consistent with the duration given in the operator specification.
2. $\tau_1 = 0$: The first action starts at time 0.
3. $\tau_{n+1} \geq \tau_n$: The new action cannot be invoked before any of the actions already added to the plan.
4. $\tau_{n+1} \leq \max(\tau'_1, \dots, \tau'_n)$: There can be no gap between the time interval covered by the current plan and the start of the newly added action.

Generating Concurrent Plans. The concurrent TALplanner algorithm will now be briefly described (Algorithm 3). The reader is referred to Kvarnström (2005) for further details.

First, the planner conjoins all goal statements (line 2) and uses the control formulas in the goal narrative to generate a set of *pruning constraints*. These constraints allow control formulas to be verified efficiently when actions are incrementally added to a plan. Specifically, each control formula may result in an *initial constraint* to be tested initially, a set of operator-specific *incremental*

Algorithm 3 Concurrent TALplanner**Input:** A goal narrative \mathcal{G} .**Output:** A plan narrative entailing the goal $\mathcal{N}_{\text{goal}}$ and the control formulas $\mathcal{N}_{\text{control}}$.

```

1  procedure TALplanner-concurrent( $\mathcal{G}$ )
2   $\gamma \leftarrow \bigwedge \mathcal{G}_{\text{goal}}$  Conjunction of all goal statements
3   $\langle \text{init}, \text{incr}, \text{final} \rangle \leftarrow \text{generate-pruning-constraints}(\mathcal{G}_{\text{control}})$ 
4   $\text{node} \leftarrow \langle \text{init}, \emptyset, 0, 0, \{\} \rangle$  (cond. queue, visited states, latest invocation time,  $t_{\text{max}}$ , plan)
5   $\text{Open} \leftarrow \langle \text{node} \rangle$  Stack (depth first search)
6  while  $\text{Open} \neq \{\}$  do
7     $\langle C, S, \tau_0, \tau_{\text{max}}, p \rangle \leftarrow \text{pop}(\text{Open})$  Current plan candidate

21          $C' \leftarrow C' \cup \{\text{prevail condition of } \mathbf{A}\}$  Add prevail condition
22         push  $\langle C', S', \rho, \max(\tau_{\text{max}}, \rho'), \langle p; \mathbf{A} \rangle \rangle$  onto  $\text{Open}$ 
23  fail

```

constraints to be tested whenever an instance of a particular operator is added to a plan, and a *final* constraint to be tested in the final solution.

The initial search node is created (line 4), as is a stack of open search nodes (for depth first search).

As long as the search space has not been exhausted (line 6), the planner retrieves the topmost node in the stack of open nodes. This node consists of a queue of constraints that remain to be evaluated (C), a set of visited states to be used in cycle checking (S), the latest invocation time of any action in the current plan (τ_0), the latest end time of any action in the current plan (t_{max}), and the current plan candidate (p).

Assuming a completely specified initial state and deterministic actions, the narrative $\mathcal{G} \cup p$ would now contain complete information about the development of the world that would result from executing exactly the plan p and nothing else. This then corresponds to a unique infinite state sequence specifying the values of all TAL fluents at all points in time. However, the current search node must only be pruned if *all possible extensions* of p violate a control formula. Given the constraints placed on successors in Definition 37.1, no action added to p can be invoked earlier than τ_0 , and therefore, all effects of actions added to p must take place at $\tau_0 + 1$ or later. Line 8 therefore generates the narrative $\mathcal{G} \cup p \cup \text{occlude-all-after}(\mathcal{G}, \tau_0)$ which has additional formulas disclaiming knowledge about fluents after time t_0 .

In lines 9–11, the planner determines whether a queued constraint is now definitely true (in which case it can be removed from the queue) or definitely false (in which case the planner has to backtrack).

Then, the planner must verify certain conditions under the assumption that no additional actions are added. A narrative \mathcal{G}'' assuming complete information is therefore generated in line 12. If this is inconsistent (which in practice can be tested efficiently given the expressivity of TALplanner operators), the planner must backtrack (line 13). If a state that is better or equal has already been visited, the planner should also backtrack (line 14). The *better-or-equal* relation can, for example, take into account resource availability, where a state that is equal in all respects except that it provides more of a particular resource can be considered strictly better.

In lines 15–16, TALplanner determines whether the current plan candidate satisfies the goal and all remaining pruning constraints. If this is the case, a solution is found and can be returned. If not, the node is expanded through the generation of a set of successors. Each successor may be given additional incremental pruning constraints, instantiated with the actual invocation timepoints and actual arguments of the corresponding action (line 20). Similarly, any *prevail conditions* (similar to preconditions but relating to the entire execution interval of an action) are added to the condition queue, to be tested when more information about future states is available.

37.7.3 Execution Monitoring

Regardless of the effort spent modeling all possible contingencies, actions and plans may fail. Robust performance in a noisy environment therefore requires some form of supervision, where the execution of a plan is constantly monitored in order to detect and recover from potential or actual failures. For example, since an AV might accidentally drop its cargo, it should monitor the condition that whenever it carries a crate, the crate remains until the AV reaches its intended destination. This is an example of a *safety constraint*, a condition that must be maintained during the execution of an action or across the execution of multiple actions. The carrier can also be too heavy, which means that one must be able to detect takeoff failures where the AV fails to gain sufficient altitude. This can be called a *progress constraint*: Instead of maintaining a condition, a condition must be achieved within a certain period of time. While some of these constraints would best be monitored at the control level, there are also many cases where monitoring and recovery should be lifted into a higher-level *execution monitor* (De Giacomo et al. 1998; Fernández and Simmons 1998; Fichtner et al. 2003; Gat et al. 1990; Ben Lamine and Kabanza 2002).

The execution monitoring system described here is based on an intuition similar to the one underlying the temporal control formulas used in TALplanner. As a plan is being executed, information about the surrounding environment is sampled at a given frequency by DyKnow (Sect. 37.6). Each new sampling point generates a

new state which provides information about all state variables used by the current monitor formulas, thereby providing information about the *actual* state of the world as opposed to what could be *predicted* from the domain specification. The resulting sequence of states corresponds to a partial logical interpretation, where “past” and “present” states are completely specified whereas “future” states are completely undefined.

Note that simply comparing the actual and predicted states and signaling a violation as soon as a discrepancy is found is not sufficient, because not all discrepancies are fatal – for example, if the altitude was predicted to be 5.0m and the current measurement turns out to be 4.984m. Also, some information might be expensive or difficult to sense, in which case the ground operator should be given more control over which information is actually gathered and used for monitoring. Sensing may even require special actions that interfere with normal mission operations. Finally, the richer the planner’s domain model is, the more it can predict about the development of the world. This should not necessarily lead to all those conditions being monitored, if they are not relevant to the correct execution of a plan. Therefore, most conditions to be monitored are *explicitly* specified, though many conditions *can* be automatically generated within the same framework if so desired.

Execution Monitor Formulas in TAL . Execution monitor formulas are expressed in a variation of TAL where the high-level language $\mathcal{L}(\text{ND})$ is augmented with a set of *tense operators* similar to those used in modal tense logics such as LTL (Emerson 1990) and MTL (Koymans 1990). Tense operators allow the expression of complex metric temporal conditions and are amenable to incremental evaluation as each new state is generated. This allows violations to be detected as early and as efficiently as possible using a *formula progression* algorithm, while the basis in TAL provides a common formal semantic ground for planning and monitoring.

Three tense operators have been introduced into $\mathcal{L}(\text{ND})$: $\text{U}(\text{until})$, $\Diamond(\text{eventually})$, and $\Box(\text{always})$. Like all expressions in $\mathcal{L}(\text{ND})$, these operators are macros on top of the first-order base language $\mathcal{L}(\text{FL})$.

Definition 37.2. (Monitor Formula). A *monitor formula* is one of the following:

- $\tau \leq \tau'$, $\tau < \tau'$, or $\tau = \tau'$, where τ and τ' are temporal terms.
- $\omega \leq \omega'$, $\omega < \omega'$, or $\omega = \omega'$, where ω and ω' are value terms.
- f , where f is a Boolean fluent term (state variable term).
- $f \hat{=} \omega$, where f is a fluent term and ω is a value term of the corresponding sort.
- $\phi \text{ U}_{[\tau, \tau']} \psi$, where ϕ and ψ are monitor formulas and τ and τ' are temporal terms.
- $\Diamond_{[\tau, \tau']} \phi$, where ϕ is a monitor formula and τ and τ' are temporal terms.
- $\Box_{[\tau, \tau']} \phi$, where ϕ is a monitor formula and τ and τ' are temporal terms.
- A combination of monitor formulas using standard logical connectives and quantification over values.

The shorthand notation $\phi \text{ U } \psi \equiv \phi \text{ U}_{[0, \infty)} \psi$, $\Diamond \phi \equiv \Diamond_{[0, \infty)} \phi$, and $\Box \phi \equiv \Box_{[0, \infty)} \phi$ is also permitted.

Tense operators use relative time, where each formula is evaluated relative to a “current” timepoint. The semantics of these formulas satisfies the following conditions (see Doherty et al. (2009) for details):

- The formula $\phi \mathbf{U}_{[\tau, \tau']} \psi$ (“until”) holds at time t iff ψ holds at some state with time $t' \in [t + \tau, t + \tau']$ and ϕ holds until then (at all states in $[t, t']$, which may be an empty interval).
- The formula $\Diamond_{[\tau, \tau']} \phi$ (“eventually”) is equivalent to $\text{true} \mathbf{U}_{[\tau, \tau']} \phi$ and holds at t iff ϕ holds in some state with time $t' \in [t + \tau, t + \tau']$.
- The formula $\Box_{[\tau, \tau']} \phi$ is equivalent to $\neg \Diamond_{[\tau, \tau']} \neg \phi$ and holds at t iff ϕ holds in all states with time $t' \in [t + \tau, t + \tau']$.

Example 37.3. Suppose that an AV supports a maximum continuous power usage of M , but can exceed this by a factor of f for up to τ units of time, if this is followed by normal power usage for a period of length at least τ' . The following formula can be used to detect violations of this specification:

$$\Box \forall av. (\text{power}(av) > M \rightarrow \text{power}(av) < f \cdot M \mathbf{U}_{[0, \tau]} \Box_{[0, \tau']} \text{power}(av) \leq M) \quad \Box$$

Note that this does not in itself *cause* the AV to behave in the desired manner. That has to be achieved in the lower-level implementations of the helicopter control software. The monitor formula instead serves as a method for detecting the failure of the helicopter control software to function according to specifications.

Monitors and Actions. In many cases, conditions that should be monitored are closely related to the actions currently being executed. Two extensions are made to facilitate the specification of such formulas.

First, monitor formulas can be explicitly associated with specific operator types. Unlike global monitor formulas, such formulas are not activated before plan execution but before the execution of a particular *step* in the plan, which provides the ability to contextualize a monitor condition relative to a particular action. An operator-specific monitor formula can also directly refer to the arguments of the associated operator.

Example 37.4. Execution should be monitored when an AV attempts to pick up a box. Since the arguments of *pickup-box* include the *av* and the *box*, the following operator-specific monitor formula can be used:

$$\Diamond_{[0, 5000]} \Box_{[0, 1000]} \text{carrying}(av, box)$$

Within 5,000 ms, the AV should detect that it is carrying the box, and it should detect this for at least 1,000 ms. The latter condition protects against problems during the pickup phase, where the box may be detected during a very short period of time even though the ultimate result is failure. \Box

Second, a set of *execution flags* allow monitor formulas to query the internal execution state of an agent. This is useful when one wants to state that a certain fact

should *hold during* the execution of an action or that an effect should be *achieved during* the execution of an action or *before* the execution of another action. For example, if an AV *picks up a crate*, it should sense the weight of the crate until it deliberately *puts down the crate*.

An execution flag is an ordinary Boolean state variable which holds exactly when the corresponding action is being executed. By convention, this state variable will generally be named by prepending “executing-” to the name of the corresponding operator: The pickup-box operator is associated with the *executing-pickup-box* execution flag, which takes a subset of the operator’s parameters. TST executors for elementary action nodes can set this flag when execution starts and clear it when execution ends.

Example 37.5. Consider the *climb(av)* operator, which should cause the AV to ascend to its designated flight altitude. Here, one may wish to monitor the fact that the AV truly ends up at its flight altitude. This can be achieved using the formula $\text{executing-climb}(av) \cup \text{altitude}(av) \geq 7.0$. \square

When it is clear from context which operator is intended, the shorthand notation EXEC can be used to refer to its associated execution flag with default parameters: $\text{EXEC} \cup \text{altitude}(av) \geq 7.0$.

Example 37.6. Whenever an AV picks up a box, it should detect the box within 5,000ms and keep detecting it until it is explicitly put down. Using an operator-specific monitor formula for pickup-box:

$\text{EXEC} \cup_{[0,5000]} (\text{carrying}(av, box) \cup \text{executing-putdown}(av, box))$

Automatic Generation of Monitor Formulas. The use of a single logical formalism for modeling both planning and execution monitoring provides ample opportunities for the automatic generation of conditions to be monitored. For example, one can automatically generate formulas verifying that preconditions and prevail conditions (which must hold throughout the execution of an action) are satisfied, that expected effects take place, and that bounds on action durations are not violated. Similarly one can automatically extract *causal links*, where one action achieves one condition that is later needed by another, and generate a formula verifying that this condition is never violated in the interval between these actions. Since there are pragmatic reasons for *not* generating all possible monitor formulas, automatic generation only takes place for those conditions that are flagged for monitoring. This provides the benefits of automatic formula generation while keeping the control in the hands of the domain designer. See Doherty et al. (2009) for details.

37.7.3.1 Recovery from Failures

Any monitor formula violation signals a potential or actual failure from which the system must attempt to recover in order to achieve its designated goals.

Recovery is a complex topic, especially when combined with the stringent safety regulations associated with autonomous flight. Goals and constraints may be time dependent, making local repairs difficult: An AV might only be allowed to fly in certain areas at certain times. Also, recovering from a failure for one AV may require changing the plans of another AV: If **heli1** fails to deliver a box of medicine on time, **heli2** might have to be rerouted. Therefore, the main focus has been on recovery through replanning. Given that the planner is sufficiently fast when generating new plans, this does not adversely affect the execution of a fully autonomous mission.

Having detected a failure, the first action of an AV is to suspend the execution of the current plan, execute an emergency break if required, and then go into autonomous hover mode. Currently, one takes advantage of the fact that the UAS Tech Lab RMAX and LinkQuads are rotor based and can hover. For fixed-wing platforms, this is not an option, and one would have to go into a loiter mode if the recovery involves time-consuming computation.

This is followed by the execution of a *recovery operator*, if one is associated with the violated monitor formula. The recovery operator can serve two purposes: It can specify emergency recovery procedures that must be initiated immediately without waiting for replanning, and it can permit the execution system to adjust its assumptions about what can and cannot be done. For example, if an AV fails to take off with a certain carrier, the associated recovery operator can adjust the AV's assumptions about how many boxes it is able to lift. This feeds back information from the failure into the information given to the planner for replanning. The implementation of a recovery operator can also detect the fact that the AV has attempted and failed to recover from the same fault too many times and choose whether to give up, try another method, remove some goals in order to succeed with the remaining goals, or contact a human for further guidance.

37.7.3.2 Execution Monitoring with Inaccurate Sensors

Monitoring should not only maximize the probability that a failure is detected but also minimize the probability of false positives, where a failure is signaled but none has occurred. Some problems, such as those caused by dropouts and communication delays, can be ameliorated by extrapolating historical values and by delaying state generation slightly to allow values to propagate through the distributed system. Noise could be minimized through sensor value smoothing techniques and sensor fusion techniques. However, inaccuracies in the detected state sequence can never be completely eliminated. Therefore, the fact that state values may be inaccurate should be taken into consideration when writing monitor formulas.

For example, the meaning of the condition $\Box \forall av. \text{speed}(av) \leq T$ is that the *sensed and approximated* speed of an AV must never exceed the threshold T . Since a single observation of $\text{speed}(av)$ above the threshold might be an error or a temporary artifact, a more robust solution would be to signal a failure if the sensed speed has been above the threshold during an interval $[0, \tau]$ instead of at a single timepoint. This can be expressed as $\Box \Diamond_{[0, \tau]} \text{speed}(av) \leq T$: It should always be the case that within the interval $[0, \tau]$ from now, the sensed speed returns to being below the threshold.

This formula is somewhat weak: It only requires that a single measurement in every interval of length τ is below the threshold. An alternative would be to require that within τ time units, there will be an *interval* of length τ' during which the AV stays within the limits: $\Box(\text{speed}(av) > T \rightarrow \Diamond_{[0,\tau]} \Box_{[0,\tau']} \text{speed}(av) \leq T)$.

37.7.3.3 Formula Progression

To promptly detect violations of monitor conditions during execution, a *formula progression* algorithm is used (Bacchus and Kabanza 1998). By definition, a formula ϕ holds in the state sequence $[s_0, s_1, \dots, s_n]$ iff $\text{Progress}(\phi, s_0)$ holds in $[s_1, \dots, s_n]$. In essence, this evaluates those parts of the monitor formula that refer to s_0 , returning a new formula to be progressed in the same manner once s_1 arrives.

If the formula \perp (false) is returned, then sufficient information has been received to determine that the monitor formula must be violated regardless of the future development of the world. For example, this will happen as soon as the formula $\Box \text{speed} < 50$ is progressed through a state where $\text{speed} \geq 50$. Similarly, if \top (true) is returned, the formula must hold regardless of what happens “in the future.” This will occur if the formula is of the form $\Diamond \phi$ (eventually, ϕ will hold), and one has reached a state where ϕ indeed does hold. In other cases, the state sequence complies with the constraint “so far,” and progression will return a new and potentially modified formula that should be progressed again as soon as another state is available.

Definition 37.3. (Progression of Monitor Formulas). The following algorithm is used for progression of monitor formulas. Note that states are not first-class objects in TAL and are therefore identified by a timepoint τ and an interpretation \mathcal{I} . Special cases for \Box and \Diamond can be introduced for performance.

```

1  procedure Progress( $\phi, \tau, \mathcal{I}$ )
2  if  $\phi = f(\bar{x}) \hat{=} v$ 
3    if  $\mathcal{I} \models \text{Trans}([\tau] \phi)$  return  $\top$  else return  $\perp$ 
4  if  $\phi = \neg \phi_1$  return  $\neg \text{Progress}(\phi_1, \tau, \mathcal{I})$ 
5  if  $\phi = \phi_1 \otimes \phi_2$  return  $\text{Progress}(\phi_1, \tau, \mathcal{I}) \otimes \text{Progress}(\phi_2, \tau, \mathcal{I})$ 
6  if  $\phi = \forall x. \phi$  // where  $x$  belongs to the finite domain  $X$ 
7    return  $\bigwedge_{c \in X} \text{Progress}(\phi[x \mapsto c], \tau, \mathcal{I})$ 
8  if  $\phi = \exists x. \phi$  // where  $x$  belongs to the finite domain  $X$ 
9    return  $\bigvee_{c \in X} \text{Progress}(\phi[x \mapsto c], \tau, \mathcal{I})$ 
10 if  $\phi$  contains no tense operator
11   if  $\mathcal{I} \models \text{Trans}(\phi)$  return  $\top$  else return  $\perp$ 
12 if  $\phi = \phi_1 \cup_{[\tau_1, \tau_2]} \phi_2$ 
13   if  $\tau_2 < 0$  return  $\perp$ 
14   elseif  $0 \in [\tau_1, \tau_2]$  return  $\text{Progress}(\phi_2, \tau, \mathcal{I}) \vee (\text{Progress}(\phi_1, \tau, \mathcal{I}) \wedge$ 
       $(\phi_1 \cup_{[\tau_1-1, \tau_2-1]} \phi_2))$ 
15   else return  $\text{Progress}(\phi_1, \tau, \mathcal{I}) \wedge (\phi_1 \cup_{[\tau_1-1, \tau_2-1]} \phi_2)$ 

```

The result of Progress is simplified using the rules $\neg \perp = \top$, $(\perp \wedge \alpha) = (\alpha \wedge \perp) = \perp$, $(\perp \vee \alpha) = (\alpha \vee \perp) = \alpha$, $\neg \top = \perp$, $(\top \wedge \alpha) = (\alpha \wedge \top) = \alpha$,

and $(\top \vee \alpha) = (\alpha \vee \top) = \top$. Further simplification is possible using identities such as $\Diamond_{[0,\tau]} \phi \wedge \Diamond_{[0,\tau']} \phi \equiv \Diamond_{[0,\min(\tau,\tau'')]} \phi$.

For this approach to be useful, it must be possible to progress typical monitor formulas through the state sequences generated during a mission using the often limited computational power available in an autonomous robotic system. The following evaluation uses one synthetic test where one can study complex combinations of time and modality. An earlier version of the actual DRC computer onboard a UASTL RMAX was used to run progression tests for formulas having a form that is typical for monitor formulas in many applications. State sequences are constructed to exercise both the best and the worst cases for these formulas.

The evaluation shows that even with the worst possible inputs, complex formulas can be evaluated in less than 1 ms per state and formula on this CPU (1.4 GHz Pentium M). One example formula is $\Box \neg p \rightarrow \Diamond_{[0,1000]} \Box_{[0,999]} p$, corresponding to the fact that if the property p is false, then within 1,000 ms, there must begin a period lasting at least 1,000 ms where p is true. For example, the previously discussed formula $\Box(\text{speed}(av) > T \rightarrow \Diamond_{[0,\tau]} \Box_{[0,\tau']} \text{speed}(av) \leq T)$ has this general form. To estimate the cost of evaluating this formula, it was progressed through several different state streams corresponding to the best case, the worst case, and two intermediate cases. A new state in the stream was generated every 100 ms, which means that all formulas must be progressed within this time limit or monitoring will fall behind. Figure 37.28 shows the average time required to progress a certain number of formulas through each state in a sequence. This indicates that 100 ms is sufficient for progressing between 1,500 and 3,000 formulas of this form on the computer onboard the UASTL RMAX, depending on the state stream. Similar results have been shown for formulas of different forms, such as $\Box \neg p \rightarrow \Diamond_{[0,1000]} \Box_{[0,999]} p$ and $\Box \neg p \rightarrow \Diamond_{[0,1000]} \Box_{[0,999]} p$ (Doherty et al. 2009).

37.7.4 High-Level Mission Specification

The ability to clearly and concisely specify missions is fundamentally important for an unmanned system to be practically useful and requires a suitable *mission specification language* that should satisfy a variety of requirements and desires. The language should be comprehensible to humans and not only useful as an intermediate representation both generated and received by software. At the same time intuitions are not sufficient: A strict formal semantics must be available. There should also be a close connection to mission execution, allowing the actual semantics of the language to be used to specify the correct operation of the system and thereby facilitating the validation of the system as a whole. A principled foundation where these issues are considered, for single platforms (vehicles) as well as for fleets of homogeneous or heterogeneous platforms, is essential for these types of systems to be accepted by aviation authorities and in society.

The mission specification language used in the HDRC3 architecture is designed to allow partial mission specifications with constraints, including resource

Fig. 37.28 Average progression time: always $\neg p \rightarrow$ eventually always p

requirements and temporal deadlines. It extends the support for highly expressive *elementary actions* in Temporal Action Logic (TAL, Sect. 37.7.1) with *temporal composite actions* that also provide a formal semantics for the high-level structure of a mission (Doherty et al. 2012). The composite action constructs in the extended logic TALF correspond closely to the control structures supported by Task Specification Trees (Sect. 37.4.3). As shown in Fig. 37.29, missions can therefore be defined either in TALF or as TSTs and can be translated in either direction. The *delegation* functionality discussed in Sect. 37.8 can then be used to delegate a mission in the shape of a TST to one or more platforms for execution, resulting in a distributed task structure.

Composite actions in TALF are characterized recursively through the general construct “with VARS do TASK where CONS”: Any composite action consists of a task TASK that should be executed in a context characterized by a set of variables VARS constrained by a set of constraints CONS. The TASK, in turn, can be an elementary TAL action or consist of a combination of composite actions using constructs such as sequential composition, parallel (concurrent) composition, conditional, (unbounded) loops, while-do, and a concurrent for-each operator allowing a variable number of actions to be executed concurrently. At the mission specification level considered here, each constraint definition can be as general as a logical formula in TAL, giving it a formal semantics. For pragmatic use in a robotic architecture, a wide class of formulas can be automatically transformed into constraints processed

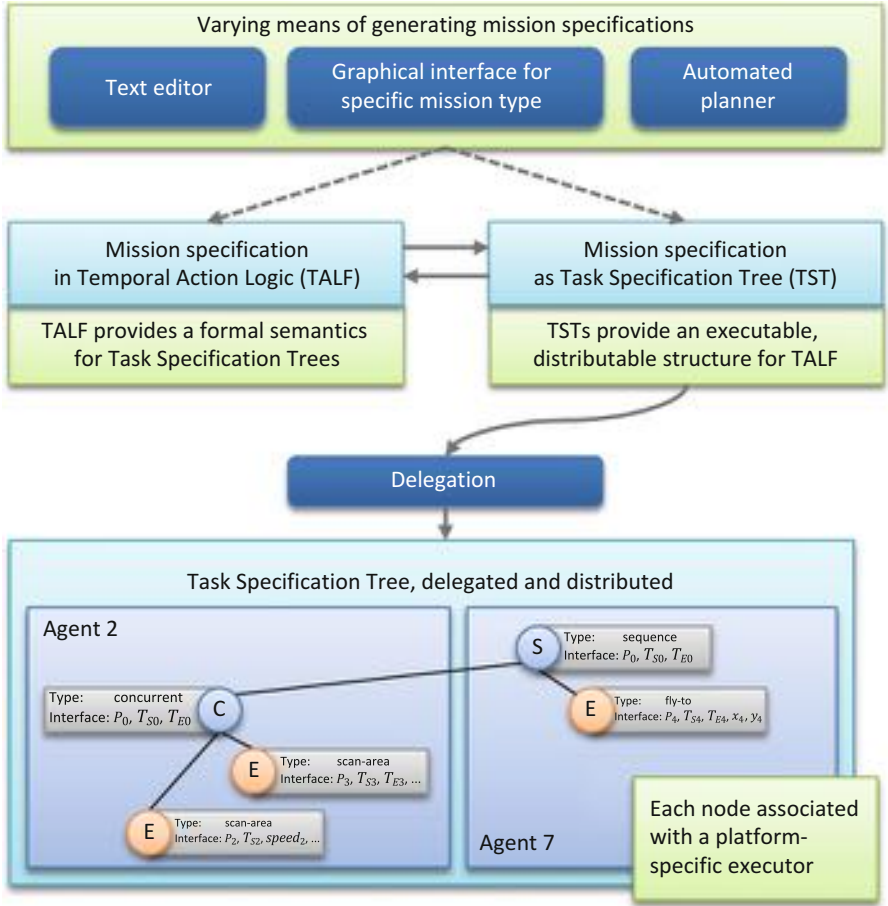

Fig. 37.29 Mission specification, translation, and delegation

by a constraint satisfaction solver, allowing a robotic system to formally verify the consistency of a (distributed) task through the use of (distributed) constraint satisfaction techniques.

A *composite action-type specification* declares a named composite action. This is useful in order to define a library of meaningful composite actions to be used in mission specifications. Each specification is of the form $[t, t'] \text{comp}(\bar{v}) \rightsquigarrow A(t, t', \bar{v})$ where $\text{comp}(\bar{v})$ is a *composite action term* such as $\text{monitor-pattern}(x, y, \text{dist})$, consisting of an action name and a list of parameters, and $A(t, t', \bar{v})$ is a *composite action expression* where only variables in $\{t, t'\} \cup \bar{v}$ may occur free. A composite action expression (C-ACT), in turn, allows actions to be composed at a high level of abstraction using familiar programming language constructs such as sequences ($A; B$), concurrency ($A \parallel B$), conditions, and loops. The associated syntax is defined as follows:

$$\begin{aligned}
\text{C-ACT} &::= [\tau, \tau'] \text{ with } \bar{x} \text{ do TASK where } \phi \\
\text{TASK} &::= [\tau, \tau'] \text{ELEM-ACTION-TERM} \mid \\
&\quad [\tau, \tau'] \text{COMP-ACTION-TERM} \mid \\
&\quad (\text{C-ACT}; \text{C-ACT}) \mid \\
&\quad (\text{C-ACT} \parallel \text{C-ACT}) \mid \\
&\quad \text{if } [\tau] \psi \text{ then C-ACT else C-ACT} \mid \\
&\quad \text{while } [\tau] \psi \text{ do C-ACT} \mid \\
&\quad \text{foreach } \bar{x} \text{ where } [\tau] \psi \text{ do conc C-ACT}
\end{aligned}$$

where \bar{x} is a potentially empty sequence of variables (where the empty sequence can be written as ϵ), ϕ is a TAL formula representing a set of constraints, ELEM-ACTION-TERM is an elementary action term such as **fly-to**(av, x, y), COMP-ACTION-TERM is a composite action term, and $[\tau] \psi$ is a TAL formula referring to facts at a single timepoint τ . For brevity, omitting “with \bar{x} do” is considered equivalent to specifying the empty sequence of variables, and omitting “where ϕ ” is equivalent to specifying “where TRUE.” Note that the $;$ and \parallel constructs are easily extended to allow an arbitrary number of actions, as in $(A; B; C; D)$.

Like elementary actions, every composite action C-ACT is annotated with a temporal execution interval. This also applies to each “composite sub-action.” For example,

$$\begin{aligned}
&[t_1, t_2] \text{ with } av, t_3, t_4, t_5, t_6 \text{ do} \\
&\quad ([t_3, t_4] \text{fly-to}(av, x, y); [t_5, t_6] \text{collect-video}(av, x, y)) \\
&\quad \text{where } [t_1] \text{has-camera}(av)
\end{aligned}$$

denotes a composite action where one elementary action takes place within the interval $[t_3, t_4]$, the other one within the interval $[t_5, t_6]$, and the entire sequence within $[t_1, t_2]$.

The with-do-where construct provides a flexible means of constraining variables as desired for the task at hand. In essence, “ $[t_1, t_2]$ with \bar{x} do TASK where ϕ ” states that there exists an instantiation of the variables in \bar{x} such that the specified TASK (which may make use of \bar{x} as illustrated above) is executed within the interval $[t_1, t_2]$ in a manner satisfying ϕ . The constraint ϕ may be a combination of temporal, spatial, and other types of constraints. Above, this constraint is used to ensure the use of an av that has a camera rather than an arbitrary av .

As the aim is to maximize temporal flexibility, the sequence operator ($;$) does not implicitly constrain the two actions **fly-to** and **collect-video** to cover the entire temporal interval $[t_1, t_2]$. Instead, the actions it sequentializes are only constrained to occur *somewhere within* the execution interval of the composite action, and gaps are permitted between the actions – but all actions in a sequence must occur in the specified order without overlapping in time. Should stronger temporal constraints be required, they can be introduced in a where clause. For example, $t_1 = t_3 \wedge t_4 = t_5 \wedge t_6 = t_2$ would disallow gaps in the sequence above. Also, variations such as gapless sequences can easily be added as first-class language constructs if desired.

Formal Semantics. To define a formal semantics for TALF, the base logic $\mathcal{L}(\text{FL})$ is first extended with support for *fixpoint formulas*. This is required for unbounded loops and unbounded recursion, which cannot be characterized in the first-order logic $\mathcal{L}(\text{FL})$. A translation is then defined from TALF into the extended base logic $\mathcal{L}(\text{FL}_{\text{FP}})$. As a result of this translation, a composite action is a theory in $\mathcal{L}(\text{FL}_{\text{FP}})$. Questions about missions thereby become queries relative to an inference mechanism, allowing operators to analyze mission properties both during pre- and post-mission phases. This also provides a formal semantics for Task Specification Trees, which can be translated into TALF, and thereby for the execution system used in the HDRC3 architecture. Details regarding translations and the resulting formal semantics are specified in Doherty et al. (2012).

Examples. In November 2011, a powerful earthquake off the coast of Japan triggered a tsunami with devastating effects, including thousands of dead and injured as well as extensive damage to cities and villages. Another effect, which became increasingly apparent over time, was the extensive damage to the Fukushima Daiichi nuclear plant which later resulted in a complete meltdown in three reactors. The exact level of damage was initially difficult to assess due to the danger in sending human personnel into such conditions. Here unmanned aircraft could immediately have assisted in monitoring radiation levels and transmitting video feeds from a closer range. Several composite actions that can be useful for the problem of information gathering in this situation will now be considered. The focus is on demonstrating the $\mathcal{L}(\text{ND})$ composite action constructs, and some aspects of the actions below are simplified for expository reasons.

Assume the existence of a set of elementary actions whose meaning will be apparent from their names and from the explanations below: **hover-at**, **fly-to**, **monitor-radiation**, **collect-video**, and **scan-cell**. Each elementary action is assumed to be defined in standard TAL and to provide suitable preconditions, effects, resource requirements, and (completely or incompletely specified) durations. For example, only an AV with suitable sensors can execute **monitor-radiation**.

In the following composite action, an AV hovers at a location $(x_{\text{av}}, y_{\text{av}})$ while using its onboard sensors to monitor radiation and collect video at $(x_{\text{targ}}, y_{\text{targ}})$:

$$\begin{aligned}
 & [t, t'] \text{monitor-single}(av, x_{\text{av}}, y_{\text{av}}, x_{\text{targ}}, y_{\text{targ}}) \rightsquigarrow \\
 & [t, t'] \text{with } t_1, t_2, t_3, t_4, t_5, t_6 \text{ do (} \\
 & \quad [t_1, t_2] \text{hover-at}(av, x_{\text{av}}, y_{\text{av}}) \parallel \\
 & \quad [t_3, t_4] \text{monitor-radiation}(av, x_{\text{targ}}, y_{\text{targ}}) \parallel \\
 & \quad [t_5, t_6] \text{collect-video}(av, x_{\text{targ}}, y_{\text{targ}}) \\
 & \quad \left. \right) \text{ where } [t] \text{surveil-equipped}(av) \wedge \text{radiation-hardened}(av) \wedge t_1 = t_3 = t_5 \\
 & \quad = t \wedge t_2 = t_4 = t_6 = t'
 \end{aligned}$$

The first part of the constraint specified in the *where* clause ensures that an AV involved in a monitoring action is equipped for surveillance and is radiation-hardened (in addition to the conditions placed on **monitor-radiation**, which include

the existence of radiation sensors). The temporal constraints model a requirement for these particular actions to be synchronized in time and for the AV to hover in a stable location throughout the execution of monitor-single. These constraints could easily be relaxed, for example, by stating that hovering occurs throughout the action but monitoring occurs in a subinterval.

The following action places four AVs in a diamond pattern to monitor a given location such as a nuclear reactor at a given distance, counted in grid cells. The AVs involved are not specified as parameters to the monitoring action but are chosen freely among available AVs, subject to the constraints modeled by sub-actions such as monitor-single:

```
[t, t'] monitor-pattern(x, y, dist)  $\rightsquigarrow$ 
[t, t'] with  $s_1, \dots, w_4, av_1, av_2, av_3, av_4$  do (
  ( $[s_1, s_2]$  fly-to( $av_1, x + dist, y$ );  $[s_3, s_4]$  monitor-single( $av_1, x + dist, y, x, y$ )) ||
  ( $[u_1, u_2]$  fly-to( $av_2, x - dist, y$ );  $[u_3, u_4]$  monitor-single( $av_2, x - dist, y, x, y$ )) ||
  ( $[v_1, v_2]$  fly-to( $av_3, x, y + dist$ );  $[v_3, v_4]$  monitor-single( $av_3, x, y + dist, x, y$ )) ||
  ( $[w_1, w_2]$  fly-to( $av_4, x, y - dist$ );  $[w_3, w_4]$  monitor-single( $av_4, x, y - dist, x, y$ )))
where
 $s_3 = u_3 = v_3 = w_3 \wedge s_4 = u_4 = v_4 = w_4 \wedge s_4 - s_3 \geq \text{minduration}$ 
```

Four sequences are executed in parallel. Within each sequence, a specific AV flies to a suitable location and then monitors the target. The target must be monitored simultaneously by all four AVs ($s_3 = u_3 = v_3 = w_3$ and $s_4 = u_4 = v_4 = w_4$), while $s_4 - s_3 \geq \text{minduration}$ ensures this is done for at least the specified duration. As flying does not need to be synchronized, the intervals for the **fly-to** actions are only constrained *implicitly* through the definition of a sequence. For example, the translation ensures that $t \leq s_1 \leq s_2 \leq s_3 \leq s_4 \leq t'$, so that each **fly-to** must end before the corresponding monitor-single.

All grid cells must also be scanned for injured people. The following generic action uses all available AVs with the proper capabilities, under the assumption that each such AV has been assigned a set of grid cells to scan. An assignment could be generated by another action or provided as part of the narrative specification. For clarity, this includes several clauses (with ϵ do, where TRUE) that could easily be omitted:

```
[t, t'] scan-with-all-uavs()  $\rightsquigarrow$ 
[t, t'] with  $\epsilon$  do
  foreach  $av$  where  $[t]$  can-scan( $av$ ) do conc
     $[t, t']$  with  $u, u'$  do  $[u, u']$  scan-for-people( $av$ ) where TRUE
  where TRUE
```

As shown below, each AV involved in this task iterates while there remains at least one cell (x, y) that it has been assigned (“owns”) and that is not yet scanned. In each iteration the variables (x', y') declared in the nested with clause range over

arbitrary coordinates, but the associated where clause ensures that only coordinates that belong to the given AV and that have not already been scanned can be selected. Also in each iteration, t_c is bound to the time at which the constraint condition is tested and u, u' are bound to the timepoints at which the inner composite action is performed. The repeated use of u, u' is intentional. The **scan-cell** action will occur over exactly the same interval as the enclosing composite action construct:

$$\begin{aligned}
 [t, t'] \text{ scan-for-people}(av) \rightsquigarrow & \\
 [t, t'] \text{ with } \epsilon \text{ do} & \\
 \quad \text{while } [t_c] \exists x, y [\text{owns}(av, x, y) \wedge \neg \text{scanned}(x, y)] \text{ do} & \\
 \quad \quad [u, u'] \text{ with } x', y' \text{ do } [u, u'] \text{scan-cell}(av, x', y') \text{ where } [t_c] \text{owns} & \\
 \quad \quad (av, x', y') \wedge \neg \text{scanned}(x', y') & \\
 \quad \text{where TRUE} &
 \end{aligned}$$

It is now possible to define a small mission to occur within the interval $[0, 1000]$, where scanning may use the entire interval while the grid cell $(20, 25)$ is monitored at a distance of 3 cells and must terminate before time 300:

$$[0, 1000]([0, 1000] \text{ scan-with-all-uavs() } || [0, 300] \text{ monitor-pattern}(20, 25, 3))$$

It should be emphasized that in the expected case, the task of generating specifications of this kind would be aided by libraries of predefined domain-related actions as well as by user interfaces adapted to the task at hand. The structure and high-level nature of the language remains important when ensuring that these tools and their output are both correct and comprehensible to a human operator inspecting a mission definition.

37.8 Collaborative Systems

Though the main focus of this chapter has been on the operation of a single unmanned aircraft, issues related to cooperation and collaboration are also essential for the successful use of such systems.

At the cooperative level, the combination of an aircraft or other robotic *platform* and its associated software is viewed as an *agent*. Humans interacting with platforms through, for example, ground control stations and other interfaces are also considered to be agents. Taken together, these agents form a collaborative system where all participants can cooperate to perform missions. One aspect of a collaborative system is that all agents are conceptually equal and independent in the sense that there is no predefined control structure, hierarchical or otherwise. A consequence is that the control structure can be determined on a mission-to-mission basis and dynamically changed during a mission.

When an unmanned system is viewed as an agent acting on behalf of humans, it is also natural to view the assignment of a complex mission to that system as *delegation* – by definition, the act of assigning authority and responsibility to another person, or in a wider sense an agent, in order to carry out specific activities. Delegation is therefore part of the foundation for collaboration in this architecture: A *delegator* can ask a *contractor* to take the responsibility for a specific *task* to be performed under a set of *constraints*. Informally, an agent receiving a delegation request must verify that to the best of its knowledge, it will be able to perform the associated task under the given constraints, which may for example, concern resource usage or temporal and spatial aspects of the mission. To ensure that a complex task is carried out in its entirety, an agent may have to enlist the aid of others, which can then be delegated particular parts of the task. This results in a network of responsibilities between the agents involved and can continue down to the delegation of elementary, indivisible actions. If such a network can be generated in a way that satisfies the associated constraints, the contractor can accept the delegation and is then committed to doing everything in its power to ensure the task is carried out. If not, it must refuse. See Doherty et al. (2013) for a formal characterization of delegation in terms of speech acts as well as a practical delegation protocol that also determines how to allocate tasks to specific agents.

Delegation requires a flexible task structure with a clear formal semantics. This role is played by Task Specification Trees (Sect. 37.4.3), whose hierarchical nature also leads to a natural recursive decomposition of tasks where the children of a node are the subtasks that can be re-delegated to other agents. For example, an automated multi-agent planner (Sect. 37.7.2) can generate a TST where elementary action nodes are not assigned to specific agents. Then, the delegation process and its embedded *task allocation* functionality (Doherty et al. 2013) can recursively determine how the plan can be executed in a way that satisfies associated constraints. The formal semantics of the task being delegated is specified through a close connection to TALF (Sect. 37.7.4). See Doherty et al. (2011, 2013) and Doherty and Meyer (2012) for further details about delegation, its close relation to *adjustable autonomy* and *mixed-initiative interaction*, and its integration with automated planning.

Legacy Systems. When an agent-based architecture is used together with an existing platform such as an unmanned aircraft, there may already be an existing legacy system providing a variety of lower-level functionalities such as platform-specific realizations of elementary tasks and resources. Existing interfaces to such functionalities can vary widely. The current instantiation of the architecture (Fig. 37.30a) directly supports the use of such legacy functionalities through the use of an agent layer and a gateway. The *agent layer* (Fig. 37.30b) encapsulates higher-level deliberative functionalities and provides a common interface for multi-agent collaboration in complex missions, including support for mission specification languages, delegation, and planning. The *gateway* must have a platform-specific implementation, but provides a common platform-independent external interface to

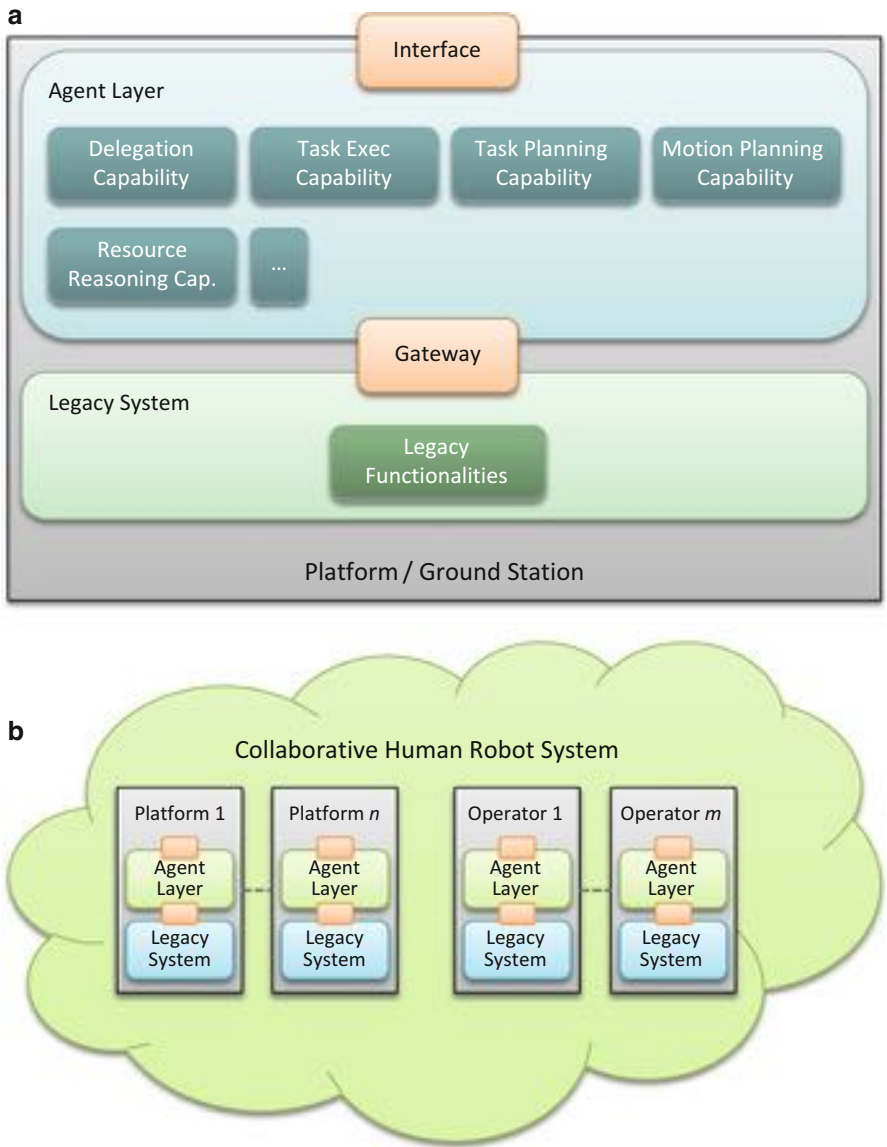

Fig. 37.30 Agents in a collaborative system. (a) Agentified platform or ground control station. (b) Overview of the collaborative human/robot system

the available legacy functionalities. In essence, this allows newly developed higher-level functionalities to be seamlessly integrated with existing systems, without the need to modify either the agent layer or the existing system. The agent layer can then be developed independently of the platforms being used.

Legacy control stations and user interfaces that human operators use to interact with robotic systems are treated similarly, through the addition of an agent layer. The result is a collaborative human/robot system consisting of a number of human operators and robotic platforms each having an agent layer and possibly a legacy system, as shown in [Fig. 37.30b](#).

37.9 Mission Applications

The research methodology used during the development of the HDRC3 architecture has been very much scenario-based where very challenging scenarios out of reach of current systems are specified and serve as longer-term goals to drive both theoretical and applied research. Most importantly, attempts are always made to close the theory/application loop by implementing and integrating results in AVs and deploying them for empirical testing at an early stage. One then iterates and continually increases the robustness and functionalities of the targeted components.

Due to the architecture described in the previous sections, it is relatively easy to build on top of existing functionalities and to add new ones in order to put together sophisticated autonomous missions. Below, two such example mission applications are described.

37.9.1 Emergency Services Assistance

The first application focuses again on the ambitious emergency services scenario discussed in the introduction. An emergency relief scenario in this context can be divided into two separate legs or parts.

37.9.1.1 Mission Leg I: Body Identification

In the first leg of the mission, a large region should be cooperatively scanned with one or more AVs to identify injured civilians. The result of this scan is a *saliency map* pinpointing potential victims, their locations, and associated information such as high resolution photos and thermal images. This information could then be used directly by emergency services or passed on to other AVs as a basis for additional tasks.

A multi-platform area coverage path-planning algorithm computes paths for n heterogeneous platforms guaranteeing complete camera coverage, taking into account sensor properties and platform capabilities.

Two video sources (thermal and color) are used, allowing for high rate human detection at larger distances than in the case of using the video sources separately with standard techniques. The high processing rate is essential in case of video collected onboard an AV in order not to miss potential victims.

A thermal image is first analyzed to find human body sized silhouettes. The corresponding regions in a color image are subjected to a human body classifier which is configured to allow weak classifications. This focus of attention allows

Algorithm 4 Saliency map construction

```

1: Initialize data structures
2: while scanning not finished do
3:   Simultaneously grab two images:  $img_{color}$ ,  $img_{thermal}$ 
4:   Analyze  $img_{thermal}$  to find potential human body regions
5:   for each region in  $img_{thermal}$  do
6:     Find corresponding region  $r_{color}$  in  $img_{color}$ 
7:     Compute geographical location  $loc$  of  $r_{color}$ 
8:     Execute human body classifier on  $r_{color}$ 
9:     if classification positive then
10:      if  $loc$  is new then
11:        add location  $loc$  to map, initialize certainty factor  $p_{body}(loc)$ 
12:      else
13:        update certainty factor  $p_{body}(loc)$ 
14:      end if
15:    end if
16:  end for
17: end while

```

for maintaining body classification at a rate up to 25 Hz. This high processing rate allows for collecting statistics about classified humans and pruning false classifications of the “weak” human body classifier. Detected human bodies are geolocalized on a map which can be used to plan supply delivery. The technique presented has been tested onboard the UASTL RMAX helicopter platform and is an important component in the lab’s research with autonomous search and rescue missions.

Saliency Map Construction. Information obtained from thermal and color video streams must be fused in order to create saliency maps of human bodies. An overview of the method used is presented in Algorithm 4. The execution of this algorithm starts when the host AV arrives at the starting position of the area to scan and is terminated when the scanning flight is finished. Its output is a set of geographical locations loc_i and certainty factors $p_{body}(loc_i)$. Refer to Doherty and Rudol (2007) and Rudol and Doherty (2008) for additional details.

After initializing the necessary data structures (line 1), the algorithm enters the main loop (line 2), which is terminated when the entire area has been scanned. The main loop begins with simultaneously grabbing two video frames. The thermal image is analyzed first (line 4) to find a set of regions of intensities which correspond to human body temperatures (details below). Then (line 6), for each of these subregions, a correspondence in the color frame, as well its geographical location loc , is calculated (details below). The calculated corresponding region in the color frame is analyzed with a human body classifier to verify the hypothesis that the location loc contains a human body (details below). If the classification is positive and the location loc has not been previously identified, then loc is added to the map and its certainty factor initialized (line 11). Otherwise, the certainty factor of that location is updated (line 13, details below).

Fig. 37.31 Example input to the image processing algorithm: Thermal images and corresponding color images

Thermal Image Processing. The image processing algorithm takes a pair of images as input and starts by analyzing the thermal image (top row of Fig. 37.31). The image is first thresholded to find regions of certain intensities which correspond to human body temperature. The image intensity corresponding to a certain temperature is usually given by the camera manufacturer or can be calibrated by the user. The shapes of the thresholded regions are analyzed, and those which do not resemble a human body, due to the wrong ratio between minor and major axes of the fitted ellipse or due to incorrect sizes, are rejected. Once human body candidates are found in the thermal image, corresponding regions in the color image are calculated.

Image Correspondences and Geolocation. Finding corresponding regions using image registration or feature matching techniques is infeasible because of the different appearance of features in color and thermal images. Therefore, a closed form solution, which takes into account information about the cameras' pose in the world, is preferred. In short, a geographical location corresponding to pixel coordinates for one of the cameras is calculated. It takes into account the camera's extrinsic and intrinsic parameters and assumes a flat world. The obtained geographical location is then projected back into the other camera image.

The method can be extended to relax the flat world assumption given the elevation model. A geographical location of a target can be found by performing ray tracing along the line going from the camera center through a pixel to find the intersection with the ground elevation map.

The accuracy of the correspondence calculation is influenced by several factors. All inaccuracies of parameters involved in calculating the position and attitude of cameras in the world contribute to the overall precision of the solution. The evaluation of the accuracy involves investigating the AV state estimation errors, pan-tilt unit position accuracy, camera calibration errors, etc. In the case of the UASTL

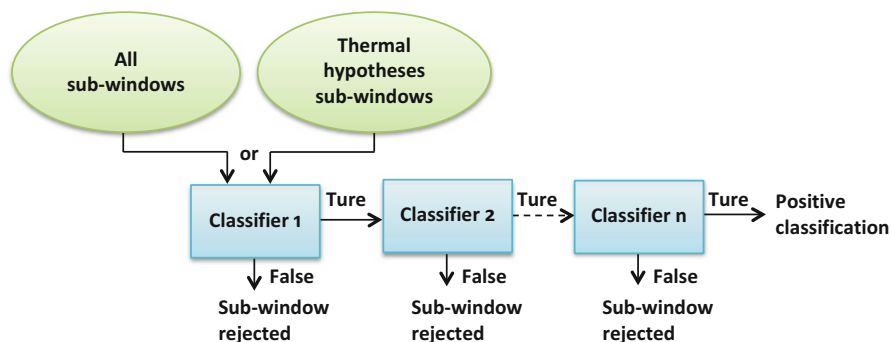

Fig. 37.32 Schematic description of a cascade classifier

RMAX, during the experimental validation, the corresponding image coordinates were within a subregion of 20 % of the video frame size (see the marked subregions in the color images in Fig. 37.31).

Human Body Classification. After calculating the coordinates of the pixel in the color image, a region with the P_c as center (the black rectangles in the bottom row images of Fig. 37.31) is analyzed by an object classifier. The classifier used was first suggested in Viola and Jones (2001). It uses a cascade of classifiers for object detection and includes a novel image representation, the integral image, for quick detection of features. Classifiers in the initial stages remove a large number of negative examples. Successive classifiers process a smaller number of sub-windows. The initial set of sub-windows can include all possible sub-windows or can be the result of a previous classification in a thermal image additionally improving processing rate. The method was also improved, for example, in Lienhart and Maydt (2002) by extending the original feature set.

The classifier requires training with positive and negative examples. During the learning process, the structure of a classifier is built using boosting. The use of a cascade of classifiers allows for dramatic speed up of computations by skipping negative instances and only computing features with high probability for positive classification. The speed up comes from the fact that the classifier, as it slides a window at all scales, works in stages and is applied to a region of interest until at some stage the candidate is rejected or all the stages are passed (see Fig. 37.32). This way, the classifier quickly rejects subregions that most probably do not include the features needed for positive classification (i.e., background processing is quickly terminated).

The implementation of the classifier used in this work is a part of the Open Source Computer Vision Library (<http://opencv.org/>), and the trained classifier for upper, lower, and full human body is a result of Kruppa et al. (2003). The classifier is best suited for pedestrian detection in frontal and backside views which is exactly the type of views an AV has when flying above the bodies lying on the ground.

The classifier parameters have been adjusted to minimize false negatives: In case of rescue operations, it is better to find more false positives than to miss a potential victim. The number of neighboring rectangles needed for successful identification has been set to 1 which makes the classifier accept very weak classifications. The search window is scaled up by 20 % between subsequent scans.

Map Building. Since the body classifier is configured to be “relaxed,” it delivers sporadic false-positive classifications. The results are pruned as follows. Every salient point in the map has two parameters which are used to calculate the certainty of a location being a human body: T_{frame} which describes the amount of time a certain location was in the camera view and T_{body} which describes the amount of time a certain location was classified as a human body. The certainty factor is calculated by $p_{body}(loc_i) = \frac{T_{body}}{T_{frame}}$. A location is considered a body if $p_{body}(loc_i)$ is larger than a certain threshold (0.5 was used during the flight tests) and T_{frame} is larger than a desired minimal observation time. Locations are considered equal if geographical distance between them is smaller than a certain threshold (depending on the geolocation accuracy) and the final value of a geolocated position is an average of the observations.

Experimental Validation. The presented technique for geolocation and saliency map building has been integrated as a perception functionality of the Control Kernel (Sect. 37.3.2) and tested in flight. A mission has then been constructed in the shape of a Task Specification Tree that indirectly makes use of the takeoff, hovering, path-following, and landing flight control modes (through FCL commands, Sect. 37.4.2.2), as well as the pan-tilt unit (through PPCL commands, Sect. 37.4.2.3).

Test flights were then performed at the Swedish Rescue Services Agency Test Area (Fig. 37.33a). Since this is a city-like closed area with road structures, buildings, etc., the video streams included different types of textures such as grass, asphalt, gravel, water, and building rooftops. An example complete push button mission setup was as follows:

- Two UASTL RMAX helicopters were used starting from H_1 and H_2 in Fig. 37.33b.
- An operator selected a rectangular area on a map where the saliency map was to be built (Fig. 37.33b).
- Onboard systems calculated the mission plan taking into account properties of the onboard sensors (such as the field of view) of both AVs. The plan consisted of two separate flight plans for the two AVs.
- The mission started with simultaneous takeoffs and flying to starting positions S_1 and S_2 in Fig. 37.33b. After arriving at the starting positions, the execution of the scanning paths autonomously began, and the saliency map building was initiated.
- Upon finishing the scanning paths at positions E_1 and E_2 , the AVs flew to the takeoff positions and performed autonomous landings.

Fig. 37.33 (a) Map of the Swedish Rescue Services Agency Test Area in Revinge, (b) A closeup view of the area where the saliency map was built. Approximate flight paths are marked with *solid lines*

Experimental Results. All 11 human bodies placed in the area were found and geolocated. Corresponding color and thermal images for the identified objects are displayed vertically as pairs in Fig. 37.34. Images 7, 9, and 14 present three falsely identified objects, caused by configuring the human body classifier to accept weak classifications. A more restrictive setup could instead result in missing potential victims. The images could additionally be judged by a human operator to filter out the false-positive classifications. Both human bodies and dummies were detected despite the lower temperature of the latter.

Figure 37.35 presents the generated saliency map. The scanning pattern segments for the platform starting in position H_2 is marked with a solid line, and its final position is marked with a cross icon. The fields of view of the color and thermal cameras are depicted with light-gray and black rectangles, respectively. These differ slightly as the two cameras have different properties as identified during calibration procedures.

The circles indicate the identified body positions. The lighter the shade of the color, the more certain the classification. As can be seen, the most certain body positions are objects number 2 and 11 (in Fig. 37.34). It is due to the fact that these body images are clearly distinguishable from the homogeneous background. Nevertheless, even body images with more cluttered backgrounds were identified.

The accuracy of the body geolocation calculation was estimated by measuring GPS positions (without differential correction) of bodies after an experimental flight. The measurement has a bias of approximately 2 m in both east and north directions. It is the sum of errors in GPS measurement, accuracy of the camera platform mounting, PTU measurement, and camera calibration inaccuracies. The spread of measurement samples of approximately 2.5 m in both east and north directions is a sum of errors of the AV's attitude measurement, the system of springs in the camera platform, and time differences between the AV state estimate, PTU angle measurement, and image processing result acquisition.

Fig. 37.34 Images of classified bodies. Corresponding thermal images are placed under color images

Fig. 37.35 The resulting map with salient points marked as *circles*. The lighter the shade of the color, the higher the detection certainty

The presented algorithm requires only a single pair of images for human body classification. In practice, however, the more pairs available, the more certain the result of a classification can become. Additionally, thanks to using the results of the thermal image analysis to focus the classification in the color image subregions, a high rate of processing is achieved (above 20 Hz for the presented results).

37.9.1.2 Mission Leg II: Package Delivery

After successful completion of leg I of the mission scenario, one can assume that a saliency map has been generated with geolocated positions of the injured civilians. In the next phase of the mission, the goal is to deliver configurations of medical, food, and water supplies to the injured. In order to achieve this leg of the mission, one would require a task planner to plan for logistics, a motion planner to get one or more AVs to supply and delivery points, and an execution monitor to monitor the execution of highly complex plan operators. Each of these functionalities would also have to be tightly integrated in the system.

For these logistics missions, the use of one or more AVs with diverse roles and capabilities is assumed. Initially, there are n injured body locations, several supply depots, and several supply carrier depots (see Fig. 37.36). The logistics

Fig. 37.36 A supply depot (*left*) and a carrier depot (*right*)

Fig. 37.37 The AV logistics simulator

mission is comprised of one or more AVs transporting boxes containing food and medical supplies between different locations (Fig. 37.37). Plans are generated in the millisecond to seconds range using TALplanner (see Sect. 37.7.2), and empirical testing shows that this approach is promising in terms of integrating high-level deliberative capability with lower-level reactive and control functionality.

Fig. 37.38 Two frames of video presenting the prototype mechanism for carrying and releasing packages using an electromagnet. An *arrow* points to a package being carried. The *top left* picture presents the onboard camera view

Achieving the goals of such a logistics mission with full autonomy requires the ability to pick up and deliver boxes without human assistance. Thus, each AV has a device for attaching to boxes and carrying them beneath the AV. The action of picking up a box involves hovering above the box, lowering the device, attaching to the box, and raising the device, after which the box can be transported to its destination. There can also be a number of carriers, each of which is able to carry several boxes. By loading boxes onto such a carrier and then attaching to the carrier, the transportation capacity of an AV increases manifold over longer distances. The ultimate mission for the AVs is to transport the food and medical supplies to their destinations as efficiently as possible using the carriers and boxes at their disposal.

A physical prototype of a mechanism for carrying and releasing packages has been developed and tested. Figure 37.38 presents two images of the prototype system. The logistics scenario has also been tested in a simulated AV environment with hardware in-the-loop, where TALplanner generates a detailed mission plan which is then sent to a simulated execution system using the same helicopter flight control software as the physical AV. The execution monitor system has been tested in this simulation as well, with a large variety of deviations tested through fault injection in the simulation system. The simulator makes use of the Open Dynamics Engine (<http://www.ode.org>), a library for simulating rigid body dynamics, in order to realistically emulate the physics of boxes and carriers. This leads to effects such as boxes bouncing and rolling away from the impact point should they accidentally be dropped, which is also an excellent source of unexpected situations that can be used for validating both the domain model and the execution monitoring system.

37.9.2 Map Building Using a Laser Range Finder

The second application presented here deals with the construction of an elevation map using a laser range finder allowing AVs to navigate safely in unknown outdoor environments.

As described in Sect. 37.5.1, the path-planning algorithms used here are based on a geometrical description of the environment to generate collision-free paths. The safety of a UAS operation therefore depends on having a sufficiently accurate 3D model of the environment. Predefined maps may become inaccurate or outdated over time because of the environment changes, for example, due to new building structures and vegetation growth. Therefore, adequate sensors and techniques for updating or acquiring new 3D models of the environment are necessary in many cases.

Among the many sensors available for providing 3D information about an operational environment, laser range finders provide high-accuracy data at a reasonable weight and power consumption. One of the reasons for the innovation in this particular sensor technology is its wide use in many industries, but laser range finders have also received a great deal of interest from the robotics community, where their main usage is in navigation and mapping tasks for ground robotic systems, such as localization (Burgard et al. 1997), 2D Simultaneous Localization and Mapping (SLAM (Montemerlo and Thrun 2007)), 3D SLAM (includes 3D position (Cole and Newman 2006)), and 6D SLAM (includes 3D position and attitude (Nüchter et al. 2004)).

The device integrated with the UASTL RMAX system is the popular LMS-291 from SICK AG (<http://www.sick.com>). This unit does not require any reflectors or markers on the targets nor scene illumination to provide real-time measurements. It performs very well both in indoor and outdoor environments. The system is equipped with a rotating mirror which allows for obtaining distance information in one plane in front of the sensor with a selectable field of view of 100 or 180° (Fig. 37.39). It gives a resolution of 1 cm with a maximum range of 80 m, or a resolution of 1 mm with a range of 8 m; an angular resolution of 0.25, 0.5, or 1.0°; and a corresponding response time of 53, 26, or 13 ms.

The laser unit has been modified to reduce its weight from 4.5 to 1.8 kg. It has then been mounted on an in-house developed rotation mechanism supporting continuous rotation of the sensor around the middle laser beam (solid line in Fig. 37.39), which allows for obtaining half-sphere 3D point clouds even when the vehicle is stationary. A similar approach to the integration of the laser range finder with an UASTL RMAX platform is used by Whalley et al. (2008).

System Integration. The 3D map building algorithm based on the data provided by LRF sensor has been integrated as a perception functionality of the Control Kernel (Sect. 37.3.2) and tested in flight. A Task Specification Tree node has been specified to achieve the required mission goals (Sect. 37.4.3). Similar to the previous application example, the takeoff, hovering, path-following, and landing flight control modes were used during the mission through Flight Control Language

Fig. 37.39 Top view of the LMS-291 scanning field and the axis of rotation using the rotation mechanism

Fig. 37.40 Overview of the reconstructed elevation map of the Revinge flight test area based on the laser range finder data (*left*) and a photo of corresponding building structures (*right*)

commands (Sect. 37.4.2.2). Additionally, the Payload and Perception Control Language (Sect. 37.4.2.3) are used to set a constant angular speed of the LRF rotational mechanism as well as the distance and angular resolutions of the sensor. The 3D maps acquired are saved in the GIS Service database and available to the deliberative services (such as path planners, discussed in Sect. 37.5).

Experimental Results. Several missions were performed during which both the LRF data and AV state estimates were collected and integrated. Figure 37.40 presents a reconstructed elevation map of the Revinge flight test area (the left side) focusing on two building structures. A photo of corresponding buildings is presented on the right side of the figure. The elevation map is built by sampling the LRF data with 1 m resolution and constructing a set of triangles in order to represent the elevation.

In order to assess the fidelity of the newly generated model, an overlay with the existing model was generated. The result is presented in Fig. 37.41a. The new map

Fig. 37.41 Results of the map building procedure. (a) Overlay of the new elevation map with the existing Revinge flight test area model. (b) Example of path planner use in the reconstructed map of the Revinge area

includes some changes in the environment, including a metal container on the left in the figure (A.) and new vegetation (B.) that was not present in the existing model.

The new models stored by the GIS Service can be used by the AV platform for path planning in order to generate collision-free paths (see Sect. 37.5.1). Since generated models are based on noisy measurements, a safety margin during the planning is used. For the UASTL RMAX, a safety margin of 6 m is used. An example of path generated by the path planner using the new model is presented in Fig. 37.41b.

The accuracy of models built with the raw LRF point clouds (without applying the scan matching algorithms) is sufficient for navigation purposes if the necessary safety margins are used. The inaccuracies introduced by the measurement errors and the uncertainty of the AV state estimate might result in narrowing down the operational environment of the AV. For example, in Fig. 37.41a a narrow passage (C.) can be excluded from the collision-free space although the corridor between the two buildings is wide enough to fly through. Further investigation of methods for improving the model quality is ongoing at the time of writing this chapter.

37.10 Conclusions

The goal of this research is the development of autonomous intelligent systems for unmanned aircraft. This chapter has described a hybrid deliberative/reactive architecture which has been developed through the years and successfully deployed on a number of unmanned aircraft. The focus was on an instantiation of this architecture with the UASTL RMAX. The architecture was described in a manner that should be useful to the unmanned aircraft research community, because it isolates generic functionality and architectural solutions that can be transferred and used on existing unmanned aircraft and also those envisioned for the future. The experimental development of such systems has wider impact since the HDRC3 architecture and its instantiation on the UASTL RMAX are an example of a new type of software system commonly known as a *software intensive system* or *cyber physical system*. Such systems are characterized by a number of features: the complex combination of both hardware and software, the high degree of concurrency used, the distributed nature of the software, the network-centric nature of the environment in which they reside, the open nature of these systems, and finally, the requirement that they are both scalable and adaptive since specification of such systems is necessarily open due to their interaction with other components not part of the system. The latter features are particularly important in the context of collaborative missions with other heterogeneous systems.

The HDRC3 architecture encapsulates many of these features. Emphasis has been placed on the importance of clean transitional interfaces between the different layers of the architecture which are inhabited by computational processes with diverse requirements in terms of temporal latency in the decision cycles and the degree to which the processes use internal models. The HDRC3 architecture is also highly modular and extensible.

The use of HCSMs separates specification of the behavior of the system from the atomic conditions and activities which are implemented procedurally. This permits the use of a real-time interpreter for HCSMs and alleviates the requirement for recompilation when new HCSMs are added to the system. The approach is also amenable to distribution where federations of HCSM interpreters can intercommunicate with each other on a single platform as is the case with the UASTL RMAX system, but also across platforms if required.

The Platform Server provides a clean declarative interface to both the suite of flight control modes and perception control modes through the use of two languages, FCL and PPCL, respectively. This approach provides a primitive language of building blocks that can be structured and used by other functionalities in the system to define higher-level task specifications. Extending the suite of basic actions in the UASTL RMAX system is done by defining new HCSMs which interface to new or existing control modes and then extending the language interface in the Platform Server.

The task specifications themselves have a well-defined and extensible language, Task Specification Trees, which are used by both the reactive and deliberative layers of the architecture as a declarative specification language for tasks. Primitive actions

defined through the Platform Server interface can be used with TSTs, or if required, new actions can be defined by specifying new node types. The execution and procedural implementation of these basic action and new node types is separated from their declarative specification through the use of node executors and a node execution facility in the reactive layer of the HDRC3 architecture.

This clean separation has a number of advantages besides extensibility and modularity. A declarative specification of tasks permits the sharing of tasks implemented in different ways across platforms. This is especially important in the context of collaborative robotics and heterogeneous robotic systems. It also permits the translation of other task languages into a common representation. The translation of the output of automated task planners is a case in point. There is a direct mapping from the declarative output of a planner to grounded executable components in the architecture.

The DyKnow system is another extensible and modular functionality. Any source in an architecture can become a stream-based data source. One naturally thinks of sensors as specific sources of data, but at another extreme, one can think of another platform as a source of streamed data or a data base or the Internet. The DyKnow system provides means for specifying, constructing, generating, using, and managing these diverse sources of data contextually at many different levels of abstraction. This is a unique component in the HDRC3 architecture that has had widespread use by other functionalities such as the execution monitoring system and the task and motion planners.

Traditionally, verification and validation of autonomous systems has been a central research issue. In the context of unmanned aircraft, a great deal of research has focused on the Control Kernel and to some extent the lower parts of the reactive layer. In terms of the reactive layer itself and in particular the highly nondeterministic functionality associated with the deliberative layer, very little effort has been put into verification and validation because tools simply do not exist yet. A great deal of research effort has gone into improving this absence of effort during the development of key functionalities in the HDRC3 architecture. Many of the functionalities there, such as the task planner, the task specification language, the mission specification language, and the execution monitoring system, each have a formal semantics based on the use of Temporal Action Logics.

In fact the use of logic is highly integrated with many of the processes evoked by deliberative functionality. The execution monitoring system is essentially a real-time dynamic model-checking system where temporal models are generated dynamically by DyKnow during the course of operation, and various constraints are checked relative to those models by evaluating formulas through progression and checking for their satisfiability. The output of TALplanner is a formal narrative structure in Temporal Action Logic. Consequently both the process of generating a plan and the resulting output can be reasoned about using inference mechanisms associated with TALplanner.

In summary, this chapter has described an empirically tested unmanned aircraft architecture that combines many years of both engineering and scientific insight acquired through the successful deployment of the UASTL RMAX system in highly

complex autonomous missions. To the extent possible, these insights have been described in a generic manner in the hope that many of the functionalities described can serve as a basis for use by others in the continued and exciting development of such systems.

transportation, formation control, swarm approaches, and intentional cooperation architectures are revised. The chapter also considers UAVs networked with other elements in the environment to support their navigation and, in general, their operation. The chapter refers theoretical work but also emphasizes practical field outdoor demonstrations involving aerial vehicles.

38.1 Introduction

This chapter considers the cooperation of multiple UAVs performing jointly missions such as search and rescue, reconnaissance, surveying, detection and monitoring in dangerous scenarios, exploration and mapping, and hazardous material handling. The coordination of a team of autonomous vehicles allows to accomplish missions that no individual autonomous vehicles can accomplish on its own. Team members can exchange sensor information, collaborate to track and identify targets, perform detection and monitoring activities (Ollero and Maza 2007), or even actuate cooperatively in tasks such as the transportation of loads.

The advantages of using multiple UAVs when comparing to a single powerful one can be categorized as follows:

- *Multiple simultaneous interventions.* A single autonomous vehicle is limited at any one time to sense or actuate in a single point. However, the components of a team can simultaneously collect information from multiple locations and exploit the information derived from multiple disparate points to build models that can be used to take decisions. Moreover, multiple UAVs can apply simultaneously forces at different locations to perform actions that could be very difficult for a single UAV.
- *Greater efficiency.* The execution time of missions such as exploration and searching for targets can be decreased when using simultaneously multiple vehicles.
- *Complementarities of team members.* Having a team with multiple heterogeneous vehicles offers additional advantages due to the possibility of exploiting their complementarities. Thus, for example, ground and/or aerial vehicles with quite different characteristics and onboard sensors can be integrated in the same platform. For instance, the aerial vehicles could be used to collect information from locations that cannot be reached by the ground vehicles, while these ground members of the team could be equipped with heavy actuators. Then, the aerial and ground vehicles could be specialized in different roles. But even considering the UAVs themselves complementarities can be found: the fixed-wing airplanes typically have longer flight range and time of flight, whereas helicopters have vertical take-off and landing capability, better maneuverability, and therefore can hover to obtain detailed observations of a given target.
- *Reliability.* The multi-UAV approach leads to redundant solutions offering greater fault tolerance and flexibility including reconfigurability in case of failures of individual vehicles.
- *Technology evolution.* The development of small, relatively low-cost UAVs is fuelled by the progress of embedded systems together with the developments on

technologies for integration and miniaturization. Furthermore, the progress on communication technologies experienced in the last decade plays an important role in multiple vehicle systems.

- *Cost.* A single vehicle with the performance required to execute some tasks could be an expensive solution when comparing to several low-cost vehicles performing the same task. This is clear for UAVs and particularly in small-size, light, and low-cost versions, where constraints such as power consumption, weight, and size play an important role.

Section 38.2 of this chapter will deal with the general concepts and contains a rough classification of systems with multiple autonomous UAVs. Then, the joint load transportation, formation control, swarm approaches, and teams with intentional cooperation are examined in more detail along Sects. 38.3–38.6. The networking of UAVs with other sensors and actuators in the environment is considered in Sect. 38.7. Finally, Sect. 38.8 concludes the chapter.

38.2 General Concepts and Classification

In the first part of this section, the concepts of coordination and cooperation are briefly presented due to their relevance in any system with multiple autonomous vehicles. Then, the important role of communications in these systems is summarized. Finally, a classification based on the coupling between the vehicles is outlined.

38.2.1 Coordination and Cooperation

In platforms involving multiple vehicles, the concepts of coordination and cooperation play an important role. In general, the coordination deals with the sharing of resources, and both temporal and spatial coordination should be considered. The temporal coordination relies on synchronization among the different vehicles, and it is required in a wide spectrum of applications. For instance, for objects monitoring, several synchronized perceptions of the objects could be required. In addition, spatial coordination of UAVs deals with the sharing of the space among them to ensure that each UAV will be able to perform safely and coherently regarding the plans of the other UAVs and the potential dynamic and/or static obstacles. Some formulations are based on the extension of robotics path planning concepts. In this context, the classical planning algorithms for a single robot with multiple bodies (Latombe 1990; LaValle 2006) may be applied without adaptation for centralized planning (assuming that the state information from all the UAVs is available). The main concern, however, is that the dimension of the state space grows linearly in the number of UAVs. Complete algorithms require time that is at least exponential in dimension, which makes them unlikely candidates for such problems. Sampling-based algorithms are more likely to scale well in practice when there are many UAVs, but the resulting dimension might still be too high. For such cases, there

are also decoupled path planning approaches such as the prioritized planning that considers one vehicle at a time according to a global priority.

Cooperation can be defined as a “joint collaborative behavior that is directed toward some goal in which there is a common interest or reward” (Barnes and Gray 1991). According to Cao et al. (1997), given some task specified by a designer, a multiple-robot system displays cooperative behavior if, due to some underlying mechanism (i.e., the “mechanism of cooperation”), there is an increase in the total utility of the system. The cooperation of heterogeneous vehicles requires the integration of sensing, control, and planning in an appropriated decisional architecture. These architectures can be either centralized or decentralized depending on the assumptions on the knowledge’s scope and accessibility of the individual vehicles, their computational power, and the required scalability. A centralized approach will be relevant if the computational capabilities are compatible with the amount of information to process and the exchange of data meets both the requirements of speed (up-to-date data) and expressivity (quality of information enabling well-informed decision-taking). On the other hand, a distributed approach will be possible if the available knowledge within each distributed vehicle is sufficient to perform “coherent” decisions, and this required amount of knowledge does not endow the distributed components with the inconveniences of a centralized system (in terms of computation power and communication bandwidth requirements). One way to ensure that a minimal global coherence will be satisfied within the whole system is to enable communication between the vehicles of the system, up to a level that will warranty that the decision is globally coherent. One of the main advantages of the distributed approach relies on its superior suitability to deal with the scalability of the system.

38.2.2 Communication and Networking

It should be noticed that communication and networking also play an important role in the implementation of these schemes for multiple unmanned vehicles. Single vehicle communication systems usually have an unshared link between the vehicle and the control station. The natural evolution of this communication technique toward multi-vehicle configurations is the star-shaped network configuration. While this simple approach to vehicles intercommunication may work well with small teams, it could not be practical or cost-effective as the number of vehicles grows. Thus, for example, in multi-UAV systems, there are some approaches of a wireless heterogeneous network with radio nodes mounted at fixed sites, on ground vehicles, and in UAVs. The routing techniques allow any two nodes to communicate either directly or through an arbitrary number of other nodes which act as relays. When autonomous teams of UAVs should operate in remote regions with little/no infrastructure, using a mesh of ground stations to support communication between the mobile nodes is not possible. Then, networks could be formed in an ad hoc fashion, and the information exchanges occur only via the wireless networking equipment carried by the individual UAVs. Some autonomous configurations

(such as close formation flying) result in relatively stable topologies. However, in others, rapid fluctuations in the network topology may occur when individual vehicles suddenly veer away from one another or when wireless transmissions are blocked by terrain features, atmospheric conditions, signal jamming, etc. In spite of such dynamically changing conditions, vehicles in an autonomous team should maintain close communications with others in order to avoid collisions and facilitate collaborative team mission execution. In order to reach these goals, two different approaches have been adopted. One, closer to the classical networks architecture, establishes a hierarchical structure and routes data in the classical down-up-down traversing as many levels of the hierarchy as needed to reach destination. The other prospective direction to assist routing in such an environment is to use location information provided by positioning devices, such as global positioning systems (GPS), thus using what it is called location aware protocols. These two techniques are compatible and can be mixed. For example, some of the levels in a hierarchical approach could be implemented using location aware methods.

38.2.3 Classification of Multi-UAV Architectures

Multi-UAV systems can be classified from different points of view. One possible classification is based on the coupling between the UAVs (see Fig. 38.1):

1. *Physical coupling.* In this case, the UAVs are connected by physical links and then their motions are constrained by forces that depend on the motion of other UAVs. The lifting and transportation of loads by several UAVs lies in this category and will be addressed in Sect. 38.3 of this chapter. The main problem is the motion-coordinated control, taking into account the forces constraints. From the point of view of motion planning and collision avoidance, all the members of the team and the load can be considered as a whole. As the number of vehicles is usually low, both centralized and decentralized control architectures can be applied.
2. *Formations.* The vehicles are not physically coupled, but their relative motions are strongly constrained to keep the formation. Then, the motion planning problem can be also formulated considering the formation as a whole. Regarding the collision avoidance problem within the team, it is possible to embed it in the formation control strategy. Scalability properties to deal with formations of many individuals are relevant, and then, decentralized control architectures are usually preferred. Section 38.4 of the chapter will deal with the formations and will also show how the same techniques can be applied to control coordinated motions of vehicles even if they are not in formation.
3. *Swarms.* They are homogeneous teams of many vehicles which interactions generate emerging collective behaviors. The resulting motion of the vehicles does not lead necessarily to formations. Scalability is the main issue due to the large number of vehicles involved, and then pure decentralized control architectures are mandatory. Section 38.5 of the chapter will be devoted to the swarm approaches.

Fig. 38.1 Graphical illustration of a possible classification for multiple UAVs systems: (a) physical coupling (3 UAVs transporting one object), (b) formations, (c) swarms, and (d) team executing tasks represented by crosses following an intentional cooperation approach. The UAVs are represented by *gray arrows*

4. *Intentional cooperation.* The UAVs of the team move according to trajectories defined by individual tasks that should be allocated to perform a global mission (Parker 1998). These UAV trajectories typically are not geometrically related as in the case of the formations. This cooperation will be considered in Sect. 38.6 of this chapter. In this case, problems such as multi-UAV task allocation, high-level planning, plan decomposition, and conflict resolution should be solved, taking into account the global mission to be executed and the different UAVs involved. In this case, both centralized and decentralized decisional architectures can be applied.

In the rest of sections of this chapter, each type of multi-vehicle system is discussed in further detail. But before to proceed with each one, a general model for each UAV of the team is presented. This model can be particularized to fit any of the types of the above classification, as it will be shown later.

38.2.4 General Model for Each UAV in the Team

Let us consider a team of UAVs that plan their actions according to a set of coordination and cooperation rules R . In particular, it is assumed that the set R includes k possible tasks $\Omega = \{\tau_1, \tau_2, \dots, \tau_k\}$ with n logical conditions requiring a change of task in the current plan. Let $E = \{e_1, e_2, \dots, e_n\}$ be a set of discrete events associated with n logical conditions requiring a change of task during the execution. Each task has a set of m parameters $\Pi = \{\pi^1, \pi^2, \dots, \pi^m\}$ defining its particular characteristics.

Systems composed of a physical plant and a decisional and control engine implementing such kind of cooperation rules R can be modeled as hybrid systems (Fierro et al. 2002; Chaimowicz et al. 2004; Fagiolini et al. 2007; Li et al. 2008). Figure 38.2 shows a simplified hybrid model that summarizes the different interactions that can be found in each member of the classification presented above.

The i -th UAV's current task has a discrete dynamics $\delta : \Omega \times E \rightarrow \Omega$, i.e.,

$$\tau_i^+ = \delta(\tau_i, e_i), \quad (38.1)$$

where $e_i \in E$ is an event (internal or external) requiring a change of task from τ_i to τ_i^+ , both from the set of tasks Ω .

It should be noticed that each task can have a different control algorithm or a different set of parameters for the same controller. The control reconfiguration is triggered in the transition between tasks associated to different events. Event activation is generated by

$$e_i = \Phi(q_i, \varepsilon_i, X_i, \bar{\mu}_i), \quad (38.2)$$

where ε_i represents the internal events (such as changes in the execution states of the tasks) and $\bar{\mu}_i$ is a vector $\bar{\mu}_i = (\mu_{i_1}, \mu_{i_2}, \dots, \mu_{i_{N_m}})$ containing the messages coming from N_m UAVs cooperating with the i -th UAV. Those messages are used, for example, in the negotiation processes involved in the intentional cooperation mechanisms and are generated onboard each UAV by a decisional module Δ (see Fig. 38.2). This module encompasses high-level reasoning and planning, synchronization among different UAVs, negotiation protocols for task allocation and conflict resolution purposes, task management and supervision, complex task decomposition, etc.

Regarding the perception of the environment, a database ED with “a priori” knowledge about the environment, including static obstacles, objects of interest, and threats can be available and updated with the new information gathered during the mission. On the other hand, object detection and localization (Merino 2007) is usually required in many applications. The state x of the object to be tracked obviously includes its position p , and for moving objects, it is also convenient to add the velocity \dot{p} into the kinematic part of the state to be estimated. But further information is needed in general. An important objective in some missions is to

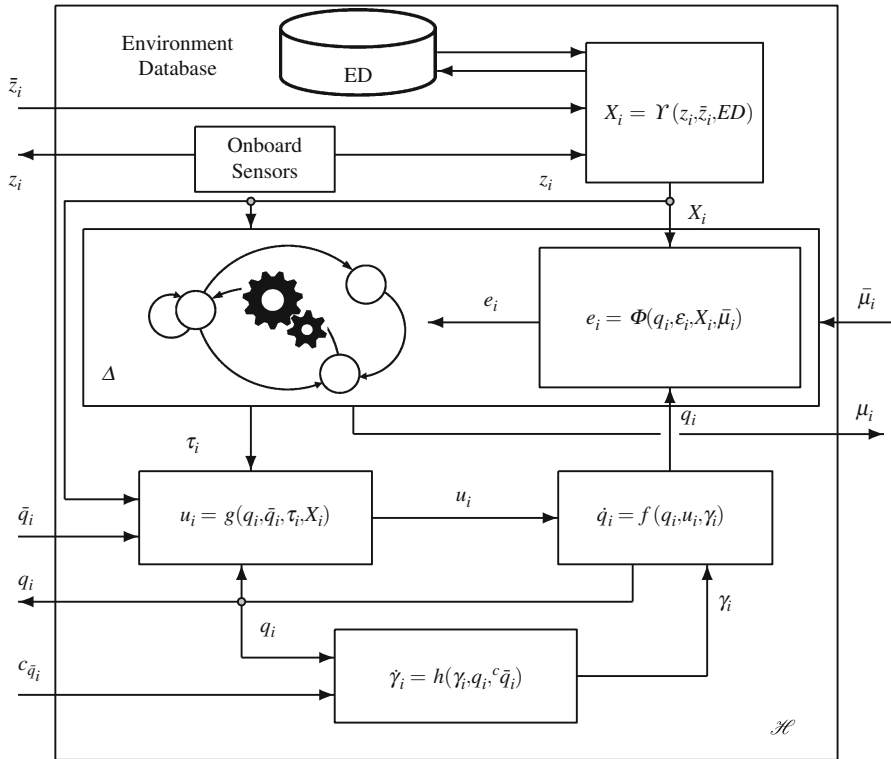

Fig. 38.2 General blocks and interactions considered in the hybrid model for each UAV described in Sect. 38.2

confirm that an object belongs to a certain class within a set Ξ (for instance, in the case of fire alarms detection, this set will include as classes of fire alarms and false alarms). Therefore, the state will include information regarding the classification of the object. Also, in certain applications, some appearance information could be needed to characterize an object, which also can help in the task of data association between different UAVs with different cameras. Additionally, this information could even include the 3D volume of the object that can be added to the obstacles database. In general, the appearance information is static and will be represented by θ .

The complete dynamic state to be estimated is composed by the status of all the objects, N_o , and the number of objects can vary with the time. The state estimated by the i -UAV at time t is then represented by the vector $x_i = [x_{i1}^T, \dots, x_{iN_o}^T]^T$. Each potential object m is defined by $x_{im} = [p_{im} \dot{p}_{im} \theta_{im}]^T$. The information about the objects will be inferred from all the measurements z_i from the sensors onboard the UAVs and \bar{z}_i gathered by the fleet of N_s UAVs that can communicate with the i -th UAV $\{\bar{z}_j, j = 1, \dots, N_s\}$. The latter vector can be completed with the measurements from sensors located around the environment, such as static

surveillance cameras, or nodes from wireless sensor networks (WSNs) deployed in the area of interest. Notice that z_i also contains the forces/torques derived from the interaction with the environment that are measured with the sensors onboard.

On the other hand, let $q_i \in \Theta$ be a vector describing the state of the i -th UAV taking values in the configuration space Θ , and let $\tau_i \in \Omega$ be the task τ that the i -th UAV is currently executing. This UAV's configuration q_i has a continuous dynamics

$$\dot{q}_i = f(q_i, u_i, \gamma_i), \quad (38.3)$$

where $u_i \in \mathcal{U}$ is a control input and $\gamma_i \in \Gamma$ models the dynamics associated to the possible physical interaction with the environment and/or other UAVs

$$\dot{\gamma}_i = h(\gamma_i, q_i, {}^c\bar{q}_i), \quad (38.4)$$

with vector ${}^c\bar{q}_i = (q_{i_1}, q_{i_2}, \dots, q_{i_{N_c}})$ containing the configurations of the N_c neighbors physically connected to the i -th UAV. Then $\gamma_i \neq 0$ only if there is physical interaction.

Regarding u_i , it is a feedback law generated by a low-level controller $g : \Theta \times \bar{\Theta} \times \Omega \times \Upsilon \rightarrow \mathcal{U}$, i.e.,

$$u_i = g(q_i, \bar{q}_i, \tau_i, X_i), \quad (38.5)$$

so that the UAV's trajectory $q_i(t)$ corresponds to the desired current task τ_i , taking into account the configurations of the N neighbors $\bar{q}_i = (q_{i_1}, q_{i_2}, \dots, q_{i_N})$ with influence in the control of the i -th UAV. This influence can be found, for example, in the control problem of swarms and formations. On the other hand, Eq. (38.5) also includes the vector $X_i \in \Upsilon$, taking values in the environment model space Υ , that encompasses estimations about forces/torques derived from the interaction with the environment, targets to the tracked, obstacles detected during the mission and/or known "a priori," threats to be avoided, etc.

In conclusion, the hybrid dynamics \mathcal{H} of the i -th UAV shown in Fig. 38.2 has \bar{z}_i , $\bar{\mu}_i$, \bar{q}_i , and ${}^c\bar{q}_i$ as inputs and z_i , μ_i , and q_i as outputs. This diagram is not intended to be exhaustive or to cover all the possible architectures and existing systems. Instead, it is aimed at providing a general overview of all the possible interactions in order to put into context the approaches presented in the next sections of the chapter.

38.3 Physical Coupling: Joint Load Transportation

The transportation of a single object by multiple autonomous vehicles is a natural extension of the moving by several persons of a large and heavy object that cannot be handled by a single person. The coordinated control of the motion of each vehicle should consider the involved forces induced by the other vehicles and the load itself. Thus, in the scheme depicted in Fig. 38.2, there is a term $\gamma_i \neq 0$ modelling those forces, which is taken into account in the design of the controller in Eq. 38.5.

It should be also mentioned that γ_i can be measured using onboard sensors. For instance, in the case of several UAVs transporting a load using ropes, a force sensor in the rope can provide a measurement of the influence of the other UAVs and the load being transported. Each UAV could be controlled around a common compliance center attached to the transported object. Under the assumption that each UAV holds the object firmly with rigid links, the real trajectories of all of the UAVs are equal to the real trajectory of the object. However, in some transportation problems, this assumption cannot be applied, and the transported object moves with a dynamic behavior that can be expressed by means of Eq. 38.4.

A suitable approach for the required coordinated control is the leader-follower scheme that will be more detailed in the next section. In this scheme, the desired trajectory is the trajectory of the leader. The followers estimate the motion of the leader by themselves through the motion of the transported object. Several examples of this approach can be found in the robotics community. The leader-follower scheme extended to multiple followers and to robots with non-holonomic constraints (Kosuge and Sato 1999) has been implemented in an experimental system with three tracked mobile robots with a force sensor. In Sugar and Kumar (2002), the decentralized control of cooperating mobile manipulators is studied with a designated lead robot being responsible for task planning. The control of each robot is decomposed (mechanically decoupled) into the control of the gross trajectory and the control of the grasp. The excessive forces due to robot positioning errors and odometry errors are accommodated by the compliant arms. In Huntsberger et al. (2004), distributed coordinated control of two rovers carrying a 2.5 m long mockup of a photovoltaic tent is presented and demonstrated as an example of the CAMPOUT behavior-based control architecture. Borenstein (2000) details the OmniMate system, which uses a compliant linkage platform between two differential drive mobile robots (Labmate) that provide a loading deck for up to 114 kg of payload.

Lifting and transportation of loads by using multiple helicopters has been also a research topic for many years motivated by the payload constraints of these vehicles and the high cost of helicopters with significant payload. In addition, the use of multiple manned helicopters is also problematic and only simple operations, like load transportation with two helicopters, can be performed by extremely skillful and experienced pilots. The level of stress is usually very high, and practical applications are therefore rarely possible. Load transportation and deployment by one and several helicopters is very useful for many applications including the delivery of first-aid packages to isolated victims in disasters (floods, earthquakes, fires, industrial disasters, and many others) and is also a basic technology for other future applications: the building of platforms for evacuation of people in rescue operations and the installation of platforms in uneven terrains for landing of manned and unmanned VTOL aircrafts. This later application would first require the installation of the supporting units defining the horizontal surface and later the installation of the surface itself.

Fig. 38.3 Three autonomous helicopters from the Technical University of Berlin (*TUB-H* model) transporting a wireless camera to the top floor of a building with a height of 12 m in May 2009. A device onboard each helicopter is equipped with a force sensor to estimate the influence of the other helicopters and the load itself – term γ_i in Eq. 38.4. The images show the mission during the actual load transportation (*left*) and shortly before the load deployment (*right*). A fourth helicopter which was used to acquire airborne video footage of the mission is visible on the *right*

The autonomous lifting and transportation by two helicopters (twin lift) has been studied since the beginning of the nineties by means of nonlinear adaptive control (Mittal et al. 1991) and H_∞ control (Reynolds and Rodriguez 1992). In Lim et al. (1999) an interactive *modeling, simulation, animation, and real-time control* (MoSART) tool to study the twin lift helicopter system is presented. However, only simulation experiments have been found until December 2007, when lifting and transportation of a load by means of three autonomous helicopters (Bernard and Kondak 2009) was demonstrated experimentally in the framework of the AWARE project. After that first successful test, the load transportation system was used again in 2009 to deploy a camera on the roof of a building with a height of 12 m (see Fig. 38.3) in the framework of the same project (Bernard et al. 2011). Notice that in this case, the physical coupling between UAS are involved through direct interactions of each unmanned aerial vehicle with the joint load.

Small-size single or multiple autonomous quadrotors are also considered for load transportation and deployment in Michael et al. (2011), Palunko et al. (2012), and Sreenath et al. (2013). Dynamically coupled quadrotors should cooperate safely to transport load, in contrast to the existing results on formation control of decoupled multi-UAV systems that are addressed in the next section.

38.4 Vehicle Formations and Coordinated Control

In the formations, the members of the group of vehicles must keep user-defined distances with the other group members. The control problem consists of maintaining these user-defined distances, and consequently the configurations of the N neighbors $\bar{q}_i = (q_{i1}, q_{i2}, \dots, q_{iN})$ in the formation should be taken into account in the control law (see Eq. 38.5). Those configurations can be either received via inter-vehicle communication or estimated using the sensors onboard. Anyway, formation control involves the design of distributed control laws with limited and disrupted communication, uncertainty, and imperfect or partial measurements.

Vehicle formation is a basic strategy to perform multi-vehicle missions including searching and surveying, exploration and mapping, active reconfigurable sensing systems, and space-based interferometry. An added advantage of the formation paradigm is that new members can be introduced to expand or upgrade the formation or to replace a failed member. The stability of the formation has been studied by many researchers that have proposed robust controllers to provide insensitivity to possibly large uncertainties in the motion of nearby agents, transmission delays in the feedback path, and the consideration of the effect of quantized information.

The close formation flight control of homogeneous teams of fixed-wing UAVs airplanes received attention in the last 10 years. The large group formation of small UAVs also offers benefits in terms of drag reduction and then increased payoffs in the ability to maintain persistent coverage of a large area. Both linear (Giulietti et al. 2000) and nonlinear control laws (Schumacher and Singh 2000) have been proposed and tested in simulation. However, practical implementations are still very scarce. In How et al. (2004) a demonstration of two fixed-wing UAVs simultaneous flying, the same flight plan (tracking waypoints in open-loop formation) is reported. In the same paper, two UAVs were linked to the same receding horizon trajectory planner, and independent timing control was performed about the designed plans.

The leader-follower approach mentioned in the previous section has been also used to control general formations where the desired positions of followers are defined relative to the actual state of a leader. It should be noted that every formation can be further divided into simplest leader-follower schemes. Then, in this approach, some vehicles are designated as leaders and track predefined trajectories, while the followers track transformed versions of these trajectories according to given schemes. In the leader-follower approach, path planning only needs to be performed in the leader workspace. The leader-follower pattern is adopted in Yun et al. (2010) to maintain a fixed geometrical formation of unmanned helicopters while navigating following certain trajectories. The leader is commanded to fly on some predefined trajectories, and each follower is controlled to maintain its position in formation using the measurement of its inertial position and the information of the leader position and velocity, obtained through a wireless modem. In Gu et al. (2006) two-aircraft formation flights confirmed the performance of a formation

controller designed to have an inner- and outerloop structure, where the outerloop guidance control laws minimized the forward, lateral, and vertical distance error by controlling the engine propulsion and generating the desired pitch and roll angles to be tracked by the innerloop controller. In the formation flight configuration, a radio control pilot maintained ground control of the leader aircraft, while the autonomous follower aircraft maintained a predefined position and orientation with respect to the leader aircraft. The leader-follower approach is applied in Galzi and Shtessel (2006) in the design of robust and continuous controllers to achieve collision-free path-tracking formation in the presence of unknown bounded disturbances acting on each UAV. In Bayraktar et al. (2004) an experiment with two fixed-wing UAVs is presented. The leader UAV was given a predetermined flight plan, and the trajectory of the UAV was updated once per second in real time through the ground station to keep the follower at a fixed distance offset from the leader. Finally, the vehicles platooning can be considered as a particular case consisting of a leader followed by vehicles in a single row. Both lateral and longitudinal control to keep the safe headway, and lateral distance should be considered. The simplest approach relies on individual vehicle control from the data received from the single immediate front vehicle (Bom et al. 2005).

Other methods are based on a virtual leader, a moving reference point whose purpose is to direct, herd, and/or manipulate the vehicle group behavior. The lack of a physical leader among the vehicles implies that any vehicle is interchangeable with any other in the formation. A solution based on a virtual leader approach combined with an extended local potential field is presented in Paul et al. (2008) for formation flight and formation reconfiguration of small-scale autonomous helicopters. And for fixed-wing models, experimental results with YF-22 research aircrafts can be found in Campa et al. (2007), validating the performance of a formation control law using also a virtual leader configuration.

Practical applications of formation control should include a strategy for obstacle avoidance and reconfiguration of the formation. The avoidance of big obstacles could be performed by changing the trajectory of the whole formation to go around the obstacle or to pass through a narrow tunnel (Desai et al. 2001). If the obstacles are smaller than the size of the formation, the vehicles should be able to compromise the formation until the obstacle is passed. In order to do so, the obstacle avoidance behavior should be integrated in the control strategy of the individual members of the formation to avoid/bypass obstacles. Hybrid control techniques have been applied to avoid obstacles and solve the formation reconfiguration (Zelinski et al. 2003).

Formation is not the only cooperative scheme for UAVs in applications such as exploration and mapping. The cooperation of multiple UAVs can be also examined from the point of view of the intentionality to achieve a given mission. Then, according to Parker (1998), it is possible to distinguish between intentional cooperation and swarm-type cooperation. Those approaches are considered in the following two sections:

38.5 Swarms

The key concept in the swarms is that complex collective global behaviors can arise from simple interactions between large numbers of relatively unintelligent agents. This swarm cooperation is based on concepts from biology (Sharkey 2006) and typically involves a large number of homogeneous individuals, with relatively simple sensing and actuation, and local communication and control that collectively achieve a goal. This can be considered as a bottom-up cooperation approach. It usually involves numerous repetitions of the same activity over a relatively large area. The agents execute the same program and interact only with other nearby agents by measuring distances and exchanging messages.

Thus, according to Fig. 38.2 the configurations of the N neighbors $\bar{q}_i = (q_{i_1}, q_{i_2}, \dots, q_{i_N})$ should be considered as well as the messages $\bar{\mu}_i = (\mu_{i_1}, \mu_{i_2}, \dots, \mu_{i_{N_m}})$ coming from N_m UAVs cooperating with the i -th UAV. Nevertheless, it should be mentioned that depending on the particular communication and sensing capabilities of the UAVs in the swarm, simplified mechanisms based on partial or imperfect information could be required. For example, the estimation of the full vector \bar{q}_i is not possible in many swarm-based systems, and partial information such as the distances with the neighbors is the only measurement available. The same is applicable to the messages interchanged that can range from data packets sent through wireless links to simple visual signals based on lights of different colors.

The concept of operations for a micro-UAV system is adopted from nature from the appearance of flocking birds, movement of a school of fish, and swarming bees among others. This “emergent behavior” is the aggregate result of many simple interactions occurring within the flock, school, or swarm. Exploration of this emergent behavior in a swarm is accomplished through a high-performance computing parallel discrete event simulation in Corner and Lamont (2004). In Kube and Zhang (1993) different mechanisms that allow populations of behavior-based robots to perform collectively tasks without centralized control or use of explicit communication are presented. Mataric (1992) provides the results of implementing group behaviors such as dispersion, aggregation, and flocking on a team of robots. In Kovacina et al. (2002) a rule-based, decentralized control algorithm that relies on constrained randomized behavior and respects UAV restrictions on sensors, computation, and flight envelope is presented and evaluated in a simulation of an air vehicle swarm searching for and mapping a chemical cloud within a patrolled region. Another behavior-based decentralized control strategy for UAV swarming by using artificial potential functions and sliding-mode control technique is presented in Han et al. (2008). Individual interactions for swarming behavior are modeled using the artificial potential functions. For tracking the reference trajectory of the swarming of UAVs, a swarming center is considered as the object of control. The sliding-mode control technique is adopted to make the proposed swarm control strategy robust with respect to the system uncertainties and varying mission environment.

The bio-inspired motivation of swarms can be found, for example, in Zhang et al. (2007), which describes an adaptive task assignment method for a team of fully distributed vehicles with initially identical functionalities in unknown task environments. The authors employ a simple self-reinforcement learning model inspired by the behavior of social insects to differentiate the initially identical vehicles into “specialists” of different task types, resulting in stable and flexible division of labor; on the other hand, in dealing with the cooperation problem of the vehicles engaged in the same type of task, the so-called *ant system* algorithm was adopted to organize low-level task assignment. Dasgupta (2008) presents a multiagent-based prototype system that uses swarming techniques inspired from insect colonies to perform automatic target recognition using UAVs in a distributed manner within simulated scenarios. In Altshuler et al. (2008) a swarm of UAVs is used for searching one or more evading targets, which are moving in a predefined area while trying to avoid a detection by the swarm (Cooperative Hunters problem). By arranging themselves into efficient geometric flight configurations, the UAVs optimize their integrated sensing capabilities, enabling the search of a maximal territory.

In general, the above approaches deal with homogeneous teams without explicit consideration of tasks decomposition and allocation, performance measures, and individual efficiency constraints of the members of the team. Those aspects are considered in the intentional cooperation schemes described in the next section.

38.6 Intentional Cooperation Schemes

In the intentional cooperation approaches, each individual executes a set of tasks (subgoals that are necessary for achieving the overall goal of the system and that can be achieved independently of other subgoals) explicitly allocated to perform a given mission in an optimal manner according to planning strategies (Parker 1998). The UAVs cooperate explicitly and with purpose but also has the limitation of independent subgoals: If the order of task completion is mandatory, additional explicit knowledge has to be provided to state ordering dependencies in the preconditions. It is also possible to follow a design based on “collective” interaction, in which entities are not aware of other entities in the team, yet they do share goals, and their actions are beneficial to their teammates (Parker 2008).

Key issues in these systems include determining which UAV should perform each task (task allocation problem) so as to maximize the efficiency of the team and ensuring the proper coordination among team members to allow them to successfully complete their mission. In order to solve the multi-robot task allocation problem, some metrics to assess the relevance of assigning given tasks to particular robots are required. In Gerkey and Matarić (2004) a domain-independent taxonomy for the multiagent task allocation problem is presented. In the last years, a popular approach to solve this problem in a distributed way is the application of market-based negotiation rules. An usual implementation of those distributed negotiation rules (Botelho and Alami 1999; Dias and Stenz 2002; Gerkey and Matarić 2002) is

based on the Contract Net Protocol (Smith 1980). In those approaches, the messages $\bar{\mu}_i = (\mu_{i1}, \mu_{i2}, \dots, \mu_{iN_m})$ coming from N_m UAVs cooperating with the i -th UAV are those involved in the negotiation process: announce a task, bid for a task, allocate a task, ask for the negotiation token, etc.

Once the tasks have been allocated, it is necessary to coordinate the motions of the vehicles, which can be done by means of suitable multi-vehicle path/velocity planning strategies, as mentioned in Sect. 38.2. The main purpose is to avoid potential conflicts among the different trajectories when sharing the same working space. It should be mentioned that even if the vehicles are explicitly cooperating through messages, a key element in many motion coordination approaches is the updated information about the configurations of the N neighbors $\bar{q}_i = (q_{i1}, q_{i2}, \dots, q_{iN})$. Formal approaches to the collision avoidance problem and different approaches that can be applied to solve it can be found in LaValle (2006) and Latombe (1990).

On the other hand, teams composed by heterogeneous members involve challenging aspects, even for the intentional cooperation approach. In Ollero and Maza (2007) the current state of the technology, existing problems, and potentialities of platforms with multiple UAVs (with emphasis on systems composed by heterogeneous UAVs) are studied. This heterogeneity is twofold: firstly in the UAV platforms looking to exploit the complementarities of the aerial vehicles, such as helicopters and airships, and secondly in the information-processing capabilities onboard, ranging from pure remotely teleoperated vehicles to fully autonomous aerial robots.

The multi-UAV coordination and control architecture developed in the European COMETS project (Gancet et al. 2005) was demonstrated for the autonomous detection and monitoring of fires (Ollero and Maza 2007) by using two helicopters and one airship (see Fig. 38.4). Regarding teams involving aerial and ground vehicles, the CROMAT architecture also implemented cooperative perception and task allocation techniques (Viguria et al. 2010) that have been demonstrated in fire detection, monitoring, and extinguishing. Multiagent (combined ground and air) tasking and cooperative target localization have been also demonstrated recently (Hsieh et al. 2007) as well as multi-target tracking (ground vehicles) with a micro-UAV (He et al. 2010).

In Maza et al. (2011) a distributed architecture for the autonomous coordination and cooperation of multiple UAVs for civil applications is presented. The architecture is endowed with different modules that solve the usual problems that arise during the execution of multipurpose missions, such as task allocation, conflict resolution, and complex task decomposition. One of the main objectives in the design of the architecture was to impose few requirements to the execution capabilities of the autonomous vehicles to be integrated in the platform. Basically, those vehicles should be able to move to a given location and activate their payload when required. Thus, heterogeneous autonomous vehicles from different manufacturers and research groups can be integrated in the architecture developed, making it easily usable in many multi-UAV applications. The software implementation of the architecture was tested in simulation and finally validated in field experiments with four autonomous helicopters. The validation process included several multi-UAV missions for civil applications in a simulated urban setting: surveillance applying

Fig. 38.4 Coordinated flights in the COMETS project involving an airship and two autonomous helicopters

the strategies for multi-UAV cooperative searching presented in Maza and Ollero (2007); fire confirmation, monitoring, and extinguishing; load transportation and deployment with single and multiple UAVs; and people tracking.

Finally, cooperative perception can be considered as an important tool in many applications based on intentional cooperation schemes. It can be defined as the task of creating and maintaining a consistent view of a world containing dynamic objects by a group of agents each equipped with one or more sensors. Thus, a team of vehicles can simultaneously collect information from multiple locations and exploit the information derived from multiple disparate points to build models that can be used to take decisions. In particular, cooperative perception based on artificial vision has become a relevant topic in the multi-robot domain, mainly in structured environments (Thrun 2001; Schmitt et al. 2002). In Merino et al. (2006) cooperation perception methods for multi-UAV system are proposed. Each UAV extracts knowledge, by applying individual perception techniques, and the overall cooperative perception is performed by merging the individual results. This approach requires knowing the relative position and orientation of the UAVs. In many outdoor applications, it is assumed that the position of all the UAVs can be obtained by means of GPS and broadcasted through the communication system. However, if this is not the case, the UAVs should be capable of identifying and of localizing each other (Konolige et al. 2003) which could be difficult with the onboard sensors. Another approach consists of identifying common objects in the scene. Then, under certain assumptions, the relative pose displacement between the vehicles can be computed from these correspondences. In Merino et al. (2006) this strategy has been demonstrated with heterogeneous UAVs. In the ANSER project (see, e.g., Sukkarieh et al. 2003), decentralized sensor data fusion using multiple aerial vehicles is also researched and experimented with fixed-wing UAVs with navigation and terrain sensors.

38.7 UAVs Networked with Sensors and Actuators in the Environment

The development of wireless communication technologies in the last 10 years makes possible the integration of autonomous vehicles with the environment infrastructure. Particularly, the integration with wireless sensor and actuator networks is very promising. The benefit of this integration can be seen from two different points of view:

- The use of UAVs to complement the information collected by the wireless sensor network (WSN), to perform as mobile “data mules,” to act as communication relays, to improve the connectivity of the network, and to repair it in case of malfunctioning nodes.
- The use of WSNs as an extension of the sensorial capabilities of the UAVs. In this case, the information about the objects in the environment will be inferred from all the measurements z_i from the sensors onboard and \bar{z}_i gathered by the fleet of N_s UAVs and nodes that can communicate with the i -th UAV $\{\bar{z}_j, j = 1, \dots, N_s\}$.

Static wireless sensor networks have important limitations as far as the required coverage and the short communication range in the nodes are concerned. The use of mobile nodes could provide significant improvements. Thus, they can provide the ability to dynamically adapt the network to environmental events and to improve the network connectivity in case of static nodes failure. Node mobility for ad hoc and sensor networks has been studied by many researchers (Grossglauser and Tse 2002; Venkitasubramaniam et al. 2004). Moreover, mobile nodes with single-hop communication and the ability to recharge batteries, or refueling, have been proposed as data mules of the network, gathering data while they are near of fixed nodes and saving energy in static node communications (Jain et al. 2006). The coordinated motion of a small number of nodes in the network to achieve efficient communication between any pair of other mobile nodes has been also proposed.

An important problem is the localization of the nodes of a WSN. This is an open problem because GPS-based solutions in all the nodes are usually not viable due to the cost, the energy consumption, and the satellite visibility from each node. In Caballero et al. (2008) a probabilistic framework for the localization of an entire WSN based on a vehicle is presented. The approach takes advantage of the good localization capabilities of the vehicle and its mobility to compute estimation of the static nodes positions by using the signal strength of the messages interchanged with the network.

However, in many scenarios, the motion of the mobile nodes installed on ground vehicles or carried by persons is very constrained, due to the characteristics of the terrain or the dangerous conditions involved, such as in civil security and disaster scenarios. The cooperation of aerial vehicles with the ground wireless sensor network offers many potentialities. The use of aircrafts as data sinks when they fly over the fixed sensor networks following a predictable pattern in order to

Fig. 38.5 Sensor deployment from an autonomous helicopter in the AWARE project experiments carried out in 2009

gather data from them has been proposed by several authors in the WSN community. In Corke et al. (2003) an algorithm for path computation and following is proposed and applied to guide the motion of an autonomous helicopter flying very close to the sensor nodes deployed on the ground.

It should be noticed that flight endurance and range of the currently available low-cost UAVs is very constrained (Ollero and Merino 2004). Moreover, reliability and fault tolerance is a main issue in the cooperation of the aerial vehicles. Furthermore, these autonomous vehicles need communication infrastructure to cooperate or to be teleoperated by humans in emergency conditions. Usually this infrastructure is not available, or the required communication range is too large for the existing technology. Then, the deployment of this communication infrastructure is a main issue. In the same way, in most wireless sensor networks projects, it is assumed that the wireless sensor network has been previously fully deployed without addressing the problems to be solved when the deployment is difficult. Moreover, in the operation of the network, the infrastructure could be damaged or simply the deployment is not efficient enough. Then, the problem is the repairing of the coverage or the connectivity of the network by adding suitable sensor and communication elements. In Corke et al. (2004) the application of an autonomous helicopter for the deployment and repairing of a wireless sensor network is proposed. This approach has been also followed in the AWARE project (Maza et al. 2010), whose platform has self-deployment and self-configuration features for the operation in sites without sensing and communication infrastructure. The deployment includes not only wireless sensors (see Fig. 38.5) but also heavier loads such as communication equipment that require the transportation by using several helicopters (see Fig. 38.3).

38.8 Conclusions

The concepts of coordinated and cooperative control of multiple UAVs deserved significant attention in the last years in the control, robotics, artificial intelligence, and communication communities. The implementation of these concepts involve integrated research in the control, decision, and communication areas. For instance, the communication and networking technologies play an important role in the practical implementation of any multi-vehicle system. Thus, the integrated consideration of communication and control problems is a relevant research and development topic.

This chapter has first reviewed the existing work on the transportation of a single load by different autonomous vehicles. In order to solve this problem, control theory based on models of the vehicles and their force interactions have been applied. The chapter also studied formation control. In this problem, the application of control theory based on models of the vehicles is dominant. However, behavior-based approaches that do not use these models have been also demonstrated. The work on swarms has been also reviewed. Approaches inspired in biology and multiagent systems are common. The problems are typically formulated for large number of individuals, but up to now, the practical demonstrations involve few physical UAVs. The intentional task-oriented cooperation of robotic vehicles, possibly heterogeneous, has been also addressed. The task allocation problem and the path planning techniques play an important role here, as well as the application of cooperative perception methods.

Finally, the chapter has explored the integration and networking of one or many UAVs with sensors and actuators in the environment pointing out the benefits of this integration. The self-deployment of the network and the motion planning to maintain quality of service are promising approaches that have been preliminarily studied but still require significant attention.

Abstract

There has been significant recent research activity attempting to streamline Unmanned Aerial Vehicle (UAV) operations and reduce staffing in order to invert the current many-to-one ratio of operators to vehicles. Centralized multiple UAV architectures have been proposed where a single operator interacts with and oversees every UAV in the network. However, a centralized network requires significant operator cognitive resources. Decentralized multiple UAV networks are another, more complex possible architecture where an operator interacts with an automated mission and payload manager, which coordinates a set of tasks for a group of highly autonomous vehicles. While a single operator can maintain effective control of a relatively small network of centralized UAVs, decentralized architectures are more scalable, particularly in terms of operator workload, and more robust to single points of failure. However, in terms of operator workload, the ultimate success of either a centralized or decentralized UAV architecture is not how many vehicles are in the network per se but rather how many tasks the group of vehicles generates for the operator and how much autonomy is onboard these vehicles. Task-based control of UAV architectures with higher degrees

M.L. Cummings
Department of Aeronautics and Astronautics, Massachusetts Institute of Technology, Cambridge, MA, USA
e-mail: m.cummings@duke.edu

of autonomy (i.e., decentralized networks) can mitigate cognitive overload and reduce workload. Mutually exclusive boundaries for humans and computers in multiple UAV systems should not be the goal of designers for either centralized or decentralized architectures, but rather more effort needs to be spent in defining mutually supportive roles such that humans and computers complement one another.

39.1 Introduction

The use of unmanned aerial vehicles (UAVs), often referred to as drones, has recently revolutionized military operations worldwide and holds similar promise for commercial settings. The U.S. Air Force now has more UAVs than manned aircraft, small UAVs are now used worldwide by various first response and police units, and they can be found fighting forest fires, monitoring wildlife and possible poachers, in cargo missions and even in entertainment.

UAVs require human guidance to varying degrees and often through several operators. Most military and government UAVs require a crew of two to be fully operational. Conventional stick-and-rudder skills have been replaced by point-and-click control so that traditional pilots are no longer needed to control such systems. Onboard automation currently determines the most efficient control response, which is true in many commercial aircraft. While one operator supervises the actual flight activity of the UAV (the “pilot”), the other operator typically monitors the UAV’s sensors, such as a camera, and coordinates with the “pilot” so that he or she can maneuver the UAV for the best system response.

There has been significant recent research activity attempting to streamline UAV operations and reduce staffing in order to invert the current many-to-one ratio of operators to vehicles. This is important not just for military operations but also for future commercial operations where air traffic controllers will direct both manned and unmanned aircraft. This chapter will discuss the implications of this staffing inversion for multiple UAV control, particularly in terms of two UAV control architectures, centralized and decentralized. It should be noted that these two architectures are not mutually exclusive and that there really exists a continuum of architectures in between these two bookends. Moreover, while there are many aspects of control architectures that are critical to consider, this chapter focuses on the human implications of such control architectures.

39.2 Operator Interaction in Centralized UAV Architectures

The shift from stick-and-rudder to point-and-click control in UAVs represents a shift in the role of humans from the need for highly rehearsed skill sets to more knowledge-based reasoning inputs. For UAVs and for fly-by-wire military and commercial aircraft, pilots are less in direct manual control of systems but more involved in the higher levels of planning and decision making, particularly for

Fig. 39.1 Human supervisory control (Sheridan and Verplank 1978)

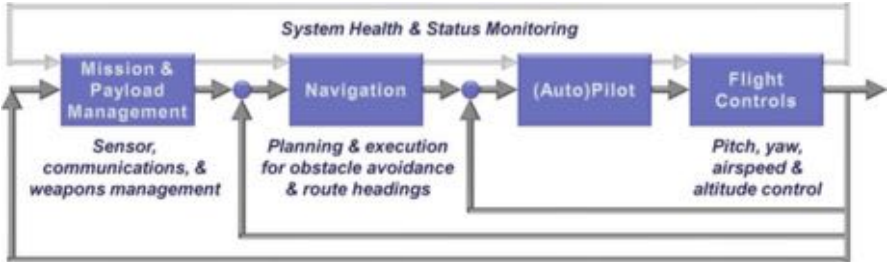

Fig. 39.2 Hierarchical control loops for a single UAV

remote operations. This shift in control from lower-level skill-based behaviors to higher-level knowledge-based behaviors is known as Human Supervisory Control (HSC). HSC is the process by which a human operator intermittently interacts with a computer, receiving feedback from and providing commands to a controlled process or task environment, which is connected to that computer (Sheridan and Verplank 1978) (Fig. 39.1).

In a centralized UAV control architecture, human supervisory control in UAV operation is hierarchical, as represented in Fig. 39.2. The innermost loop of Fig. 39.2 represents the basic guidance and motion control loop, which is the most critical loop that must obey physical laws of nature such as aerodynamic constraints for UAVs. In this loop, the autopilot optimizes local control (keeping the aircraft in stable flight), and while UAV pilots could theoretically take control in this loop, with inherent time latencies that can cause pilot-induced instabilities, this loop is generally left to the automation.

The second loop, the navigation loop, represents the actions that some agent, whether human or computer, must execute to meet mission constraints such as routes to waypoints, time on targets, and avoidance of threat areas and no-fly zones. In most current systems, humans enter GPS coordinates as waypoints, and then the system automatically flies to these waypoints. Only now are more advanced automated path planners that generate entire missions instead of serial waypoints starting to appear in operationally deployed UAV systems.

The outermost loop of Fig. 39.2 represents the highest levels of control, that of mission and payload management. In this loop, sensors must be monitored and decisions made based on the incoming information to meet overall mission requirements.

In the mission management loop, human operators provide the greatest benefit since their decisions require knowledge-based reasoning that includes judgment, experience, and abstract reasoning that in general cannot be performed by automation.

Finally, the system health and status monitoring loop on the top of Fig. 39.2 represents the continual supervision that must occur, either by a human or automation or both, to ensure all systems are operating within normal limits. This control loop is a highly intermittent loop in terms of the human, i.e., if the human is engaged in another task, with the highest priority given to the innermost loop, health and status monitoring becomes a distant, secondary task.

From the human-in-the-loop perspective, if the inner loops fail, then the higher (outer) loops will also fail. The dependency of higher loop control on the successful control of the lower loops drives human limitations in control of a single and, especially so, for multiple UAVs. If humans must interact in the guidance and motion control loop (e.g., manually fly a UAV), the cost is high because this effort requires significant cognitive resources. What little spare mental capacity is available must be divided between the navigation and mission management control loops. Violations of the priority scheme represented in Fig. 39.2 have led to numerous crashes (Williams 2004). When operators become cognitively saturated or do not correctly allocate their cognitive resources to the appropriate control loops in the correct priorities, they violate the control loops constraints, potentially causing catastrophic failure.

39.3 Operator Capacity in Centralized UAV Architectures

In centralized UAV systems supervised by a human, the primary consideration for system design is how many vehicles a single controller can effectively supervise. Since this supervisor has to interact with each vehicle individually, just how many vehicles can be effectively and safely controlled will primarily be driven by the amount of autonomy onboard the aircraft, which is subsumed across the four loops as shown in Fig. 39.2.

By increasing UAV autonomy, operator workload will theoretically be reduced as it could reduce the number of tasks for the operator, and it should reduce the level of interaction even at the highest levels of control in Fig. 39.2. For example, those UAVs that are flown in an autopilot mode relieve the operator from the manual flying tasks that require significant cognitive resources. This frees the operator to perform other critical tasks like mission planning and imagery analysis.

While there have been many studies that have attempted to experimentally derive the number of UAVs a single operator can control in a given setting (e.g., Ruff et al. 2002; Dixon et al. 2003; Cummings and Guerlain 2007), model-based approaches are generally more useful in determining not only an upper bound, but also provide insight into how much autonomy will be needed if a certain number of UAVs in a system is desired.

Fig. 39.3 The relationship between interaction, neglect, and wait times (Cummings and Mitchell 2008)

One such approach is the fan-out approach (Olsen and Wood 2004), which predicts the upper bound of the number of vehicles a single operator can control given the amount of autonomy in a vehicle as represented through its neglect time (NT) and the required human-computer interaction called interaction time (IT). The fan-out model was later modified to account for wait times that would inevitably be experienced by the system due to human inefficiencies. This adjustment provides a more realistic and lowered upper bound (Cummings and Mitchell 2008). For example, one UAV can operate in a period of NT, and during that period of NT, the operator can attend to other vehicles. However, if an operator fails to notice that a UAV needs assistance (such as needing a new goal once a waypoint has been achieved), or becomes engrossed in a mission plan for a UAV with a system malfunction, one or more UAVs can wait for the operator's attention, causing a delay for one or more vehicles.

Figure 39.3 represents how NT, IT, and wait times (WT) interrelate. Point A represents a discrete event that occurs after a period of neglect time, which causes the vehicle to require immediate operator assistance such as an engine loss. NTs may not be so clearly observable, as exemplified by Point B, which represents performance degradation causing vehicle performance to drop below the NT performance threshold, e.g., a slow degradation of an inertial navigation system. In both NT cases in centralized UAV architectures, once performance has dropped below an acceptable level requiring human interaction, the UAV must wait until the operator recognizes and solves the problem and so that the UAV can move to another NT state. Point C illustrates the system time delay if the problem is not addressed at the appropriate time.

Equation 39.1 represents the fan-out mathematical relationship where NT and IT are as defined above. However, it should be noted that IT should account for not just the time an operator inputs commands to a UAV, but also it should include delays where an operator has entered a command and waits for a system's response.

Wait times that add delays to the necessary ITs are accounted for in a separate term as defined by Eq. 39.2.

$$FO = \frac{NT}{IT + WT} + 1 \quad (39.1)$$

$$WT = \sum_{i=1}^X WTQ_i + \sum_{j=1}^Y WTSA_j \quad (39.2)$$

WT: Wait time

WTQ: Queuing wait time

WTSA: Wait time caused by a loss of situation awareness

X = Number of human-automation interaction queues that build

Y = Number of time periods in which a loss of SA causes wait time

In Eq. 39.2, WTQ, or wait time due to queue, results when multiple UAVs require attention, but the operator can only serially attend to them, effectively causing a queue to form for the operator's attention. For example, if an operator is controlling two UAVs on a search mission and both require the operator to insert waypoints near-simultaneously, the second UAV may have to loiter in place while the operator attends to the first. Assuming the operator can switch attention quickly once the first UAV is back to NT, the time the second UAV waits in the queue (WTQ) is effectively the IT for the first vehicle.

WTSA, or wait time due to a loss of situation awareness, is perhaps the most difficult wait time component to model because it represents how effectively an operator can manage his or her attention. Situation awareness (SA) is generally defined as having three levels, which are (1) the perception of the elements in the environment, (2) the comprehension of the current situation, and (3) the projection of future status (Endsley 1995). While SA can decrease under high workload due to competition for attentional resources (Andre and Wickens 1995), it can also decrease under low workload due to boredom and complacency (Rodgers et al. 2000). If an operator does not realize a UAV needs attention (and thus experiences a loss of SA), the time from the initial onset of the need for IT to actual operator recognition of the problem could range from seconds to minutes.

Thus, Eq. 39.2 categorizes system wait times as the summation of wait times that result from queues due to near-simultaneous arrival of events that require human intervention plus the wait times due to the operator loss of SA. Wait times increase overall IT and reduce the number of vehicles a single operator can supervise.

In terms of operator capacity, Eq. 39.2 demonstrates that as a UAV's degree of autonomy increases (expressed as an increase in NT), holding all other parameters equal means that a single operator could control more vehicles. Consequently, for a fixed NT (or degree of autonomy), operator capacity could be increased by making the ground control station interactions more streamlined (i.e., lower IT) or ensuring all the correct alarms are in place so that operators do not miss critical points of interventions (i.e., lower WTSA).

Table 39.1 Levels of autonomy

| LOA | Automation description |
|-----|--|
| I | The computer offers no assistance: human must take all decision and actions |
| II | The computer offers a complete set of decision/action alternatives |
| III | The computer offers a selection of decisions/actions |
| IV | The computer suggests a plan and executes that suggestion if the human approves (management by consent) |
| V | The computer suggests a plan and allows the human a restricted time to veto before automatic execution (management by exception) |
| VI | The human is not involved in the decision-making process; the computer decides and executes autonomously |

Table 39.2 Multiple UAV Study Comparison

| | Experiment | LOA | Max UV# |
|---|----------------------------------|--------|---------|

A meta-analysis of several previous studies looking at various levels or degrees of automation/autonomy in centralized single operator control of multiple UAVs, particularly at the mission management level (the outermost loop in Fig. 39.2), demonstrates that as NT increases (meaning the degree of autonomy increases), the maximum number of unmanned vehicles a single operator can control increases (Cummings and Mitchell 2008) (Tables 39.1 and 39.2 and Fig. 39.4). The levels of autonomy (LOAs) in Table 39.1 are loosely modeled on Sheridan’s levels of automation framework (Sheridan and Verplank 1978). While there have been numerous other levels of automation and autonomy proposed for UAVs, as recently highlighted by a 2012 Department of Defense report (Defense Science Board 2012), such frameworks pose many problems. These LOAs used here only illustrate increasing degrees of autonomy and thus NT and are not meant to be normative.

As shown in Fig. 39.4, research has previously demonstrated that with very low levels of mission management automation, a single operator can supervise at best only two UAVs. However, given high neglect times enabled by higher degrees of autonomy (i.e., UAVs plan their own routes and obstacle avoidance, only seeking high-level mission plan approval), experimentally operators have

Fig. 39.4 Meta-analysis of previous experiments demonstrating increased operator capacity for increasing neglect time (as expressed by levels of automation)

successfully controlled up to 12 Tomahawk Land Attack Missiles (TLAM), which are highly automated missiles that navigate on their own. These vehicles are effectively one-way UAVs, controlled in much the same way as UAVs through GPS commands. WASMs, or wide area search munitions, are also similar weapons that are launched from another aircraft and then fly themselves until they find their assigned target. Curiously the number of WASMs and TLAMs, which are highly automated and operate in centralized control systems, a single operator can simultaneously control (8–12) is very similar to the number of airplanes a single air traffic controller can handle (~11, Hilburn et al. 1997). Arguably, manned aircraft have similar degrees of autonomy since the pilot onboard is expected to obey all the high-level commands of the controller.

One of the limitations common across the studies in Table 39.2 is the lack of measurable *system-level* performance metrics. In general for the studies in Table 39.2, the performance of the operators was deemed acceptable as a function of expert observation, which is a valid method for performance assessment (Endsley and Garland 2000) but is not generalizable across domains and only useful as a descriptive and not predictive metric. Thus, a system-level performance metric should capture both aspects of human and automation performance, which indicates an objective level of goodness and/or satisficing (Simon et al. 1986) (i.e., a “good enough” solution as opposed to optimal). Such system-level metrics are often referenced as key performance parameters (KPPs) (Joint Chiefs of Staff 2007).

Towards this end of developing more comprehensive KPPs for multiple UAV systems, a recent study demonstrated that the number of UAVs that a single operator can control in a centralized architecture is not just a function of the level of decision

Fig. 39.5 Operator capacity as a function of mission constraints

support automation but is inextricably tied to both mission complexity and overall system performance (Cummings et al. 2007). Using human experimentation in a multiple UAV simulation test bed and a simulated annealing (SA) technique for heuristic-based optimization, operator performance was predicted to be significantly degraded beyond approximately five UAVs with approximately levels 3–4 of autonomy as defined in Table 39.1. The optimal range was predicted to be between 2 and 4 vehicles (Fig. 39.5). Interestingly, in a different single operator-multiple UAV study with an entirely different test bed but similar levels of autonomy and centralized architecture, the optimal number was experimentally determined to be ~ 4 UAVs (Cummings and Mitchell 2008).

The KPP in Fig. 39.5 is cost, which takes into account not just operational costs such as fuel but also the cost of missed targets and cost in terms of mission delays introduced by inefficient human interactions. The solid curve in Fig. 39.5 represents a theoretically perfect human operator, and the dotted line represents more realistic human performance that accounts for delays due to inefficient decision making, communication problems, cognitive load, etc. Thus, the performance of the system (the automation *and* the operator) can vary both as a function of the operator but also can vary due to the operational constraints such as number of targets and operational costs. This variation is why it is important to explicitly link system performance to operator capacity.

39.4 Operator Interaction in Decentralized UAV Architectures

While Fig. 39.2 demonstrates supervisory control at the single vehicle level, which for centralized multiple UAV control is simply replicated for each vehicle under control, Fig. 39.6 represents a notional system architecture that will be required for single operator control of multiple decentralized UAVs. In order to achieve this futuristic system, operators will need to interact with an overall automated mission and payload manager, which coordinates a set of tasks for a group of vehicles, instead of individually tasking each vehicle. This effectively represents a decentralized architecture, where operators convey high-level goals to an automated mission manager (such as requesting that an area be searched), which then allows the UAVs to coordinate across the group to determine how to assign particular tasks, which may be dynamic. In a decentralized architecture, navigation and motion control tasks are necessarily subsumed by automation.

The decentralized architecture provides a substantial benefit in that the operator and his or her ground control station do not become a single point of failure, i.e., if the operator has intermittent or loss of communications with the vehicles, the system can still function. For example, because the network of vehicles communicates with one another, if one vehicle breaks down, another can take its place. Another advantage is that the system is robust to lapses in operator situation awareness and delays since vehicles do not necessarily have to wait for commands. However, emergent UAV behavior in such systems can be complex and confusing for an operator, and if the system operates in a suboptimal fashion, it could be difficult for operators to correct problems unless they have the ability to understand and then execute the necessary commands to correct the system.

For operators supervising a decentralized system, the fan-out approach as depicted in Eq. 39.1 cannot be used to estimate operator capacity, since for centralized systems, the assumption is that the vehicles have their own independent NTs and ITs, which drives the overall number of vehicles that can be controlled. Since operators only provide high-level goals at the mission and payload management level, they do not have an IT for each vehicle but rather an IT for high-level interaction with the team. Similarly for NT, there is not distinct per vehicle NT, since they work together.

In control of a decentralized UAV network, the question of operator capacity is driven by how many *tasks* an operator can handle instead of how many *vehicles*. Under task-based, decentralized control, a human operator provides high-level control by approving which tasks should be completed by the team of vehicles without directly tasking a particular vehicle. Then the decentralized network of vehicles chooses how to allocate the approved tasks among themselves and can make tactical-level changes on their own, such as switching tasks.

In controlling a network of collaborative, decentralized UAVs, the operator could control, for example, 2, 20, 200, or even 2,000 UAVs, as long as the tasks generated by the group of UAVs were manageable by a single operator. Determining the task load manageable by a single operator can roughly be thought of as the number of

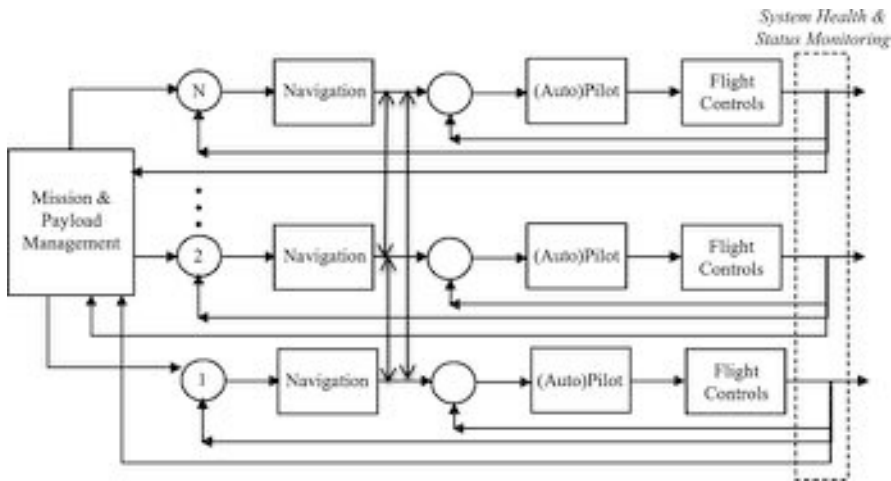

Fig. 39.6 Decentralized control for multiple UAVs

tasks that can be successfully accomplished over the course of the mission. While this number will, of course, vary widely across different missions and with different mixes of vehicles and people, there is one proxy metric that can be used across any decentralized UAV system for workload comparison, which is the concept of utilization.

Utilization refers to the “percent busy time” of an operator, i.e., given a time period, the percentage of time that person is busy. In supervisory control settings, this is generally meant as the time an operator is directed by external events to complete a task (e.g., replanning the path of a UAV because of an emergent target) or attending to internal tasks like responding to text messages. What is not included in this measurement is the time spent monitoring the system, i.e., just watching the displays and/or waiting for something to happen. The concept of utilization as a mental workload measure has been used in numerous studies examining supervisory controller performance (Schmidt 1978; Rouse 1983; Cummings and Guerlain 2007; Donmez et al. 2010). These studies generally support that when tasked beyond 70 % utilization, operators’ performances decline.

In terms of the previously discussed IT and NT terms, utilization can generally be thought of as $IT/(NT + IT)$ on the aggregate task level. It can be used to describe an operator’s response to task load in centralized UAV architectures as well as decentralized, but it is especially useful for decentralized system analysis given the operator’s interaction at the meta-level instead of the individual vehicle level, which reflects the architecture of Fig. 39.6.

In order to determine whether decentralized systems provide any utility in terms of reduced workload and improved performance as compared to centralized UAV architectures, a set of studies was compared that span increasing degrees of

autonomy and increasing task loads, summarized in Table 39.1. In the first experiment at the lowest degree of autonomy (Nehme et al. 2008), operators controlled 2–8 mostly centralized unmanned ground vehicles (UGVs), which resulted in four different experiment levels. For this experiment set, the individual vehicles relied on the human for goal setting but had some ability to share local navigation information with one another.

In the second experiment with three experimental levels (Nehme 2009), a single operator controlled various mixes of five multiple unmanned aerial and underwater vehicles, with slightly more autonomy in the sense that vehicles would not only path plan themselves, but if the operator did not assign an ultimate goal within a prespecified time, the vehicles would assign themselves to the nearest target. However, the operator could override any individual vehicle and redirect not only its path but its ultimate goal as well.

The last experiment with four increasing task load levels represented the highest degree of decentralization, in that operators could only specify a task list to a group of five unmanned aerial and unmanned surface ships. The vehicles negotiated among themselves through a consensus-based bundled algorithm which vehicle would be assigned to which task, and each vehicle determined its own route. The operator could only insert and reprioritize tasks but never direct an individual vehicle. Two different studies were included that used this test bed which focused on medium (Cummings et al. 2010) and high (Clare and Cummings 2011) levels of task loading.

In order to directly compare these different studies, the average tasks per minute were determined, which shows how many tasks in each experiment the operator was expected to complete over an average 1-min time interval. Performance scoring was aggregated into low, medium, and high categories since the performance metrics used in each of the sets of experiments could not be directly compared. Low means that for the specific study, that condition resulted in the worse performance and, respectively, for the high performance ranking. Lastly, the average utilization, which is the percentage of time the operator was busy performing tasks required by the system, was also listed.

Figure 39.7 illustrates that for each of the three sets of experiments, utilization increased with an increasing task load, which is expected and also an internal validity check. In addition, Fig. 39.7 also illustrates that as the degree of decentralization increases, (i.e., more autonomy across a network of vehicles and less direct control by a human operator), utilization decreases. Interestingly all three experiments had an experimental level of ~8 tasks/min and the most decentralized architecture allowed the average operator to work less by 11 % as compared to the more centralized architecture (and 3 % less than the somewhat centralized architecture (Nehme 2009)). And in no case did the centralized architectures produce lower utilizations for similar task loads.

In terms of performance, each of the observed data points in Table 39.3 are color coded in Fig. 39.7 to reflect the relative performance score, with red indicating the worst performance; yellow demonstrates moderate performance, and green represents the best performance. Recall that each of these scores is a relative ranking so caution is advised in interpretation. In general the lower utilizations

Fig. 39.7 Utilization for the average tasks/minute for the experiments in Table 39.3

Table 39.3 Task load, workload, and performance for three multiple UAV architectures with increasing autonomy

| Experiment | Architecture | Primary task load | Average tasks/min | Performance | Average utilization |
|--|--|------------------------|-------------------|-------------|---------------------|
| #1: Unmanned ground vehicles (Nehme et al. 2008) | Mostly centralized, with some navigation sharing | 2 vehicles | 1.70 | Low | 0.59 |
| | | 4 vehicles | 4.02 | Medium | 0.68 |
| | | 6 vehicles | 5.34 | Medium | 0.70 |
| | | 8 vehicles | 8.09 | Medium | 0.78 |
| #2: Unmanned aerial and underwater vehicles (Nehme 2009) | Somewhat centralized with some autonomous path planning and goal selection, 5 vehicles | Same-type vehicles | 4.90 | Medium | 0.52 |
| | | 2 different types | 5.59 | High | 0.64 |
| | | All different vehicles | 8.00 | Low | 0.70 |
| #3–4: Unmanned ground and aerial vehicles, medium (Cummings et al. 2010) and high (Clare and Cummings 2011) workload | Decentralized, 5 vehicles | 23.3 tasks | 3.96 | High | 0.44 |
| | | 30 tasks | 4.05 | High | 0.48 |
| | | 43.3 tasks | 7.30 | Medium | 0.65 |
| | | 50 tasks | 7.90 | Medium | 0.67 |

produced the best performances, with the caveat that little work has been done in terms of the possible negative impact of low task load on performance (in one exception, see Cummings et al. 2013). For all studies, performance suffered when

the 70 % utilization threshold was exceeded, with only the somewhat centralized study participants exhibited markedly worse performance.

For the somewhat decentralized (Nehme 2009) and more decentralized experiments (Cummings et al. 2010; Clare and Cummings 2011), there appears to be a nonlinear relationship in the 6 tasks/min and below regions, which is not evident in the centralized experiment (Nehme et al. 2008). More work is needed to determine why such nonlinear relationships exist, the nature of the critical point for the sharp rise, and how a system could be better designed to reduce the sharp increases in workload.

39.5 Conclusion

Taken together, the results from both the centralized and decentralized sets of experiments demonstrate that decentralized, task-based control of UAV architectures with higher degrees of autonomy can mitigate cognitive overload and reduce workload. While a single operator can maintain effective control of a relatively small network of centralized UAVs, decentralized architectures are more scalable, since adding additional agents also adds computational capability (assuming the tasks generated by the system do not linearly increase). Moreover, the decentralized UAV framework is robust to a single point of failure, since no single agent is globally planning for the fleet.

In terms of workload for a supervising operator, the ultimate success of either a centralized or decentralized UAV architecture is not how many vehicles are in the network per se but rather how many tasks the group of vehicles generates for the operator and how much autonomy is onboard these vehicles so that neglect time can be increased. And while this increasing autonomy in a decentralized network of UAVs can mean reduced workload for the operator, it also adds significant more complexity to the system, which not only means increased developmental costs than a centralized network but also one that is much harder to certify as safe.

Another caveat to the use of increased autonomy to mitigate workload across a UAV network is that such increased autonomy and increased neglect times can exacerbate a loss of operator situation awareness, as well as promote complacency and skill degradation (Parasuraman et al. 2000). Management-by-exception architectures, which occur when automation takes action based on some set of predetermined criteria and only gives operators a chance to veto the automation's decision, have been shown to improve operator performance (Cummings and Mitchell 2006). However, in such control schemes, operators are also more likely to exhibit automation bias, a decision bias that occurs when operators become over-reliant on the automation and do not check to ensure automated recommendations are correct (Mosier and Skitka 1996). Automation bias is a significant concern for command and control systems, so it will be critical to ensure that when higher levels of automation are used, especially at the management-by-exception level, this effect is minimized.

Lastly, while it is critical to consider the mental workload of a supervisor of multiple UAVs, the ability of the human to add value to the performance of a team of UAVs cannot be overlooked. In one study that examined whether human supervisors added value in a search and track task for a decentralized, highly autonomous network of UAVs, results in a controlled study show that a 30–50% increase in overall system performance, particularly in the search task, could be achieved by letting humans coach the automation (Cummings et al. 2012). Thus, instead of attempting to dictate mutually exclusive boundaries for human and computers in multiple UAV systems, either centralized or decentralized, more effort needs to be spent in trying to define mutually supportive roles such that humans and computers complement one another.

UAV Health Management Issues

Kai Goebel and Michael J. Roemer

Kimon P. Valavanis and George J. Vachtsevanos

Reliability, availability, maintainability, and safety of UAVs, and more generally of other unmanned systems, are a critical concern for the OEM and user communities. The development and application of emerging Prognostics and Health Management and Condition-Based Maintenance (CBM) technologies to all UAV classes is recognized as a key enabler for their effective utility in multiple application domains.

UAV Health Management addresses fundamental technologies and their application to UAVs that relate to monitoring and sensing strategies for health management, data acquisition and processing/analysis onboard and off-board the vehicle, fault diagnosis and failure prognosis algorithms, as well as fault-tolerant control routines that enhance the UAV's useful life and mitigate potential catastrophic events. CBM methods and tools are also covered that take advantage of the prevailing paradigm shift from scheduled or breakdown maintenance towards maintenance practices that are based on the current condition of these assets.

► **Integrated Vehicle Health and Fault Contingency Management for UAVs** by Roemer and Tang presents various concepts for integrating real-time vehicle health assessment and fault contingency management technologies for UAVs. The presented integrated vehicle health management (IVHM) and automated contingency management (ACM) system architecture are shown to support real-time, onboard health state assessment and fault management so that UAVs can enjoy greater autonomy and survivability during anomalous operating conditions. Selected

real-time system identification and automated health assessment algorithms are presented that can readily identify the dynamics and performance limitations of degraded UAV systems. Additionally, a high-level mission adaptation approach is presented to estimate the safe flight operating envelope after the occurrence of faults. Reconfigurable fault-tolerant control techniques that directly utilize the identified UAV subsystem dynamic models have been developed and tested in simulation. Finally, proof-of-concept demonstrations are presented using NASA engine and aircraft dynamic models with simulated engine and actuator faults.

► **Automated Failure Effect Analysis for PHM of UAV** by Snooke describes how model-based simulation can be employed to automatically generate the system-level effects for comprehensive sets of component failures on systems within the aircraft. The results of the simulation can be used in several ways. They can be used to produce a system-level failure modes and effects analysis (FMEA) for aircraft systems. They can be used to identify the sensors necessary to discriminate remotely between different failures on the aircraft. Once a set of sensors have been chosen for placement on the vehicle, the simulation results can also be used to generate diagnostic and prognostic software for deployment on the vehicle. Using automated FMEA safety analysis software is more efficient than doing the same work without software and also provides a guaranteed level of performance. Using the results of this analysis can provide sensor selection and diagnostic capability while retaining some of the benefits of rule-based diagnostic systems. Alternative model-based techniques have been widely used to create diagnostic systems in a variety of domains, and these approaches are compared with the diagnostic capability provided by a failure effect-oriented technique from the perspective of the UAV application.

► **Prognostics Applied to Electric Propulsion UAV** by Goebel and Saha explores the technical underpinnings of how to perform prognostics and shows an implementation on the propulsion of an electric UAV. An accurate run-time battery life prediction algorithm is of critical importance to ensure the safe operation of the vehicle if one wants to maximize in-air time. Current reliability-based techniques turn out to be insufficient to manage the use of such batteries where loads vary frequently in uncertain environments. A particle filter is shown as the method of choice in performing state assessment and predicting future degradation. The method is then applied to the batteries that provide power to the propeller motors.

► **Actuator Fault Detection in UAVs** by Ducard is dedicated to actuator fault detection systems for UAVs, with two main requirements: real-time capability and modularity. After defining the terminology employed in this field, it first reviews some commonly used techniques in FDI systems, followed by presenting briefly the mathematical model of a UAV that serves as a basis for the design of two actuator FDI systems. The first method presents and illustrates the multiple-model approach, whereas the second method presents an FDI system, which is based on a single model. Both methods are enhanced by a mechanism that actively tests actuators in order to efficiently detect and isolate actuator faults and failures. Advantages and drawbacks of each method are stated issues of robustness and are discussed against model uncertainties and external perturbation. In addition, aspects of computational

load are addressed. The FDI systems applied to a realistic model of an unmanned aircraft and the performance of the methods are shown in simulation.

► **Experimental Validation of Fault Detection and Diagnosis for Unmanned Aerial Vehicles** by Chamseddine, Hadi Amoozgar, and Zhang investigates the problems of fault detection, diagnosis, and fault-tolerant control for UAVs. It first presents a detailed overview of existing experimental research focusing on fixed-wing as well as rotorcraft UAVs including single-rotor and multi-rotor helicopters. It then discusses three Kalman filters employed for actuator fault detection and diagnosis, namely, the unscented Kalman filter, the two-stage Kalman filter, and the adaptive two-stage Kalman filter. The three filters are experimentally applied to a quadrotor helicopter UAV test bed, and results are shown, compared, and discussed.

► **Fault Detection and Diagnosis for NASA GTM UAV with Dual Unscented Kalman Filter** by Zhang investigates a simultaneous state and parameter estimation-based fault detection and diagnosis (FDD) scheme applied to a realistic nonlinear six degree-of-freedom fixed-wing unmanned aerial vehicle (UAV) model, the NASA GTM (generic transport model). By introducing partial loss faults in actuators into the NASA GTM, a Dual Unscented Kalman Filter (DUKF) algorithm is applied for the purpose of online estimation of both flight states and fault parameters. A Bayesian rule is then used for detection and isolation decision-making. The developed FDD scheme is implemented in both the nonlinear GTM and the linear parameter-varying (LPV) representation of the nonlinear GTM. Simulation results show satisfactory results for detecting and diagnosing the control effectors faults.

► **Fault Diagnosis of Skew-Configured Inertial Sensor System for Unmanned Aerial Vehicles** by Yoon, Kim, Bae, Kim, and Kim presents fault detection and isolation scheme to handle three successive faults in the skew-configured inertial sensors of an unmanned aerial vehicle. The skew-configured inertial sensors are composed of the primary inertial measurement unit and the redundant secondary inertial measurement unit. Since small unmanned aerial vehicles are restricted by cost and payload space, the secondary small and low-cost inertial measurement unit is installed with a skewed angle in addition to the primary inertial measurement unit. In the hybrid fault detection and isolation scheme, a parity space method and an in-lane monitoring method are combined to increase system tolerance to the occurrence of multiple successive faults during flight. The first and second faults are detected and isolated by the parity space method. The third fault is detected by the parity space method and isolated by the in-lane monitoring method based on the discrete wavelet transform. Hardware-in-the loop tests and flight experiments with a fixed-wing unmanned aerial vehicle are performed to verify the performance of the proposed fault diagnosis scheme.

Abstract

This chapter presents various concepts for integrating real-time vehicle health assessment and fault contingency management technologies for unmanned air vehicles. The presented integrated vehicle health management (IVHM) and automated contingency management (ACM) system architecture is shown to support real-time, onboard health state assessment and fault management so that UAVs can enjoy greater autonomy and survivability during anomalous operating conditions. Selected real-time system identification and automated

health assessment algorithms are presented that can readily identify the dynamics and performance limitations of degraded UAV systems. Additionally, a high-level mission adaptation approach is presented to estimate the safe flight operating envelope after the occurrence of faults. Reconfigurable fault-tolerant control techniques that directly utilize the identified UAV subsystem dynamic models have been developed and tested in simulation. Finally, proof-of-concept demonstrations are presented using NASA engine and aircraft dynamic models with simulated engine and actuator faults. Simulation results and remarks on future work are also presented.

41.1 Introduction

At the forefront of technology in today's military, unmanned systems are highly desired by combatant commanders (COCOMs) for their versatility and persistence. Through their expanding roles in areas such as surveillance; signals intelligence (SIGINT); precision target designation; mine detection; and chemical, biological, radiological, and nuclear (CBRN) reconnaissance, unmanned systems have made key contributions to the Global War on Terror. Unmanned system technology has gone from a prolonged period of limited acceptance and utilization spanning a couple of decades starting with the early drones, to proving and expanding their value in Desert Storm and Kosovo, to a multifaceted, highly desired resource with the recent conflicts in Iraq and Afghanistan. As of October 2008, coalition unmanned aircraft systems (UAS) (exclusive of hand-launched systems) have flown almost 500,000 flight hours in support of Operations Enduring Freedom and Iraqi Freedom; unmanned ground vehicles (UGVs) have conducted over 30,000 missions, detecting and/or neutralizing over 15,000 improvised explosive devices (IEDs); and unmanned maritime systems (UMSs) have provided security to ports [Office of the Secretary of Defense Unmanned Systems Roadmap (2009–2034)].

UAVs and their supporting systems and personnel are seeing a dramatic increase in the operational tempo they support compared to what was originally planned or designed. In addition, modern unmanned technology is still very young, measuring the maturity of any particular platform in years and hundreds of thousands of flight hours for the most mature and heavily utilized, rather than decades and tens of millions of flight hours for many manned platforms. Add to this the fact that many platforms in high demand entered low-rate production while still under advanced concept technology demonstration (ACTD) programs and had not been fully vetted through the traditional process of going to full production. With the military under continued strain to do "more with less" (people, money, etc.), one begins to understand why early data from a 2003 OSD UAV reliability study reports that the proportions of human error versus mechanical, system, and environmentally induced mishaps are nearly reversed between UAVs and the aggregate of manned aircraft, i.e., human error is the primary cause of roughly 85 % of manned mishaps, but only 17 % of unmanned ones. The report also states the cumulative mishap rate (i.e., class A accidents per 100,000 h of flight) of 32 for predator, 334 for

pioneer, and 55 for hunter (16 since the major reliability improvements in 1996). In comparison to manned aviation mishap rates, general aviation aircraft suffer about 1 mishap per 100,000h, regional/commuter airliners about a 10th that rate, and larger airliners about a 100th that rate [Unmanned Aerial Vehicle Reliability Study, Feb, 2003, Office of the Secretary of Defense].

Clearly, there is a significant opportunity for both integrated vehicle health management (IVHM) and automated contingency management (ACM) technologies to be deployed, which will help UAVs reach the reliability and safety statistics attained by manned systems. The combination of these features will also help provide the opportunity to reconfigure the appropriate UAV control systems in the event of failures with the aim of increasing the survivability of the aircraft. Enhanced supervisory control methodologies and associated algorithms have been developed for optimizing the operations and performance of such systems due to changing environmental conditions and system degradation (Vachtsevanos et al. 2005, 2006; Bodson 1995; Byington et al. 2004; Volponi and Wood 2005; Litt et al. 2004; Tang et al. 2005). However, in order to provide a truly comprehensive level of integrated fault isolation and accommodation for potentially hundreds of fault scenarios that could be encountered in flight requires a dynamic, model-based fault contingency management concept that can make decisions “on the fly,” under fault conditions that were never expected or accounted for previously. Hence, a dynamically reconfigurable control architecture that can support on-line fault contingency management based on faults being detected in real time is the key enabling issue to be addressed.

This chapter presents the development of a hierarchical architecture and enabling techniques for a real-time aircraft fault contingency management system with the following features:

1. A hierarchical architecture that integrates real-time system health identification, control reconfiguration, and high-level reasoning.
2. The dynamics and performance limitation of the degraded/damaged system are estimated on-line in real time.
3. Adaptive reconfigurable control will be utilized to stabilize and recover the system using the system dynamic model identified on-line in real time.

NASA’s Modular Aero-Propulsion System Simulation (MAPSS) engine model and Generic Transport Model (GTM) have been utilized in proof-of-concept simulation studies, and preliminary results are presented.

41.2 Integrated IVHM and ACM Overview

As shown in Fig. 41.1, the core functionality of the integrated vehicle health management (IVHM) and automated contingency management (ACM) system is to use the real-time health information from detected/isolated faults to evaluate a system’s capability for performing its future operations. The ACM system will perform the contingency analysis including the assessment of controller capabilities and core operational capabilities based on reduced system functionality.

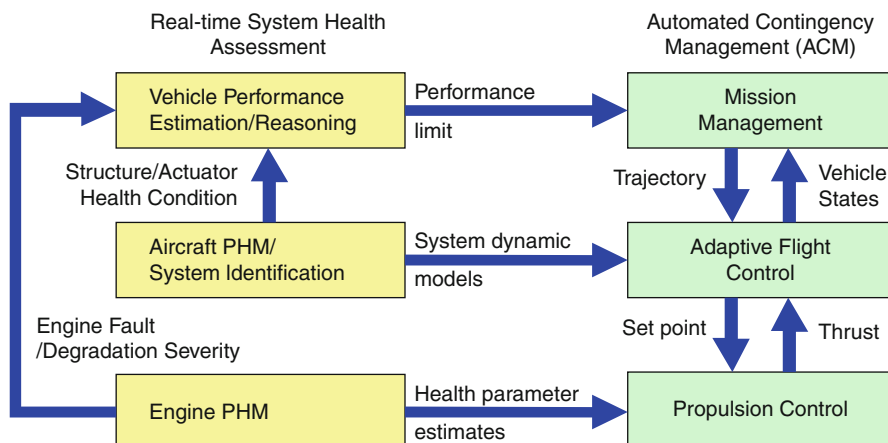

Fig. 41.1 A conceptual system overview

The analysis results will form the basis for the new constraints of the system's operation. If the current mission operation plan is incapable of being satisfied, then operation replanning and optimization becomes necessary under the new constraints in order to respond both intelligently and efficiently to the changes of system's health status or environment.

Within this architecture, UAV subsystem faults are detected by prognosis and health management (PHM) modules in real time. At the core of the real-time system health assessment modules is a real-time on-line system identification technique that can rapidly track time-varying parameters. The fault accommodation functionalities are provided in three levels. At the lowest (subsystem) level, fault-tolerant control strategies are utilized to accommodate the fault in the subsystem. A propulsion example is utilized in Fig. 41.1. However, it can also be a fault-tolerant controller for an EMA flight actuator at the subsystem level. At the flight control level, an adaptive control architecture is utilized to compute a time-varying model of the plant dynamics. Using the identified dynamics, the controller calculates the commands required to achieve the desired system responses as specified by a set of flying-qualities models. At the mission level, results from the system health assessment modules are utilized to estimate achievable system performance. The adaptive mission planner can then adjust/optimize mission commands based on the estimated performance of the degraded system.

41.3 Real-Time System Health Identification and System Performance Estimation

In order to adapt to the changing operational environment, fault conditions, or performance degradation, it is very important that the IVHM system possesses the

capability to identify/update various models in real time so that the appropriate control can be applied. This chapter will present two system/health identification techniques that have been developed and evaluated in simulation studies using NASA engine and aircraft models. These include (1) a real-time strong tracking system identification (SID) algorithm for adaptive flight control and (2) a self-tuning Kalman filter algorithm for engine health assessment (Tang et al. 2007a). Based on the health assessment and newly identified UAV dynamics, the operational flight envelop in real time can be assessed to ensure safe flight regimes are utilized under compromised conditions.

41.3.1 Real-Time Strong Tracking System ID Algorithm

The discrete state-space model or equations of motion for a UAV can often be stated (in discrete format) as

$$y(n) = \theta(n)^T \phi(n) + v(n) \quad (41.1)$$

where $y(n)$ is a measurable system state or output, $\theta(n)$ is a vector representing the parameters to be tracked/estimated, $\phi(n)$ is the regressor vector, $v(n)$ represents the modeling error, and n is a time step index. For example, if the parameters (C and D) of a linear output equation ($y = Cx + Du$) are being tracked with this algorithm, then $\theta(n)$ would be a vector considering of a row of the C matrix and a row of the D matrix and $\phi(n)$ would be a vector of the states and inputs, i.e., $(x^T; u^T)^T$. The same simple linear formulation can be applied to estimate aerodynamic coefficients of a nonlinear equation of motion when it can be linearized or the nonlinear terms can be wrapped into the regressor vector. The least square algorithm drives $\theta(n)$ toward its true value, θ^* , by a modified least squares algorithm that seeks to minimize an augmented cost function (Bodson 1995):

$$J(\theta(n)) = \frac{1}{2} \sum_{k=n-N+1}^n \lambda^{n-k} \|y(k) - \theta(n)^T \phi(k)\|^2 + \alpha \|\theta(n) - \theta(n-1)\|^2 \quad (41.2)$$

where λ is the time-varying forgetting factor, which will be modified adaptively according to a fault detection module. α is the weighting coefficient that adjusts the influence of the derivation of the current estimate from the previous estimate.

The augmented cost function includes one additional term that restricts the movement of the estimate, $\theta(n)$, in the temporal dimension. Similarly, another term can be added to restrict the movement of $\theta(n)$ in the spatial dimension, e.g., $\beta \|\theta(n) - \hat{\theta}\|^2$, where $\hat{\theta}$ is an a priori estimation of $\theta(n)$. This formulation will further help when $\theta(n)$ does not deviate too much from $\hat{\theta}$ and result in a more

robust estimate in the presence of noisy measurements. However, at the same time, extra computational burden is introduced.

As an improvement for fast detection and tracking in real time, a change detection scheme and a time-varying forgetting factor can be integrated with the above algorithm. When an abrupt change in prediction residuals is detected, a smaller forgetting factor is utilized to discount “old” data and place more weight on the latest measurements. This mechanism helps to improve system response when an abrupt fault occurs.

41.3.2 Self-Tuning Kalman Filter (STKF)

In order to make the onboard subsystem models adaptive to potential performance variations due to performance degradation or anomalous conditions, an STKF can be designed to implement the capability to adjust its performance through the tuning of health parameters which are introduced to the system dynamics as “virtual states.” This technique has been applied to aircraft engine fault diagnosis in recent years (Volponi and Wood 2005). For example, the health parameters for a typical gas turbine engine can be defined as

$$X_c = (\eta_{\text{Fan}} w_{\text{Fan}}, \eta_{\text{LPC}}, w_{\text{LPC}}, \eta_{\text{HPC}}, w_{\text{HPC}}, \eta_{\text{LPT}}, w_{\text{LPT}}, \eta_{\text{HPT}}, w_{\text{HPT}}) \quad (41.3)$$

where X_c is the augmented virtual states including the efficiency and flow capacity of fan, low- and high-pressure compressors, and low- and high-pressure turbines. The tuning parameters are embedded in the Kalman filter design. If sensor outputs deviate from nominal condition values due to component degradation and/or faults, the Kalman filter will attribute the cause of sensor output deviations to the tuning parameters, so that the residuals of state/output estimates will remain small. At the same time, the values of the tuning/health parameters will be a good estimate of engine component health condition as long as the underlining engine model is reasonably accurate.

The accuracy of the underlining subsystem model significantly affects the performance of the fault detection, isolation, and estimation (FDIE) algorithm presented in the previous section. Discrepancies between model outputs and sensor measurements caused by modeling mismatch can be mistakenly considered as a fault effect leading to a false alarm. Therefore, a technical challenge for this type of model-based approach is building an accurate, real-time subsystem model that is robust to unmodeled system dynamics, engine-to-engine variation, and nominal deterioration over time. To solve this problem, empirical modeling is often introduced to capture the modeling mismatch using neural networks (NNs) and improve the accuracy of the physics-based subsystem model. The resulting hybrid model consisting of both a physics-based baseline model and a neural network-based empirical model is often utilized in real-time engine health management applications as illustrated in Fig. 41.2.

Fig. 41.2 Hybrid engine modeling for online real-time engine health management

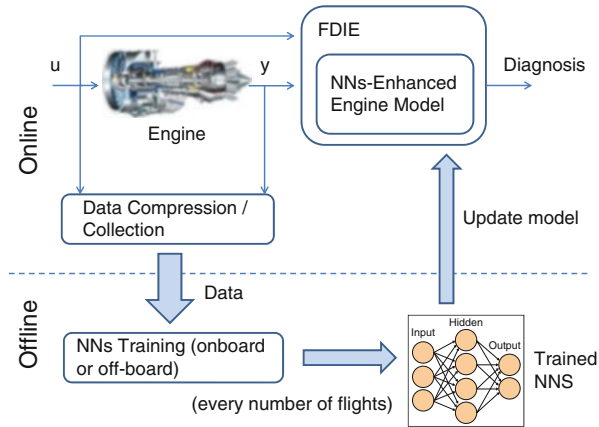

Fig. 41.3 Effects of high pressure compressor degradation on engine parameters

41.3.3 Engine Health Management

Let us further examine the previous engine model tuning example in terms of modeling the potential degradation and how it can be used within the IVHM system architecture. Engine performance monitoring exploits the availability of monitored gas path parameters, including spool speeds, temperatures, pressures, and flow rates at key points in the engine. Degradations in the engine’s performance will commonly manifest themselves as gradual shifts away from expected values corresponding to the current operating state of the engine, as illustrated in Figs. 41.3 and 41.4 (based on simulation results on C-MPASS engine model running at sea level static maximum power). It is recommended that the engine performance monitoring module implement a model-based approach based upon detecting and classifying these shifts as they occur. This technology assesses signal

Fig. 41.4 Effects of low pressure compressor degradation on engine parameters

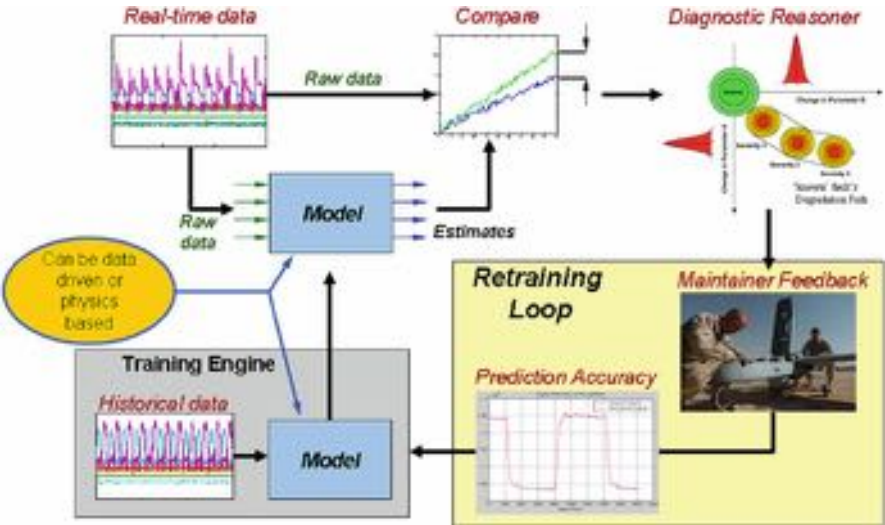

Fig. 41.5 Model based anomaly detection, diagnostics, and trending

health and system performance by employing a combination of signal processing, statistics, and data-driven modeling techniques. The process is illustrated in Fig. 41.5. Measured engine parameter data are input to the model, which provides expected values as output. These expected values are then evaluated relative to the original measured data to determine the residual value. These residual values used together form a pattern which can then compared to the characteristic degradations like those depicted in Figs. 41.3 and 41.4. Subsequent reasoning can then be applied to isolate the source of the performance degradation to a specific section of the engine. The techniques described here have been

implemented successfully in various gas turbine engine applications. Consideration of mechanical vibrations in the engine's moving parts augments the engine performance evaluation to form a more complete propulsion monitoring system. Such techniques can be applied to drive train components specific to the engine such as rolling-element bearings. In addition, engine orders ($1\times$, $2\times$, and higher harmonics of running speed) can be tracked to provide indications of a variety of faults.

Critical component prognostics techniques based on fatigue accumulation models for specific components and engine configurations can provide an estimate of the remaining life before maintenance or overhaul is required. These models are typically a function of specific usage, mission profiles, speeds, and loads and can be adjusted by diagnostic indicators of the existence of faults. If such models are unavailable, then a much simpler approach can be implemented which only tracks total accumulated cycles (TAC) to provide a rudimentary approach to assessing engine life consumption. This approach, applied to gas turbines, monitors very generalized engine speed movements to gauge the severity of thermal transients and assess usage accumulation.

41.3.4 Flight Control Actuator Health Management

Linear actuators are used extensively in UAVs for everything from manipulation of flight control surfaces to weapon release systems. One commonly applied type of actuator is the electromechanical actuator (EMA), which uses an electric motor and gear set to produce linear or rotary motion. EMAs have some advantages over equivalent hydraulic actuators; less weight, size, and complexity, characteristics that allow them to gain acceptance for aerospace applications.

Prognostics and health management for EMAs typically employ two types of approaches to yield an overall assessment of EMA health. A model-based approach utilizing only command and response information from the EMA's controller employs a core group of diagnostic features, including local gear stiffness, frictional damping, and torque constant to determine EMA system health. In this implementation, the model-based approach illustrated in Fig. 41.5 utilizes command signals as input and exercises a model of the actuator system varying the values for the three diagnostic features until a suitable match is found, measured by a minimization of the residual between the modeled response and the measured response. The set of the three diagnostic features then serve as the axes of a three-dimensional failure space wherein different failure modes propagate through the failure space on different, unique paths. A second technique can utilize vibration data collected from an accelerometer to monitor the characteristics of the rolling elements in the actuator. This type of approach utilizes traditional vibration-based features to determine overall actuator health. Results from the two approaches can then be evaluated by a higher-level reasoning structure as described in the next section.

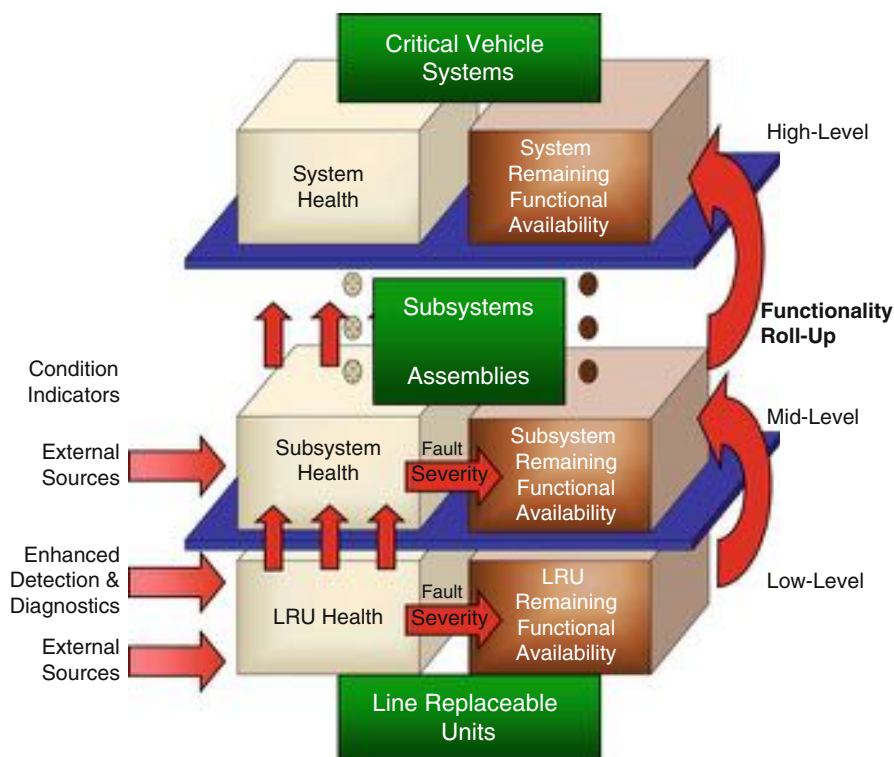

Fig. 41.6 Hierarchical reasoning

41.3.4.1 Vehicle- and Subsystem-Level Reasoning

One of the key aspects distinguishing an IVHM approach from a basic health and usage monitoring capability is an enhanced reasoning capability utilized to provide a vehicle-wide assessment of the implications of any detected failure mechanisms on the overall capability of the vehicle. Reasoning, within an IVHM system, processes condition or health indicators obtained from the subsystem-specific health modules to determine the current health state of the vehicle and its constituent subsystems. This goes beyond the basic diagnoses of observed indications by attempting to quantify the remaining functionality, which has been reduced by the indicted failure mode(s). The reasoning engine employs a hierarchical architecture, as illustrated in Fig. 41.6, to not only identify failure modes of line replaceable components (LRC) but also determine the functional impact in terms of remaining functional/operational availability at the subsystem and vehicle levels. When analyses result in an ambiguous outcome, the reasoner works to isolate the root cause or at least reduce the ambiguity group. The reasoner also attempts to provide estimates of the severity of the underlying failure and the remaining useful life of the LRC where prognostic capabilities are available. The reasoned results output by

the IVHM system provide real-time health and remaining functionality information useful to operations personnel for decision support.

At the lowest level, diagnostic reasoning seeks to classify latent failure mode indications from raw sensor data or diagnostic feature data processed by the subsystem-specific modules. The mid-level of the reasoning architecture is employed to determine the overall functional availability of the constituent subsystems, i.e., what are the implications of the detected failure modes on the functional availability of the subsystem? The vehicle- or system-level reasoning, the highest level of onboard reasoning, shares this task of determining and quantifying functional availability, but from a vehicle- or system-wide perspective. At this highest level, the functional availability assessments, or condition indicators, from all underlying subsystems are utilized to determine the capability of the vehicle to continue operations as expected or needed.

41.3.4.2 Prognostics

Performing onboard prognostics for a given set of LRUs or subsystems within the UAV IVHM system architecture is desirable but often times a challenge due to the necessary information and models needed to perform the task in real time. One such technique that has been shown to be useful for performing on-line prognostics for critical UAV subsystems is called the particle filter. Particle filtering is an emerging and powerful methodology for sequential signal processing based on the concepts of Bayesian theory and sequential importance sampling (SIS) and is suitable for the embedded applications onboard the IVHM system's embedded element. Particle filtering can be used for a wide range of applications in science and engineering and is very suitable for nonlinear systems or in the presence of non-Gaussian process/observation noise. For example, the technique has been successfully used in the diagnosis and prognosis of a helicopter gearbox fault, gas turbines, and electrochemical batteries at Impact. The fault diagnosis procedure fuses and utilizes the information present in a feature vector (observations) with the objective of determining the operational condition (state) of a system and the causes for deviations from desired behavioral patterns. From a nonlinear Bayesian state estimation standpoint, this task is accomplished by the use of a particle filter-based module built upon the nonlinear dynamic state model.

One particular advantage of this particle filtering approach is the ability to characterize the evolution in time of the above-mentioned nonlinear model through modification of the probability masses associated with each particle, as new feature information is received. Furthermore, the output of the fault diagnosis module, defined as the current expectation of each Boolean state, provides a recursively updated estimation of the probability for each fault condition considered in the analysis. The probability density function (PDF) estimates for the system's continuous-valued states provide swift transition to failure prognosis algorithms, which is a primary advantage for a particle filter-based diagnosis framework. Since prognosis intends to project the current condition of the indicator in the absence of future measurements, it necessarily entails large-grain uncertainty. These facts suggest a prognosis scheme based on recursive Bayesian estimation techniques, combining

Fig. 41.7 Illustration of prognostics

both the information from fault growth models and on-line data obtained from sensors monitoring key fault parameters (observations or features).

The particle filtering-based approach for prognosis bases long-term predictions for the failure evolution on both an accurate estimation of the current state and a model describing the fault progression. This procedure tends to reduce the uncertainty associated with long-term predictions by using both the current state PDF estimation and a record of corrections made to previous computed predictions. Thus, the particle filtering algorithm serves the dual purpose of managing uncertainty and providing a means to continuously adapt the fault progression model. The probability of failure at any future time instant is estimated by combining both the weights of predicted trajectories and specifications for the hazard zone, as shown in Fig. 41.7: 6. The resulting Remaining Useful Life PDF provides the basis for the generation of confidence intervals and expectations for a prognosis.

41.3.5 Dynamic Flight Envelope Assessment

The flight envelope of a UAV or any air vehicle represents the ranges of altitudes and speeds over which it effectively operates. This envelope may be drawn as a series of constraining curves on the altitude-Mach number plane. These constraints may arise owing to aerodynamic or propulsion considerations (e.g., the characteristics of the flight surfaces wings, and ailerons) or the power plant characteristics. The flight envelope (as determined for any particular aircraft) is usually an approximation and may be represented as a “doghouse plot” as shown in Fig. 41.8.

Fig. 41.8 Representative flight envelope

The flight envelope in Fig. 41.8 is bounded by four curves. Points which are well within the envelope (such as “A” and “B”) represent “comfortable” operating points, where the aircraft has considerable excess capacity for maneuvers. Points close to the edges of the envelope (“C” and “D”) represent operation of the aircraft close to its limits, and thus, there is limited capacity for maneuvers at these points.

Faults in UAV subsystems may affect the flight envelope significantly. Anomalies may occur in a variety of forms such as abrupt changes in aerodynamics, failed actuators, loss of propulsion, and damaged structures or control surfaces. In order to maintain vehicle stability and safe flight under adverse conditions, detection of the aircraft current state and prediction of achievable performance must be accomplished through onboard systems, in real time, and communicated to the flight control system, mission management system, and pilot. This onboard system must allow decision making to reduce risk while operating in the presence of uncertain information from various subsystems.

For example, severe engine faults may reduce the available thrust, which affects the maximum speed and the service ceiling curves. Similarly, damages in the control surfaces may cause loss of lift or increased drag. This would lead to higher stall speeds, while also affecting the service ceiling and maximum speed. Thus, the flight envelope would shrink due to engine or flight control surface faults.

The maximum speed attainable by the aircraft depends on the maximum engine thrust, as well as the wing area and the minimum attainable drag coefficient. This may be expressed as

$$\begin{aligned}\tau_{\max} &= \frac{1}{2} \rho(H) C_{d_{\min}} A_w V_{\max}^2 \\ V_{\max} &= \sqrt{\frac{2\tau_{\max}}{\rho(H) C_{d_{\min}} A_w}}\end{aligned}\quad (41.4)$$

where τ_{\max} is the maximum thrust, ρ is the density of air (as a function of altitude H), $C_{d_{\min}}$ is the minimum drag coefficient, A_w is the wing area, and V_{\max} is the

maximum possible air speed. Thus, loss of thrust due to engine degradation as well as increased drag owing to wing damage may both reduce the maximum speed, which shrinks the flight envelope to the right.

Similarly, the stall speed may be calculated as

$$W = \frac{1}{2} \rho(H) C_{L_{\max}} A_w V_s^2$$

$$V_s = \sqrt{\frac{2W}{\rho(H) C_{L_{\max}} A_w}} \quad (41.5)$$

where W is the weight of the aircraft, $C_{L_{\max}}$ is the maximum lift coefficient, and V_s is the stall speed. Reduced lift (owing to wing faults) could thus cause the stall speed to increase, which shrinks the flight envelope to the left.

Due to the experimentation and modeling capabilities available to the author, dynamic flight envelope estimation was initially investigated for severe engine faults. The reduction in the flight envelope due to an engine fault was simulated using the NASA MAPSS engine model (Parker and Melcher 2004). Specific engine faults were seeded into the MAPSS model which causes significant efficiency and flow capability loss in several engine components. The corresponding changes in the flight envelope were then estimated in real time by estimating the maximum thrust that the engine could produce under a particular level of degradation. As illustrated in Fig. 41.9, the maximum thrust estimate was provided by an artificial neural network which was trained off-line using the data from high-fidelity engine model simulations with engine controllers in the loop.

41.4 ACM System Optimization

Most ACM strategies for large-scale dynamical systems, such as an aircraft, rely on heuristic information about a reduced set of severe, frequent, and testable fault modes, a reasonable number of active controllers, and a mapping between the fault modes and the control reconfiguration routines. Such a strategy has the ability to adaptively switch from one controller to another, if control limits are reached, and by this switching action, critical mission objectives can be realized. This chapter presents a new approach in which an optimization problem is dynamically formulated and solved on-line to solve the optimal contingency strategy constrained by the available performance and resource. A typical cost model is expressed in terms of such elements as on-time execution of critical components, time to complete the mission, tracking error, fuel consumption, etc. Costs are computed in real time and may change dynamically.

Analytically, the objective of the ACM system is to optimize the utility of the vehicle with impaired capability to accomplish an assigned mission. The ACM system can be formulated as an optimization problem in two levels:

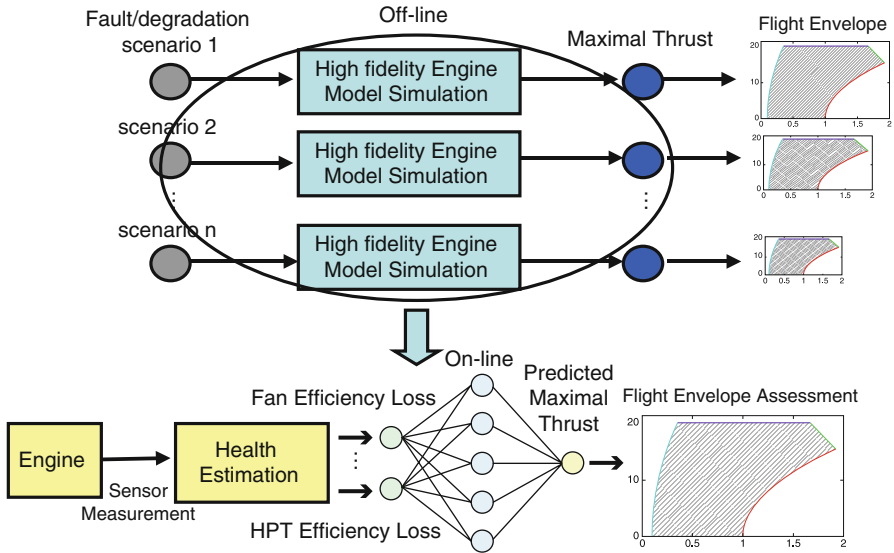

Fig. 41.9 Neural network-based dynamic flight envelope estimation for severe engine faults

High (mission)-level planner:

$$J(M) = \max_M U(P_e, P_r, M, M_{\text{com}}) \quad (41.6)$$

Lower (control reconfiguration) level:

$$J(R) = \max_R P_e(F_m, P_r, R, M) \quad (41.7)$$

where U is a cost function that quantifies the usefulness of the vehicle to accomplish its mission. U is a function of the available prognostic information (P_r), the system's closed loop performance (P_e), and the mission objectives (M and M_{com}). P_e is a function of fault mode F_m , future prediction P_r , as well as any restructuring/reconfiguration R applied to the system and current mission objective M . F_m is a vector of indicators (0 or 1) that characterizes the fault modes detected on the aircraft; R is a vector of indicators that characterizes all restructuring applied to the system. M_{com} describes the mission assigned to the aircraft. M allows the fault-tolerant control architecture, specifically the mission adaptation and resource management components, to modify the parameters of the assigned mission and redistribute available resources based on the vehicle's current performance, P_e . At the high level, mission adaptation and resource redistribution (M) allow the control architecture to pursue relaxed mission objectives in order to achieve greater vehicle usefulness U . At the lower level, the objective is to optimize vehicle performance P_e while satisfying the mission constraints, through

restructuring and reconfiguration, R . Practically, the above optimization problems have to be solved while adhering to various constraints including system dynamics and resource limitations.

While this generic problem formulation applies to all of the ACM levels (mission management, adaptive flight control, and propulsion control) in Fig. 41.1, the focus of this chapter is adaptive flight control. Fault-tolerant propulsion controls and mission reconfiguration are discussed in the previous publications (Tang et al. 2005, 2007b).

41.4.1 Model Predictive Control

Model predictive control (MPC) is a particularly effective method for control reconfiguration due to its ability to handle constraints and changing model dynamics systematically. MPC relies on an internal model of the system, which can be identified on-line in real time using the strong tracking system identification algorithms described in previous section.

System failures can be handled naturally in an MPC framework via changes in the input constraints and internal model. For example, actuator limit and rate constraints can be written as:

$$\begin{aligned} u_i^l &\leq u_i(t) \leq u_i^h \\ \Delta u_i^l &\leq \dot{u}_i(t) \leq \Delta u_i^h \end{aligned} \quad (41.8)$$

for actuator inputs u_1 through u_m . If actuator i becomes jammed at position \tilde{u}_i , the MPC controller can be made to accommodate the changes by simply changing the constraints on input i to

$$\begin{aligned} \tilde{u}_i &\leq u_i(t) \leq \tilde{u}_i \\ 0 &\leq \dot{u}_i(t) \leq 0 \end{aligned} \quad (41.9)$$

Structural failures can also be handled in a natural fashion by changing the system dynamics model used to make prediction in either an adaptive fashion, a multi-model switching scheme or in this case, by using a real-time system identification module to provide the estimated degraded system dynamics.

MPC fault-tolerant control can be cast as a constrained model-following problem as shown in Fig. 41.10. The controller comprises three main components: the block “real-time system ID” which performs identification of the fault’s effects on system dynamics, a “reference model” which uses pilot commands to generate a reference trajectory for the aircraft’s state vector, and the MPC controller whose objective is to track the reference trajectory, using the output of “real-time system ID” to update its internal model, constraints, etc. The pilot gives commands to the reference model, and the goal of the controller is to cause the aircraft to track the resultant trajectory. At each time step, the MPC controller chooses an input sequence which minimizes the difference between the predicted future trajectory, given by the reference model

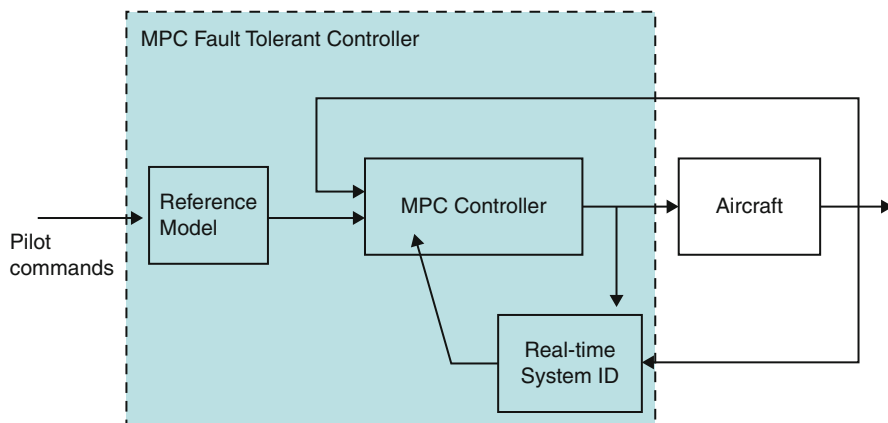

Fig. 41.10 MPC fault tolerant control architecture

under the assumption that the pilot's inputs are constant over the prediction horizon, and the predicted trajectory of the aircraft.

41.5 Flight Envelope Assessment and Fault-Tolerant Control Simulation Results

The NASA MAPSS engine model (Parker and Melcher 2004) was utilized to simulate engine faults for the evaluation of the fault detection and resulting dynamic flight envelope assessment techniques previously described. The self-tuning Kalman filter was used to identify and estimate the severity of the faults in terms of efficiency loss and/or flow capacity loss. At the flight control level, the NASA GTM aircraft model (Bailey et al. 2005) was utilized, and various actuator faults including control effectiveness loss and stuck actuators were simulated. Some select simulation results are presented below.

41.5.1 Dynamic Flight Envelope Assessment

In order to quantify the flight envelope, it was assumed that the thrust produced by the MAPSS model was utilized by an aircraft with certain predetermined characteristics. The characteristics of the aircraft are listed in Table 41.1. Within the simulation, pressure and temperature were varied as shown in Fig. 41.11, with the pressure assumed to drop roughly exponentially with altitude, while the temperature drops linearly with altitude up to a point, beyond which the temperature stays constant.

Table 41.1 Aircraft characteristics

| Parameter | Explanation | Value | Units |
|------------|---------------------------------------|--------|-------|
| A_w | Surface area of wings | 27.88 | m^2 |
| C_{Lmax} | Maximum lift coefficient before stall | 1.6 | None |
| C_{dmin} | Minimum drag coefficient | 0.01 | None |
| Φ | Equivalence ratio at sea level | 0.7 | None |
| M | Total mass of aircraft | 10,780 | Kg |
| T_{SL} | Sea level thrust | 130 | kN |

Fig. 41.11 Variation of pressure and temperature with altitude

Figure 41.12 shows a plot of the instantaneous flight envelope for a given level of engine fault. The NASA MAPSS software was modified with a new plot showing the estimated flight envelope. The result in Fig.41.13 shows how the flight envelope shrinks as a function of the engine fault severity level (in this case, the HPT efficiency loss).

41.5.2 Detection of Control Effectiveness Loss

With the strong tracking recursive identification algorithm, the A and B matrix of the linearized aircraft state-space model are identified in real time. Various scenarios including elevator/rudder/aileron/throttle effectiveness loss and aircraft weight loss have been simulated and evaluated with the fault-tolerant controller.

Figure 41.14 shows the identified control effectiveness change by the strong tracking recursive identification algorithm and the comparison with the result from classic recursive least square method. The true value is changed from 1.98 to 0.198

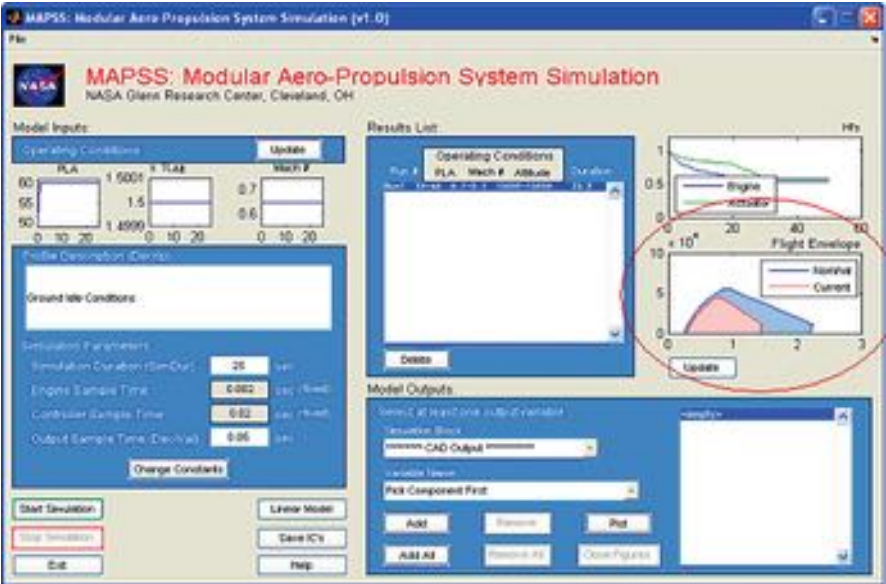

Fig. 41.12 Dynamic flight envelope assessment results added to NASA MAPSS GUI

Fig. 41.13 Flight envelope reduction due to severe engine fault added to NASA MAPSS GUI

at $t = 20$ s (i.e., a 90 % control effectiveness loss). The result shows that the tracking performance of the strong tracking recursive identification algorithm (blue solid curve) outperforms the classic recursive least square method algorithm (red dashed curve) in tracking a sudden change in control effectiveness of the elevator.

Fig. 41.14 Detection of control effectiveness loss

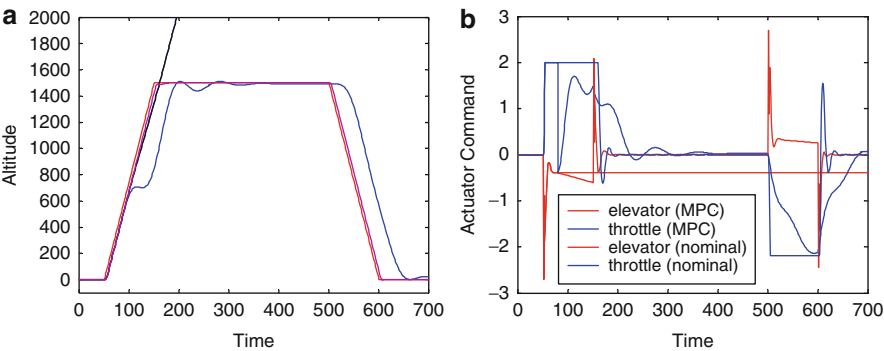

Fig. 41.15 MPC simulation results with stuck elevator actuator ($t = 75$). (a) Altitude response and (b) controls

41.5.3 Model Predictive Control for Stuck Elevator

An adaptive model predictive controller that utilizes the system dynamic model identified in real time was developed and tested with a stuck elevator fault scenario. A classic altitude hold controller was developed which utilizes throttle to control airspeed and elevator for altitude tracking. As shown in Fig. 41.15, after the occurrence of a stuck elevator fault at time 75, the aircraft would keep climbing up

without the fault-tolerant controller because the elevator is stuck at a climbing-up position (the black curve in Fig. 41.15a). With the adaptive MPC controller, throttle is used to control longitudinal dynamics, and the aircraft was able to accomplish the mission (the red curve in Fig. 41.15a) with degraded performance (the dashed blue curve in Fig. 41.15a). The elevator and throttle controls and the comparison with nominal controls are shown in Fig. 41.15b.

41.5.4 Prognostics-Enhanced ACM System

The safety of the unmanned vehicle involved in long-duration missions is dependent on not only the current health state (diagnostics) but also near-future health states (prognostics) as well. While a diagnostics-driven ACM system can react to and compensate for faults and performance degradation after they are detected, it cannot hope to overcome the fact that it will always be a reactive paradigm. As a result, the control strategies may in fact not be optimal over a longer period of time. By incorporating near-term prognostic information, undesirable future states of the system may be avoided or deferred through a suitable change in the control strategy while achieving required (or relaxed) mission objectives. In case a failure in certain system component is inevitable, a prognostics-enhanced ACM system can possibly minimize the effect or propagation of the failure by appropriate control reconfiguration and isolation strategies.

To illustrate the concept, one can consider the case of emergency landing of a distressed aircraft with a rudder failure (floating rudder with total loss of control authority). The loss of control is taken up by the engines operating in a thrust-enhanced, differential throttle mode. However, traditional engine time constants are too slow to be used in this situation. A fast-response engine controller is needed to reduce the time constants by pushing the engine operation more aggressively. As a result, engine stall margin and engine life can be significantly reduced which may lead to catastrophic engine failure. Therefore, competing requirements on aircraft performance (demanding aggressive engine operation) and engine safety (demanding mild engine operation) must be considered within the ACM framework.

The ACM strategy implemented is a supervisory safety verification controller (SSVC) which is a middle-level controller that determines low-level control configuration (switching between slow-response and fast-response engine controllers) at a certain decision interval. This level of control specifies parameters that the low-level controllers must assume in order to reallocate the controls once a fault has been diagnosed. It must be noticed that the low-level controllers (either slow or fast response) are responsible for the stability and performance of the engine while the SSVC optimizes the engine operation to achieve required aircraft performance while avoiding any violations of engine safety limits. Since the SSVC only operates at a near real-time decision interval (typically every couple of seconds), more computationally demanding optimization algorithms can potentially be applied at this level of controls.

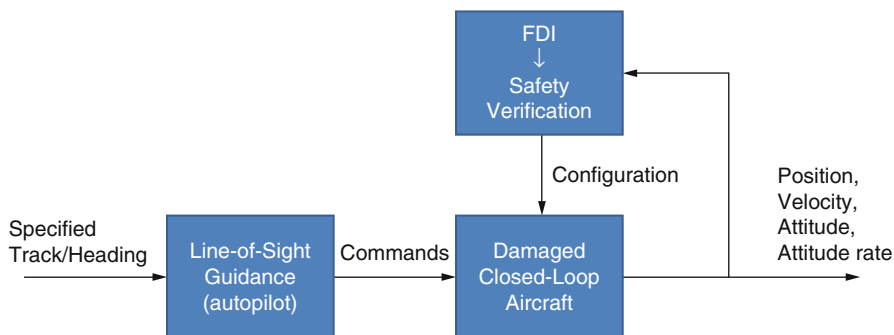

Fig. 41.16 Diagram of the safety verification controller using diagnostics and prognostics

Figure 41.16 illustrates the overall structure of a supervisory safety verification controller. The aircraft states including diagnostic and prognostic information are fed into an FDI/safety verification module which, in turn, computes the optimal control configuration given the fault and mission profile. The adopted configuration dictates which low-level controls are used and how the control is allocated (i.e., whether a conservative or aggressive policy should be adopted at any given time). A cross-track guidance system is adopted in lieu of a pilot as a baseline to provide commands to the flight controller (DeCastro et al. 2011).

For this emergency landing case study with rudder failure, the UAV's contingency envelope can be defined by three criteria:

1. Performance criteria: The maximum allowable error from the reference trajectory is 1,500 feet.
2. Operability limits: Engine stall margin is maintained above zero to avoid immediate loss of thrust and potential engine failure.
3. Prognostic (life) limits: The prognostic criteria penalize any trajectory or control policy that results in a large probability of accumulated engine failure by the end of the mission.

When considering engine prognostic algorithms, various types of prognostic algorithms may be used to track engine damage, including particle filter, Kalman filter, or data-driven algorithms. In order to use these algorithms in the supervisory control, the essential behavior of the algorithm is abstracted to a finite-state machine (FSM). The automaton discretizes the trajectory of the engine damage index and assigns transition probabilities to each node as a discrete-time Markov chain. Figure 41.17 shows how the probability of crossing the failure threshold is mapped to an FSM. The unsafe set corresponds to the failed state of the engine. It is important to note that the abstraction allows the prognostic model to be captured in the ACM optimization in a simplified way without losing essential information.

To demonstrate the overall reconfiguration concept, simulations are executed with the GTM simulation using only fast and slow engine control reconfiguration options. In the following scenarios, a new control decision is made every 10 s.

Fig. 41.17 Transforming a prognostic algorithm into a finite-state machine

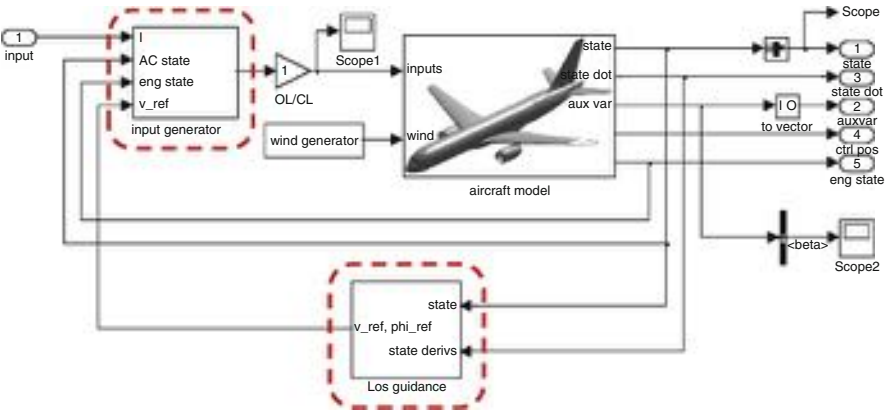

Fig. 41.18 Simulink diagram of the NASA full-scale GTM with safety verification control capability

The additive uncertainties to simulate effects such as wind gusts were modeled as Gaussian noise on each of the aircraft’s states. A Simulink model developed for this study is shown in Fig. 41.18.

In this simulated scenario, the GTM is making a series of coordinated turns to reduce the cross-track error to a specified parallel track to prepare for landing. The cross-track trajectory is shown in Fig. 41.19. For the 200-s simulation, the reconfiguration policy along with the trajectories on the aircraft’s lateral position and the stall margin between engines are shown in Fig. 41.20. The policy switching is dominated initially by the stall margin requirement by starting in the slow configuration. After 80 s, the control attempts to meet the cross-tracking performance

Fig. 41.19 UAV cross-track trajectory

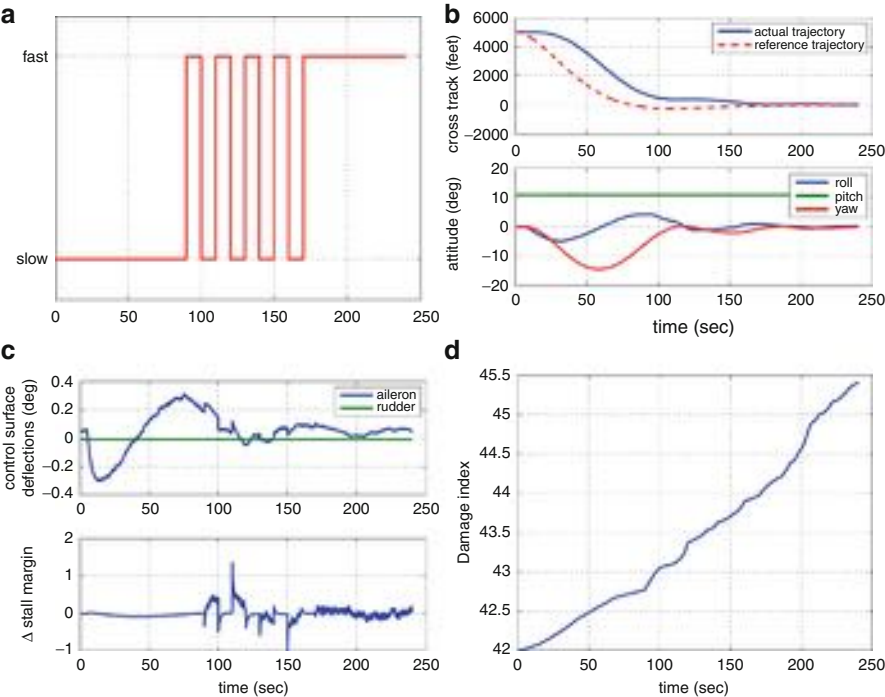

Fig. 41.20 Optimal configuration and states for SSVC with consideration of prognostics. (a) Optimal control sequence, (b) aircraft states, (c) aircraft control inputs and engine stall margin, and (d) engine damage index

requirement by switching to the fast configuration. The ACM strategy switches at every decision instant in order to improve the remaining useful life of the engine, thereby reducing the probability of failure before the end of the mission. Although the controls are not configured to mitigate bumpy transfer, the switching does not introduce oscillations in the overall response of the aircraft. Both the cross-track performance error and stall margin remain below thresholds throughout the horizon. The figure also shows the role of the prognostic model on the ensuing damage accumulated on the engines during the maneuver. The hypothetical hybrid abstraction of the prognostic algorithm is applied, assuming that the system is

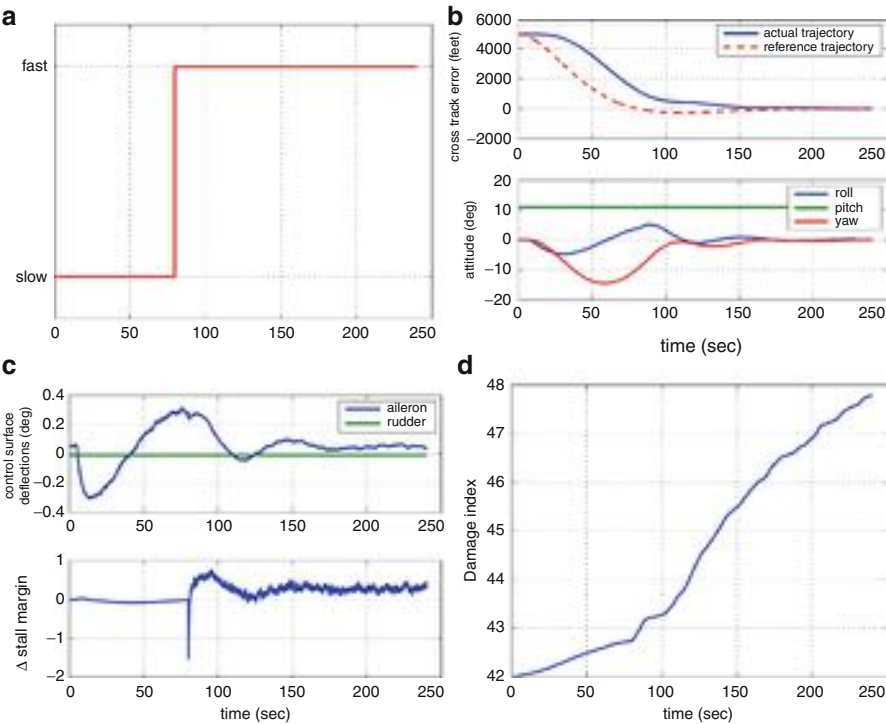

Fig. 41.21 Optimal configuration and states for SSVC without consideration of prognostics. (a) Optimal control sequence, (b) aircraft states, (c) aircraft control inputs and engine stall margin, and (d) engine damage index

initially in the moderate damage state. When prognostic information is included in the optimization, the damage index reaches 45.5 at the end of the mission.

As a comparison, the UAV cross-track control results without engine prognostics in the loop are shown in Fig. 41.21. Similar to the previous result, the ACM policy switching is dominated initially by the stall margin requirement by starting in the slow configuration. After 80 s, the control attempts to meet the cross-tracking performance requirement by switching to the fast configuration and remains in this control configuration for the duration of this simulation. As a result, the engine damage index has grown to about 48 (as compared to 45.5 in the previous simulation) at the end of the simulation. This is a clear evidence of an engine safety threat when engine life (prognostics) has been ignored in the ACM optimization.

41.6 Conclusions and Future Work

This chapter presented selected technologies for implementing an integrated aircraft health assessment and fault contingency management system. An innovative hierar-

chical fault contingency management architecture that integrates real-time system health management functionality, high-level reasoning, control reconfiguration, and automated contingency management modules has been developed. Real-time system identification and health assessment algorithms have been implemented to identify the dynamics and performance limitation of the degraded system. An intelligent approach has been developed to estimate safe flight envelope after the occurrence of engine faults. MPC-based reconfigurable fault-tolerant control techniques have been developed and tested in simulation to accommodate flight actuator faults using the system dynamic model identified in real time. Simulation studies using the NASA MAPSS engine model and GTM aircraft model have successfully demonstrated the feasibility of the presented concept and architecture. This chapter further explored a more advanced topic on incorporating prognostic information in a proactive ACM system. Simulation studies on a GTM aircraft model have been conducted and demonstrated the benefits of using near-term prognostics in control reconfiguration. This capability upgrades the conventional diagnostics-based reactive fault-tolerant strategies to a prognostics-enhanced proactive fault accommodation paradigm.

To further develop the ACM concept and eventually integrate it into real-world autonomous systems, several important issues need to be addressed. First, the diagnostic and prognostic information fed into the ACM system have to be reliable, accurate, and available in real time. This is certainly a challenging requirement on the design of onboard PHM system. Prognosis uncertainty management is another important issue that affects the performance of the ACM system significantly. In practice, accurate and precise prognostics has proven rather difficult to accomplish; thus, uncertainty management and reduction techniques have to be implemented before the prognostics can be optimally utilized by the ACM system. Furthermore, in order for ACM systems to be used in safety-critical aerospace applications, they must be proven to be highly safe and reliable. Rigorous methods for ACM system verification and validation (V&V) must be developed to ensure that ACM+P system software failures will not occur, to ensure the system functions as required, to eliminate unintended functionality, and to demonstrate that certification requirements can be satisfied.

Abstract

This chapter describes how model-based simulation can be employed to automatically generate the system-level effects for comprehensive sets of component failures on systems within the aircraft. The results of the simulation can be used in several ways. They can be used to produce a system-level failure modes and effects analysis (FMEA) for aircraft systems. They can be used to identify the sensors necessary to discriminate remotely between different failures on the aircraft. Once a set of sensors have been chosen for placement on the vehicle, the simulation results can also be used to generate diagnostic and prognostic software for deployment on the vehicle.

Using automated FMEA safety analysis software is more efficient than doing the same work without software and also provides a guaranteed level of performance. Using the results of this analysis can provide sensor selection and diagnostic capability while retaining some of the benefits of rule-based diagnostic systems. Alternative model-based techniques have been widely used to create diagnostic systems in a variety of domains, and these approaches are compared with the diagnostic capability provided by a failure effect-oriented technique from the perspective of the UAV application.

42.1 Introduction

Prognostics and health management (PHM) comprises the technology and systems needed to enable UAVs to monitor their own state. Based on that monitoring, the PHM systems need to make assessments of mission readiness that can be utilized by higher-level planning in the decision modeling area. One recent UK Project specifies the goal that for use in unsegregated airspace, PHM systems should be capable of replicating the fault detection, assessment, and decision-making ability of pilots. The current generation of computer systems falls far short of the high-level reasoning and decision-making capabilities of an experienced pilot; however, this limitation can be mitigated by the use of sophisticated and high-coverage lower-level fault detection and reconfiguration capabilities.

This chapter will show how model-based reasoning and simulation can be used to automate the process of producing a comprehensive failure modes and effects analysis and how this information can then be used to assist in the assessment of diagnostic capability and sensor selection. The techniques of this chapter were combined and integrated during the first phase of a UK government-funded program: Autonomous Systems Technology Related Airborne Evaluation and Assessment (Astraea 2009). The aim of the ASTRAEA program is to enable the routine use of UAS (Unmanned Aircraft Systems) in all classes of airspace without the need for restrictive or specialized conditions of operation. This is achieved through the coordinated development and demonstration of key technologies and operating procedures required to open up the airspace to UAS.

42.1.1 Prognostics

Prognostic capability provides a forecast of some future occurrence that may impact on a system. This general concept is interpreted in different ways dependent on the level of abstraction being used. To component engineers, the aim is usually to predict component failure or wear out before failure or degradation occurs that will negatively impact on system behavior. Competing objectives for reduced maintenance schedules and cost lead to activities such as condition-based maintenance. Prognostics at this level are inherently difficult and require detailed numerical monitoring and usage data. In some domains such as mechanical systems symptoms

such as increased vibration can provide prognostic indicators; however, in other areas such as electrical components, there are often very few if any indications prior to catastrophic component failure. In some systems data such as usage pattern logging can be used in models that predict degradation and assist in condition-based maintenance. The specialist modeling and limited applicability of these systems are outside of the scope of this chapter.

At the systems or mission level, prognosis involves the ability to reason about the impact of the loss of low-level functionality on higher-level objectives. For example, the detection of a fuel leak may require a change of mission objective (abort, emergency landing, etc.), and the prognostic task is to determine available scenarios and select appropriate action. The prognostics and health management (PHM) area is responsible for developing the technology and systems needed to enable UAVs to monitor their own state. Based on that monitoring, the PHM systems need to make assessments of mission readiness that can be utilized by higher-level planning in the decision modeling area. These tasks are usually considered as the vehicle health management systems and are addressed in other chapters of this book. The input information to these prognostic tasks is the result of system or subsystem design and diagnosis, and this will be the focus of this chapter.

42.2 Model-Based Reasoning

Model-based systems and qualitative reasoning (MBS&QR) as a visible subfield of artificial intelligence can be traced back some 20 years to the publication of seminal collection of papers in the field (Bobrow 1984; Hamscher et al. 1992), although there was of course earlier work in this area (de Kleer 1977; Brown et al. 1982).

Model-based reasoning encapsulates a number of key concepts identified in (Price et al. 2006b; Peischl and Wotawa 2003) as follows:

- Separation of system model from problem solving. Model-based systems are based on a separation of the problem-solving algorithm from the model of the domain. Once a library of appropriate component models has been established, only a structural description of the respective device or system (e.g., obtained from design data) is required to automatically generate a system model and, based on it, problem-solving software dedicated to this device or system.
- Compositionality. Since systems are assembled from standard components and the behavior (and misbehavior in the case of a fault) of the system emerges from the behavior of these components, establishing a model library is feasible and entails collecting models of (correct and faulty) behavior of such standard components. This is important: this kind of model-based reasoning cannot be performed if the overall behavior of the system cannot be composed from the behaviour of the components and the way in which they are linked. Where there is compositionality of models, a high degree of reuse is possible, as well as prediction of what will happen in unexpected circumstances such as failure situations.

- Existence of different abstract problem solvers. The combination of generic domain independent problem solvers and compositional models of a domain can produce model-based systems that are able to reason efficiently about a product using relatively easy to obtain and objective design data.
- Modeling at different levels of abstraction. In diagnosis, for example, modeling different kinds of problems may well involve modeling different phenomena and at different levels of detail. However, while there may be a need for quantitative and or semiquantitative models, qualitative models provide a nice solution for representing phenomena at a higher level of abstraction.

Model-based reasoning (MBR) appears in standard AI texts (Luger 2002) and has been widely used in several domains for a variety of tasks as documented in the review by Price et al. (2006a). In particular, the efficiency and coverage provided by qualitative models have many advantages in the early stages of design and in the natural abstraction of explanations provided by such simulations and analysis. The efficiency of MBR is particularly suited to the task of failure modes and effects analysis due to the high level of system state coverage required combined with the large number of failure modes to be considered. An FMEA must present failure modes and associated risk together with the possible causes of the failure mode. The abstraction provided by QR (Kuipers 1986) makes it possible to identify failure modes and effects using language that is intuitive to an engineer. For example, an explanation that a *low-pressure* failure mode has the effect of *reduced engine output power or shutdown* and is caused by a *pipe blocked* fault may be derived directly from a qualitative model. Detailed numerical models are often difficult to obtain, particularly early in the design process when it is still feasible to change the design and sensing requirements. This consideration is of particular importance if the objective is to design diagnosis capability and mitigation into the system rather than retrofitting it to a completed design.

The major limitation of qualitative techniques is that in some circumstances the simulation can predict alternative behaviors. For example, a qualitative electrical circuit containing a bridge network may predict current flow in either direction across the bridge resistance because the flow depends on the ratio of the surrounding resistance values. Similarly, for systems that use a qualitative representation of time, there may be alternative behavior predictions dependent upon the ordering of events within the same qualitative time period. This chapter considers a modeling strategy that ensures qualitative ambiguity does not become a limiting factor and that it is related to physical system characteristics that have real behavioral significance. Given these constraints qualitative ambiguity actually provides useful additional information by identification of critical parameters within the system and can be addressed by adding additional constraints to the model (effectively making explicit a design specification) or appealing to selected numerical simulation for particular situations.

The following sections will consider how model-based reasoning can be used to automatically generate a comprehensive FMEA. This report contains a great deal of diagnostic information and may also be used to create workshop diagnosis or to automatically generate a diagnostic system.

42.3 Failure Modes and Effects Analysis

Manual FMEA is generally carried out by identification of failure modes and subsequent derivation of system effects and potential root causes, such as component failure, by an engineering team. Automated FMEA generally approaches the problem from the bottom up by performing system simulation for each potential fault and interpreting the resulting behaviors in terms of system functionality (Price 1998).

The main concept is that a description of the overall behavior of a system can be constructed by knowing the structure of a system and the behavior of each of its components. In order to determine the behavior of the system when a failure occurs, it is only necessary to replace the component that has failed with a version of the component that reproduces the faulty behavior, and the model of the system will then reproduce the effects of the failure for the whole system.

Figure 42.1 shows the different levels of reasoning needed to perform model-based simulation of a system containing electrical and/or fluid flow components. The system description is usually provided at the component level – the system is described in terms of its components and their states and connections. This can be mapped onto the resistive state of all components, and the state of the overall system can be determined qualitatively (CIRQ). Flow and effort variables are global in nature and cannot be derived by propagating local component input/output behavior. At the qualitative level, a generalized solver (Lee 1999) can be used to determine global current and voltage in the electrical domain or pressure and

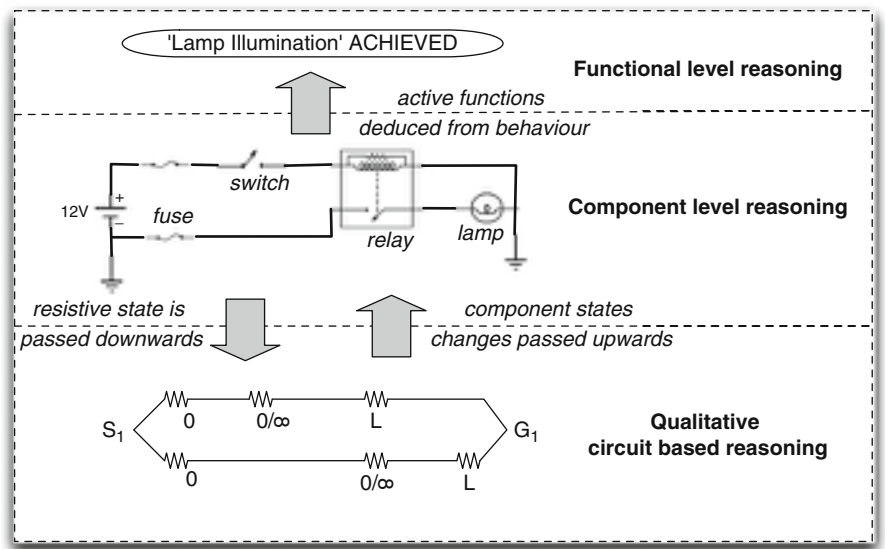

Fig. 42.1 Levels of electrical simulation

flow in a hydraulic or fluid transfer system. Alternative approaches such as bond graphs (Borutzky 2010; Mukherjee and Karmakar 1999) can also be used to provide similar information, although this may require more modeling effort and careful consideration of the causal flow through the circuit. For the purpose of FMEA, and the generation of rule-based diagnostics, and as a natural consequence of qualitative analysis, a state-based modeling approach is often adequate at the component level and used in preference to a complex dynamic numerical model for most cases. For states or subsystems where a qualitative or state-based model cannot provide the required behavioral detail or is unable to answer the required questions, numerical models can be used.

Changes to the effort and flow variables may result in changes in component state (e.g., if current is now flowing through a relay, then it may close, changing the state of the relay component, necessitating further qualitative simulation). Eventually, the state of the system will either stabilize or oscillate. Local component behavior such as the filling of a tank or the logic of an electronic control unit (ECU) is modeled at the component level often using finite state machines (FSM) (Harel and Politi 1998). The FSM representation is widely used to represent abstracted system or component behavior, being used to represent systems as diverse as communications protocols (SDL) and software behaviour (UML) (UML 2011). The results of the interchange between the component level reasoning and the qualitative electrical reasoning can be abstracted to the functional level and returned in terms of which functions of the system have occurred.

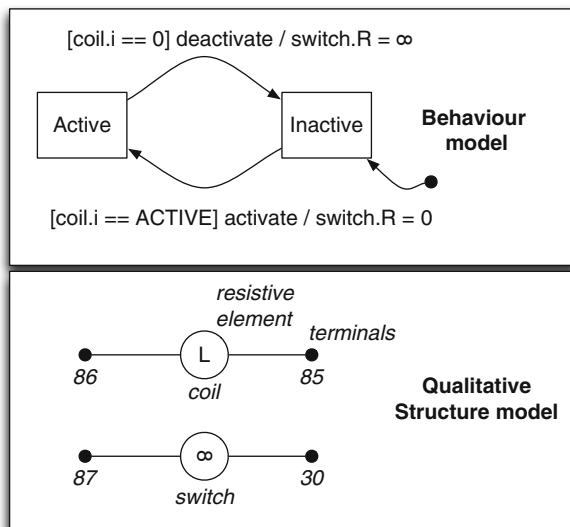

Figure 42.1 illustrates the relationship between the three levels for a very simple system, but these techniques work for electrical/electronic systems with several thousand components and produce useful FMEA results that pinpoint significant potential failures early in the design process.

To summarize the information required:

- Component models or a component library. Each model contains structural information such as a resistance network between the terminals of the component and also behavioral information such as a state chart that controls changes to the structural elements.
- A system schematic that connects individual component instances.
- A description of the system functions and which behaviors provide these functions.

A choice must be made as to the level of granularity required for the qualitative variables. A minimal but surprisingly powerful scheme for qualitative resistance is $\{0, \text{load}, \infty\}$. In this scheme, an open switch has ∞ resistance and a closed switch has zero resistance, and a power-consuming device is represented as a load. From this information the simulation can derive that a fractured wire will cause a motor to stop or that a bad connector (load) will lower the voltage across a motor. This is enough information to derive functional effects of an FMEA and for diagnosability analysis. There are situations where a finer-grained model is useful, for example, when dealing with event durations using a qualitative scale such as $\{\text{day}, \text{hour}, \text{second}, \text{mS}, \text{uS}\}$ is useful to avoid ambiguity. For example, if two components have state-changing behavior, the potential event ordering ambiguity between a tank

Fig. 42.2 Example simple relay component model

emptying and a relay switching is resolved. The tank model may specify that at nominal flow a partly filled tank will take “hours” to empty whereas the relay will switch in “mS.” Care must be taken with the semantics of such a scheme since qualitatively it is specifying that *any number* of sequential events in one qualitative timeslot will finish before any events in the next timeslot. Therefore, the qualitative model must not be too fine grained, and each level must represent a qualitatively significant and distinct region of behavior.

A major benefit of the qualitative modeling scheme is that the models are highly reusable since none of the numerical parameters are present. The model library will therefore contain a single model to represent a whole class of actual device part numbers. For example, a single model covers many “normally open single pole” relays. As an example Fig. 42.2 shows a structural and behavioral model for a basic relay. Such models are easy to produce and can be used in early stage design before detailed parameterization of the system is possible allowing early failure mode analysis and diagnosability characterization to be carried out.

The failure behaviors for each component failure mode are provided by a modification of the nominal component structure or behavior model. For example, a blocked pipe will simply change the resistance of the pipe to “infinite.” These faults are created for each type of component and are stored in the component library as part of the component description. Faults are then automatically inserted for each instance of the component present in a system. This section has described how nominal and failure behavior can be generated; however, an FMEA report is required to summarize the abnormal behavior of each failure in terms of the impact on the system functions. To automate this requires the system functions to be provided in a machine-readable form. The next section describes briefly

one approach to this known as the functional interpretation language (Bell et al. 2007) that was developed specifically for behavioral interpretation and abstraction.

42.4 Functional Description

Functional reasoning is a term that includes a number of knowledge representation techniques aimed at capturing the purpose or intent of an engineered system. Functional modeling has been in use for a number of years, and there are a variety of methods (see Far and Halim Elamy 2005; van Wie et al. 2005 for a comparative summary), both for deriving the behavior of a system from knowledge of its structure and component function and also for interpreting system behavior. Interpretation and verification tasks benefit particularly well from inclusion of relatively small amounts of functional information. Functional modeling is an important aspect of techniques such as MADe (PHM Technology) where a standardized taxonomy of functions is used together with a structured framework for modeling system functional dependencies.

MADe is used to model systems in order to identify and report on potential functional, monitoring, and maintenance issues in system design. This enables failure analysis to be conducted concurrently with system design using fuzzy cognitive mapping and bond graph simulations.

In the case of FMEA, a simple functional model is able to interpret many hundreds of qualitative variable values into the state of a set of system functions. One approach considers functions as having four states as shown in Table 42.1. The function state is determined from the state presence or absence of the function triggers and expected effects.

An example functional model fragment is shown in Fig. 42.3 for an aircraft fuel transfer function. The functions are linked to the simulation via the triggers and effects produced from the simulation. In this example “TVL.TR” are valve positions and “OC.WT” are fuel tanks used in the trigger and effect expressions, respectively. This functional interpretation language allows hierarchies of functions to be formally specified and relates the function to its purpose within a deployment environment (larger system) and identifies the behavior (triggers and effects) that determines the state of the function. In this example the behavior is linked to a qualitative simulation that returns values such as “FORWARD” and “REVERSE” for flow direction and “FUEL” or “AIR” as the substance present in pipes. This

Table 42.1 Function states

| Trigger | Effect | Function state |

functional language is tailored for FMEA and captures risk associated with function failure as severity and detectability using the interpretation required by the engineer.

42.4.1 Generating FMEA Results

FMEA unlike fault tree analysis (FTA) (Vesely 2011) normally considers the effects of all possible individual component faults. While it is possible to consider multiple faults in an automated FMEA analysis, the effort involved precludes this in a manual analysis. In an automated FMEA, the number of concurrent faults considered is limited only by the simulation time available since it grows exponentially with the number of faults. One approach is to limit multiple fault analysis to combinations of faults with combined component failure likelihood above some threshold. This will have the effect of considering only combinations of less reliable components. The increase in output is generally not as great as the increase in simulation time since many combined faults will produce effects no worse than the individual failures or the combined effects of individual failures and thus add nothing extra to the FMEA output. It is only combinations that lead to effects that are not part of the effects of the individual faults that require additional reporting.

An FMEA report can be automatically generated by comparing the results from a simulation of nominal system behavior with the results of a simulation of a version of the system for each possible component fault. The differences between the two simulations comprise the effect of the component failure (e.g., a function occurs at

some point in the simulation of nominal system behavior, but fails to occur in the same state when there is a specific component failure). More details of this technique are given in Price et al. (2006a).

The system needs to be simulated in its different operating modes in order to identify the possible effects of a failure. That means that it is necessary to decide how the system should be exercised during simulation in order to cover all operating modes. Normally an engineer will provide a set of inputs that cause the system to enter all of its operating modes and configurations. For example, in an aircraft fuel system such as the example in Fig. 42.4, the valve positions may be changed to encounter normal fuel feed, fuel transfer operations, and fuel cross feed configurations. The set of inputs chosen is referred to as the scenario. On occasion an engineer may decide to only deal with a subset of system operation, and this will limit the effects that will be observed to those observable during the selected operations.

For simplicity the fuel supply system fragment in Fig. 42.5 will be used to illustrate the FMEA generation. A fuel tank is used to supply an engine via several pipes using a single pump. A flow sensor, a pressure sensor, and an isolation valve are present in addition to a three-way valve that is not used in this system fragment.

The FMEA generation system operates in the following way. The system is simulated for the chosen scenario with no failures present, and all observable values are recorded for each step of the simulation. The system model is reconfigured for each component failure. Each step of a failure simulation is compared with the non-failure simulation and the differences are recorded.

The automatically generated FMEA provides a description of the observable effects of each fault. These effects are consistent, providing all potential effects in qualitative terms. Figure 42.6 shows a fragment of an FMEA generated from the example in Fig. 42.5. Due to the qualitative nature of the analysis, the results are naturally presented as qualitative differences (such as value higher than expected).

The FMEA results are ordered by significance and are inspected by engineers to identify how significant failures can be mitigated, either by decreasing the effect of the failure (e.g., by providing backup systems) or improving the detection of the failure (e.g., by adding sensors) or reducing the occurrence of the failure (e.g., by using more robust components). Risk priority numbers (RPN) can be generated for each failure item if required for a criticality analysis and comprise the product of severity, detectability, and occurrence. The likelihood of the failure is stored as part of the component failure model, and the detectability and severity are associated with the failure of function and are therefore part of the functional model as can be seen in Fig. 42.3.

The FMEA report provides a consistent report that covers all component failures of specific types, and this consistency and coverage provides a basis for generating diagnostics that will be explored in the next section.

The selection of the scenario is an area where the engineer can have an influence on the FMEA. The aim is to exercise all of the system functions that are of interest for the faults to be considered. If the behavior associated with a function is not exercised, any fault in the components that are involved in producing the behavior

Fig. 42.4 Fuel system example

Fig. 42.5 Example fuel system fragment

will not produce effects, and the report will not be able to include that component fault as a cause of the function failing. For most systems it is only necessary to exercise each function individually since the worst effects of component faults are already present. It is possible that specific combinations of function activations or function operating modes could cause faults to have an effect that is worse (higher risk function failures) than the individual function activations, and in these cases the relevant function states need to be included in the FMEA. Including additional function combinations in the scenario has no disadvantage other than increased execution time, since the results will only need to include those that produce additional effects. One strategy sometimes used is to exercise individual functions and then “all functions” together if this is possible or largest physically possible subset if not.

Systems that contain backup and/or redundant functions need to be identified in the functional model with the relevant triggering conditions and the FMEA and functional model configured accordingly; the FMEA will then note that the backup function has been activated when a relevant fault occurs. A selective multiple fault analyses would be needed to determine the effects of faults in both the primary and nonredundant systems. Functional models such as (Bell 2006) identify fundamental meta-function types such as warning/telltale, fault mitigating, interlocking, and recharging, providing strong indications that the scenario and components involving these functions need particular consideration.

42.5 Sensor Selection and Diagnosability Analysis

Diagnosis is a fertile application area for artificial intelligence methodologies. Techniques range from rule-based expert systems and case-based reasoning to black-box approaches such as neural networks and have been applied to a wide variety of applications, for example, Travé-Massuyès and Milne (1997). This section will focus on model-based techniques because unlike black-box techniques

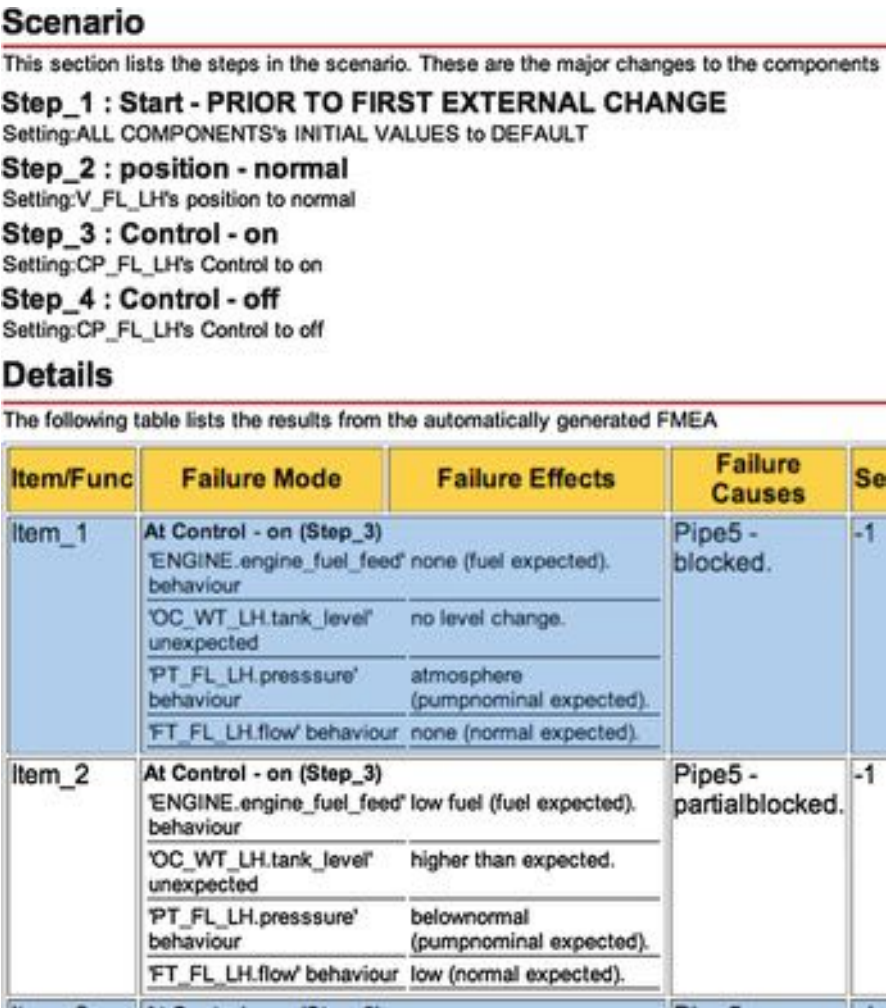

Fig. 42.6 FMEA fragment, for example, system

they can explain how a result was obtained and unlike rule-based expert systems or case-based techniques, model-based method do not require large amounts of historical data, training sets, or rules to be obtained from engineers. The traditional consistency-based diagnosis approach is outlined in Fig. 42.7 and is flexible and generic with widely used tools available (Forbus 1990; Forbus and de Kleer 1993; Kuipers 1994; Struss and Price 2003); however, these approaches do require that the model executed in real time, probably onboard the aircraft, to enable the discrepancy in actual and predicted behavior to be used to detect faults.

This approach does not necessarily require fault models for components: however, this can lead to the possibility of the production of physically impossible

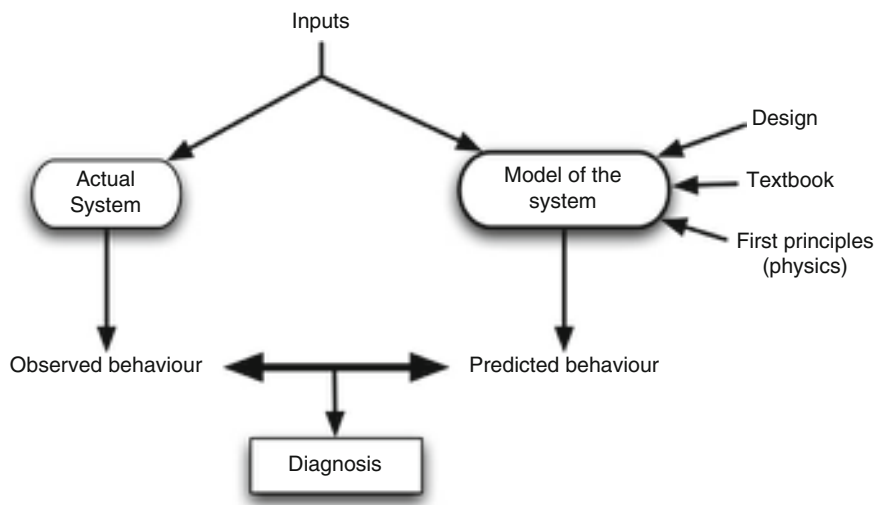

Fig. 42.7 Model-based diagnosis

diagnoses; for example, the classic example of three lamps in parallel with a battery, in the case where two lamps fail as well as a correct diagnoses, the possibility that the battery has failed and the lamp has failed (produces light when no power is applied) is produced. The kinds of problems stem from only having models of correct behavior, since the diagnostic system has no knowledge of how a component can fail. Qualitative models significantly reduce the amount of work required to specify fault models of components with most faults being modeled as simple changes to structural or behavioral elements. Automated FMEA relies on having fault models available for all component failure modes of interest.

Onboard model execution and certification concerns have led to a different approach to model-based diagnosis based on automated FMEA results that uses off-line models and simulation to produce sets of diagnostic rules that can be used as the basis of an onboard system. The rule set can then be used to perform diagnosability analysis. Automated FMEA data provides a great deal of diagnostic data. A comprehensive set of possible component faults is included, and the resulting effects for wide coverage of the system functional states will be available. Furthermore, and unlike a manually generated FMEA, an automated FMEA is produced by simulation and will provide accurate, consistent, and detailed effects for each fault. The results can therefore be processed automatically to produce diagnostic rules (symptoms) for each fault. In addition, the automated FMEA has been validated by an engineer providing higher confidence that the failure modes and causes are reasonable.

Once a set of diagnostic rules is produced, it can be tuned and combined with other techniques such as Bayesian networks (BN) (Ben-Gal 2007) to produce an efficient onboard system that is able to calculate the probability a fault will exist given a set of symptoms and thus provide ranked sets of potential faults. A BN (Fig. 42.8) is able to accommodate an incomplete set of diagnostic rules

Fig. 42.8 Bayesian diagnostic network

or uncertainty in the observations, thus making the system less sensitive to the numerical thresholds set for qualitative values and also to the states produced the FMEA scenario. Due to its statistical nature, a BN can operate with whatever symptom and fault data is available, for example, symptoms produced by hand from manual FMEA or symptoms that are incomplete or contain contradictory evidence. Other than thresholds, the network uses three basic numerical measures:

Symptom leak – probability that the symptom will be observed even though there are no faults. By default this is set to 0 for symptoms generated from an automated FMEA symptoms to indicate the symptom will not be observed unless a relevant fault exists. It may be decided that certain observations are more likely to be spurious than others due to sensor or system characteristics.

Prior – probability that the fault has occurred prior to any symptoms. This is the fault occurrence number in FMEA (or 0.01 default)

Fault – probability that the symptom will be observed given the fault. By default this is set to 1 for the auto FMEA symptoms to indicate the symptom will be observed if the fault exists. Other values may be used for some symptom or fault categories because the effects predicted by the FMEA are less or more significant than can be determined qualitatively. For example, leaks may not always produce a *measurable* pressure drop, even though theoretically any leak would produce some drop in pressure. Engineering experience can also be captured and added into the model over time. For example, if a valve was found to make a characteristic sound (which can be detected), then this symptom can be added and conditional probabilities added based on how often the sound was reported for each fault.

When one or more symptoms are observed, these values are propagated through the network to produce an ordered list of possible faults. A confidence value is associated with each predicted fault allowing decisions to be made within the higher-level control elements of the system.

42.5.1 Generating Symptoms from an FMEA

The automated FMEA contains a lot of diagnostic information in the form of component fault – effect relationships. In addition these relationships are validated

once an engineer has considered the FMEA. For convenience the symptoms are categorized into three types, although algorithms that generate the symptoms generate whichever type is necessary based on the number of observations needed and to ensure symptoms are able to exonerate faults if required:

- *Single value*, for example, *pressure transducer value = out of range low*. In this situation a symptom is a simple value that does not occur during normal operation and directly indicates one or more faults.
- *Multiple value*, for example, *level = empty AND low level switch = on*. Two values may be linked to indicate an inconsistency in system operation caused by a fault. Typically, this is because two values measure physically related properties and should be consistent in the absence of a fault.
- *Conditional IF* (*pump = on*), *pressure monitor = high* or *IF (Valve SOV4 commanded OPEN), Open Sensor is not responding OPEN*. Conditional symptoms may be used when a value is only indicative of a fault in specific operating modes or configuration. For example, a low-pressure reading might only be significant when a pumping operation is in progress. If no pumping is carried out, then the symptom does not apply (pressure will be expected to be low). The condition specifies if the observation is valid. For the diagnostic net (discussed in following paragraph), the distinction between multiple value and conditional symptoms is important because the symptom observations are not entered to the net for an invalid symptom.

During diagnosis symptoms with a satisfied condition are valid, and valid symptoms may either indicate a fault if the overall symptom is satisfied or exonerate a fault if the overall symptom is false. Invalid symptoms are not applicable in the state or operating mode being considered.

The FMEA report provides differences of observable values, for example, *when PIPE5 is blocked, PT_FL_LH pressure is below normal when normal was expected*. This type of information can be used to produce the kind of fault-symptom information needed by the online diagnostic system. The symptoms should be as simple as possible while still providing a definite indication of the associated fault. The FMEA produces output in the form of the difference between nominal and failure operation at each step of a scenario, exercising the system. An example may be *After switch X closed and switch Y closed, Obs A=L when Obs 1=H expected*. The FMEA information does not directly provide a symptom because it is usually not known explicitly what is expected. The symptoms must therefore be based only on identification of abnormal observations. The FMEA item above plus additional simulation data generated during the FMEA production is used to produce a symptom of the form: *condition = {(X, closed), (Y, closed), (Obs B, Active)}; observation = {(Obs B, L)}; faults = {Pipe1 Blocked, Pipe2 blocked}*. To produce symptoms, additional nominal observations are often required such as the value of *Obs B* in the example.

Valid symptoms must satisfy two constraints. Firstly, a symptom should only be present when the associated fault is present. Secondly, it is desirable to detect as many faults as possible in as many operating states as possible. The first constraint requires that any potential symptom be identified such that it is not satisfied in any

nominal operating mode; however, it can be satisfied for other faults if general symptoms are required. There are efficient set theory algorithms for performing this kind of search; one specific example used for this application can be found in Snooke and Price (2012).

The second constraint implies symptoms should be general and therefore contain the fewest measurements, such that the first constraint is satisfied. Simply using symptoms that include every available observable value produced from the component failure simulations will create a very limited diagnostic system because faults will only be diagnosable in the states contained in the FMEA scenario. The simulations carried out to produce an automated FMEA provide a *subset* of the possible failure and nominal system states. To produce symptoms that diagnose faults over the majority of system states requires generalization of the effects of faults. Such generalization is achieved by reducing the number of observations in the symptom, in particular by excluding those that are not relevant to the fault being diagnosed.

42.5.2 Associating Measurement to Functions

The functional model (also used to interpret the FMEA) is the enabling concept that indirectly provides abstract-guiding knowledge-facilitating extrapolation of symptoms to system states that were not present in the FMEA. Measurements are associated with system functions based on the achievement and failure of functions across the entire FMEA. Given a comprehensive set of failures, this provides a simulation-derived description of which functions each component/measurement affects and is used to indicate a measurement has some behavioral or structural “causal” relationship to a function based on evidence of failure effect from the FMEA. Often these will simply be different value measurements from the same sensor; however, this is not assumed. By associating these abnormal measurements with functions that simultaneously fail, a mapping of function-associated measurements is created. Even measurements structurally adjacent to external triggers will be affected by faults in the connecting components. For example, *switch.position == on* is a trigger; however, the current flow through the *switch.contact* will be affected by faults such as the contact being stuck or wiring faults in the switch circuit and will be associated with any functions that are affected by any of the switches failure modes. This produces a set of measurements that agree with engineering expectation of all the components used within the implementation each function. However, even if this is not clear, there must be a structural or behavioral relationship between the function and associated measurements, as required for measurement selection.

A measurement-function mapping in turn allows an assessment of the relevance of measurements associated with a fault; measurements associated with functions that are never affected during the exercising of the fault (which should include at least all individual system functions) can be considered irrelevant and are removed from the set of measurements to be used as candidates for any symptom that will

diagnose the fault. This prevents symptoms being generated that rely on spurious correlations between measurements and faults due to the incomplete coverage of the system state space during the FMEA.

42.5.3 Fault Exoneration

Diagnostic symptoms may be required to be negated to perform fault exoneration – a symptom expression evaluating to false needs to indicate fault absence. For example, consider a lamp with a plausible symptom:

lamp == inactive AND switch == on implies faults {lamp blown, switch dirty, lamp wire fractured}

If the switch is off, then *switch == on* is false resulting in a false symptom expression, but this does not imply the lamp is OK – it could be blown. Manually crafted symptoms are often conditional so that symptom absence will exonerate associated faults. This is because engineers consider the implication of not seeing the symptom as well as its presence. In some applications such as a BN-based diagnostic system may require that symptoms exonerate faults. This also allows better fault detection by allowing evidence from nominally operating parts of a system to contradict evidence from very general symptoms, hence reducing the set of possible faults. That is, a symptom expression must not exonerate a fault for an observation where the fault exists and to achieve this requires additional checks in the symptom generation algorithm. Fault exoneration requires that the algorithms include additional features to ensure that observations are included in the conditional part of the symptom as necessary to ensure the symptom is only valid in operating states such that the symptom can be negated.

42.5.4 FMEA Coverage and Symptom Generation

The coverage provided by the FMEA can have an influence on the selection measurement strategy required to generate symptoms. For example, consider Fig. 42.9. Assume the functions A and B were not exercised simultaneously during the FMEA. There will be an entry in the FMEA for fault *w2 fracture* when the switch *sw1* is closed providing the effect *function A failed (function B is inoperative)*. One of the symptoms generated from this simulation requires the state of *w1* and *sw1*. Wire *w1* is allowed because it is associated with *Function A* (as are all the other wires on the path through *sw1* and *l1*). The symptom generation search algorithm determines that state of the switch is included in the conditional part of the symptom because if the switch is not closed, electrical activity in *w1* can say nothing about the fault in *w2* (it depends on the state of *Function B*). The symptom correctly predicts the fault *w2 fracture* when *function A* only is active but falsely exonerates the fault when both functions are triggered because *w1* is active when the condition is true but the symptom is false. Using a BN the probabilities could be adjusted to reflect this;

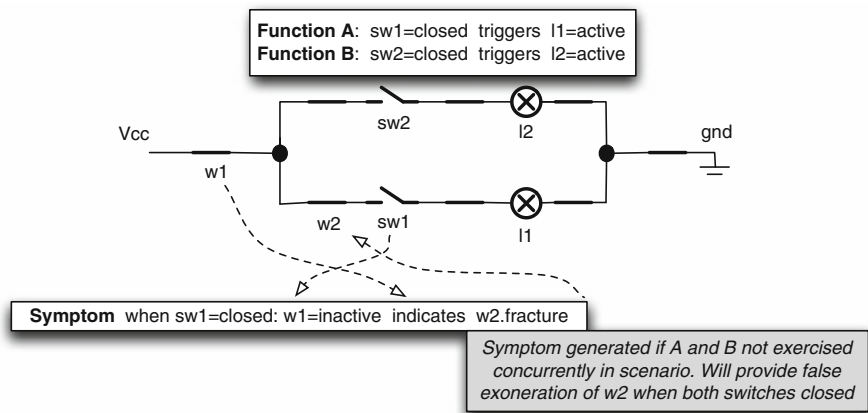

Fig. 42.9 Exoneration of faults

however, more accurate consideration of the operating modes of the system will lead to more accurate diagnoses (higher confidences in the predicted fault). One approach to achieving this is to exercise both of the functions simultaneously in the FMEA scenario, forcing the symptom generation to include additional measurements in the symptom, for example, the position of switch *sw2*. Thus by extending the scenario to close both switches and exercise both functions simultaneously will produce the symptom *when sw1 closed and sw2 open: w1 inactive indicates w2 fracture* to be generated since A is failed and B is active, allowing *w1* to be used.

There may be many possible permutations of functions and particularly function states available making exercising of all in the FMEA an unattractive proposition. In addition it is necessary to detect any spurious symptoms, although this can be done by further simulation. An alternative is to disallow measurements associated with several functions if any of the functions are inactive or unexpected. For the *w2* fault, this will remove *w1* as a candidate measurement for the symptom since *w1* is associated with the inoperative *function B*. Thus, *w1* will not be used in any symptoms generated for Fig. 42.9 unless both switches are closed in the FMEA scenario. The symptom *when sw1 closed: I1 inactive indicates w2 fracture* and similar for the other wires on that branch will be generated. Notice that both these revised symptoms apply to more specific operating conditions than the original and are only valid (usable) when function B is not activated. The symptom can only exonerate *w2* when function B is not activated (*sw 2* open) and function A is activated (*sw1* closed) and *w1* is not inactive. Measurements of *w1* are less useful than measurements of *I1* in diagnosing *w2 fractured*.

The measurement selection technique described addresses the incomplete set of low-level operating states inherent in the FMEA and ensures that irrelevant measurements are not included in symptoms, and hence that symptoms are extrapolated

Fig. 42.10 Example symptoms

| Symptoms | | |
|----------|---|------|
| Id | Description | Leak |
| S1 | PT_FL_LH is "atmosphere" | 0.0 |
| S2 | ENGINE.engine_fuel_feed is "low fuel" | 0.0 |
| S3 | OC_WT_LH.tank_level is "higher than expected" | 0.0 |
| S4 | PT_FL_LH is "belownormal" | 0.0 |
| S5 | FT_FL_LH is "low" | 0.0 |
| S6 | OC_WT_LH.tank_level is "lower than expected" | 0.0 |
| S7 | FT_FL_LH is "high" | 0.0 |
| S8 | ENGINE.engine_fuel_feed is "air" | 0.0 |
| S9 | PT_FL_LH is "pumpnominalabovenormal" | 0.0 |
| S10 | PT_FL_LH is "ambiguous(short)" | 0.0 |
| S11 | Condition: CP_FL_LH is "on" FT_FL_LH is "zero" | 0.0 |
| S12 | Condition: CP_FL_LH is "on" OC_WT_LH.tank_level is "no level change" | 0.0 |
| S13 | Condition: CP_FL_LH is "on" ENGINE.engine_fuel_feed is "zero" | 0.0 |
| S14 | Condition: CP_FL_LH is "on" PT_FL_LH is "zero" | 0.0 |

to be as general as possible. Conversely the decision as to which measurements are relevant is derived from the entire set of failure and non-failure states encountered during the FMEA. Given a reasonably comprehensive FMEA that exercises all system functions and includes faults for the majority of components, symptoms can be produced that are general enough to cover a great deal of the system state that is not explicitly included in the FMEA without producing spurious symptoms (Snooke and Price 2012). Analysis of the actual coverage of the derived symptom set is covered in a later section on diagnosability assessment. Since a diagnostic system based on the symptoms will use positive and negative evidence of each failure to derive a final likelihood of each fault, a “complete” set of symptoms is not necessary, and probabilistic techniques such as BN allow for a degree of uncertainty in the symptoms.

Figure 42.10 shows an example set of symptoms generated from the simple example system shown in Fig. 42.5. Most of these symptoms are single abnormal values; however, notice that several conditional symptoms have been generated (S11–S14) to allow values that occur when the system is inactive to become symptoms when the operating conditions change. For more complex systems, the combinations of values and conditions required become greater and provide symptoms that detect unusual effects and are particularly useful when a system has many operating modes with symptoms specific to each.

Once the set of symptoms have been generated, the FMEA is used to produce a matrix of fault-symptom pairs. An example fragment is shown in Fig. 42.11,

| | | | | |
|-----|----------------|-----|---|------|
| F23 | Pipe1 leak | S8 | ENGINE.engine_fuel_feed is "air" | 0.99 |
| F24 | Pipe6 blocked | S9 | PT_FL_LH is "pumpnominalabovenormal" | 0.99 |
| F25 | Pipe7 blocked | S9 | PT_FL_LH is "pumpnominalabovenormal" | 0.99 |
| F12 | Pipe6 fracture | S10 | PT_FL_LH is "ambiguous(short)" | 0.99 |
| F14 | Pipe7 fracture | S10 | PT_FL_LH is "ambiguous(short)" | 0.99 |
| F1 | Pipe5 blocked | S11 | Condition: CP_FL_LH is "on" FT_FL_LH is "zero" | 0.99 |
| | | | Condition: CP_FL_LH is "on" | |

Fig. 42.11 Fragment of an example fault-symptom mapping

example fault-symptom mapping, showing fault number, fault name, symptom number, symptom name, and (default) confidence value. In a real system, there are likely to be one or more faults associated with a symptom, and each fault may be associated with one or more symptoms.

42.6 Diagnosability Assessment

Ideally, any system fault could be diagnosed to the individual component that has failed; however, during design, there is a trade-off between the amount of sensing possible for a system and the diagnostic capability. It is useful to be able to investigate the relationship between the number and placement of sensors and the resultant ability to detect faults and subsequently isolate faults to a specific component or line replaceable unit (LRU). One of the benefits of model-based simulation is easy access to many system parameters, allowing analysis of those that might provide the required diagnosability at a given cost. Alternatively the question might be reversed to analyze how many sensors would be required to be able to provide a given level of diagnosis. On the ASTRAEA project, two types of analysis were performed; the first provides an ordered list of sensors that can provide the maximum number of diagnosed faults, and the second provides an ordered list prioritized by the ability to isolate a fault. In practice a whole variety of compromises must be made, and these “what if” analyses are used to inform higher-level engineering decisions.

Symptom ranking is carried out using a recursive procedure starting with no included symptoms or detected faults and consists of the following steps:

1. From the remaining symptoms that have not been considered, find the symptom(s) that provide the maximum number of additional faults, that is, the number of faults detected by the symptom that are not already located by previously considered symptoms. These are termed the “next best symptoms”
2. Add each of the “next best symptoms” in turn to the included symptoms and also add any failures it detects to the faults detected list.
3. If the symptom has not already been found and included in the overall results, then include it in the results in the correct place (according to the number of

symptoms) and carry out the procedure again excluding the current symptom from the available symptoms.

This will generate sets of symptoms for each number of observations that can diagnose the most faults. For further information and examples of the software tools used, see (Snooke 2009; Snooke and Price 2012). Where several symptoms each diagnose the same number of faults, they are all outputted. For the example circuit in Fig. 42.1, the following summary is produced:

```
Ordered symptom information
1 combinations of 1 SYMPTOMS indicate 11 FAILURES (1 partitions)
1 combinations of 2 SYMPTOMS indicate 18 FAILURES (2 partitions)
1 combinations of 3 SYMPTOMS indicate 24 FAILURES (3 partitions)
1 combinations of 4 SYMPTOMS indicate 28 FAILURES (5 partitions)
8 combinations of 5 SYMPTOMS indicate 28 FAILURES (6--7 partitions)
28 combinations of 6 SYMPTOMS indicate 28 FAILURES (7--9 partitions)
56 combinations of 7 SYMPTOMS indicate 28 FAILURES (8--10 partitions)
70 combinations of 8 SYMPTOMS indicate 28 FAILURES (8--11 partitions)
56 combinations of 9 SYMPTOMS indicate 28 FAILURES (9--11 partitions)
28 combinations of 10 SYMPTOMS indicate 28 FAILURES (10--12 partitions)
8 combinations of 11 SYMPTOMS indicate 28 FAILURES (11--12 partitions)
```

The first of these provides:

```
ENGINE.engine{\_}fuel{\_}feed = none AND CP{\_}FL{\_}LH.Control = on
INDICATES FAULTS:
Pipe5.blocked; Pipe5.fracture; Pipe2.blocked; Pipe3.blocked; Pipe1.
blocked;
Pipe6.blocked; Pipe6.fracture; Pipe7.blocked; Pipe7.fracture; Pipe4.
blocked;
Pipe4.fracture
```

The second entry considers the best pair of sensors:

```
ENGINE.engine{\_}fuel{\_}feed = none AND CP{\_}FL{\_}LH.Control = on
INDICATES FAULTS:
Pipe5.blocked; Pipe5.fracture; Pipe2.blocked; Pipe3.blocked; Pipe1.
blocked;
Pipe6.blocked; Pipe6.fracture; Pipe7.blocked; Pipe7.fracture; Pipe4.
blocked;
Pipe4.fracture

ENGINE.engine{\_}fuel{\_}feed = low fuel
OC{\_}WT{\_}LH.tank{\_}level = higher than expected
FT{\_}FL{\_}LH.flow = low
INDICATES FAULTS:
Pipe5.partialblocked; Pipe2.partialblocked; Pipe3.partialblocked;
Pipe1.partialblocked; Pipe6.partialblocked; Pipe7.partialblocked;
Pipe4.partialblocked
```

In this case, there are three symptoms that all indicate the same set of failures and any one could be used. Sometimes there may be several sets of (nonequivalent) symptoms able to discriminate the same number of faults. In the example above, this occurs for 5 symptoms, where 8 different combinations of symptoms indicate 28 faults (though not necessarily the same 28 faults). They may have different

fault-isolating capability dividing the faults into six or seven partitions provided by different combinations of the chosen symptom set. These partitions each contain a set of one or more faults that are indistinguishable using the selected set of observations used by the selected symptoms. From the above table, it is clear that 4 symptoms are adequate to identify all 28 faults present in the FMEA of the system:

```
ENGINE.engine{\_}fuel{\_}feed = none AND CP{\_}FL{\_}LH.Control = on
INDICATES FAULTS: Pipe5.blocked; Pipe2.blocked; Pipe3.blocked;
Pipe1.blocked; Pipe6.blocked; Pipe7.blocked; Pipe4.blocked

ENGINE.engine{\_}fuel{\_}feed = low fuel
OC{\_}WT{\_}LH.tank{\_}level = higher than expected
FT{\_}FL{\_}LH.flow = low
INDICATES FAULTS: Pipe5.partialblocked; Pipe2.partialblocked; Pipe3.
partialblocked; Pipe1.partialblocked; Pipe6.partialblocked;
Pipe7.partialblocked; Pipe4.partialblocked

ENGINE.engine{\_}fuel{\_}feed = air
INDICATES FAULTS:
Pipe2.fracture; Pipe2.leak; Pipe3.fracture; Pipe3.leak; Pipe1.
fracture;
Pipe1.leak

ENGINE.engine{\_}fuel{\_}feed = none AND CP{\_}FL{\_}LH.Control = on
OC{\_}WT{\_}LH.tank{\_}level = lower than expected
INDICATES FAULTS: Pipe5.fracture; Pipe6.fracture; Pipe7.fracture;
Pipe4.fracture
OC{\_}WT{\_}LH.tank{\_}level = lower than expected
INDICATES FAULTS: Pipe5.leak; Pipe6.leak; Pipe7.leak; Pipe4.leak
```

This analysis demonstrates that the fuel feed detected by the engine is the most important available diagnostic indicator, followed by an incorrect fuel level in the tank. The flow and pressure sensors are not even necessary to detect a full set of faults. However, the engineer could decide that the engine fuel feed is not a feasible observation by using knowledge outside the scope of the modeling and simulation; removing it and running the analysis again, the flow meter then becomes an important sensor.

It is also possible to maximize the fault isolation capability using a modified version of the symptom-ranking algorithm that maximizes the number of fault partitions instead of simply the number of faults. Selecting the most useful measurements leads to 7 symptoms that can identify all 28 faults and divides them into 10 separate sets of (indistinguishable) faults. Maximizing for fault isolation leads to 12 partitions of faults using various combinations of the following 12 symptoms:

```
(Pipe2.partialblocked Pipe3.partialblocked Pipe1.partialblocked
Pipe6.partialblocked Pipe7.partialblocked) (Pipe5.partialblocked
Pipe4.partialblocked) (Pipe4.leak) (Pipe5.leak Pipe6.leak Pipe7.leak)
(Pipe2.leak Pipe3.leak Pipe1.leak) (Pipe2.fracture Pipe3.fracture

This in fact includes all the symptoms in Fig. 42.4 because S2, S3, and S5 turn out to be identical as mentioned above.

The above paragraphs assume that all faults are equally important in terms of diagnosis. In practice, there are several additional considerations. Often there is a limit to the granularity required by fault isolation due to the presence of LRUs. There is no requirement to be able to isolate a fault beyond a single LRU.

Observations may also fall into categories including basic system sensing that must be available for nominal operation and groups of additional observations that only make sense to provide as single units (sensors). Including these additional factors in the sensor selection allows further structuring of the symptoms, observations, and measures used to select symptom permutations.

42.7 Conclusion

This chapter is concerned with methods and technologies needed to be able to routinely fly UAVs safely in commercial airspace. The techniques described in this chapter contribute to this goal in several ways:

- They automate the generation of failure effects for an FMEA report, providing consistent results for a complete set of component failure modes. It can be guaranteed that results are produced for all component failure modes that are modeled.
- The generated FMEA results can be arranged as failure-symptom pairs with the same consistency and can be linked to specific symptoms that are observable by an online system.
- The failure-symptom pairs have been integrated into a larger diagnostic system, where other failure-symptom pairs will have been produced by other methods.
- Further analysis can indicate the most effective points within the system being diagnosed to place sensors, assisting in the decision of where sensors should be placed when designing the system.

A number of existing modeling and analysis techniques can be integrated to provide models and design analysis that allow diagnosability and diagnosis to be designed in rather than bolted on, and this can form the basis of a lightweight verifiable onboard diagnostic system. Both of these aspects are essential when comprehensive system health information is required to enable mission level objectives to be decided in an automated environment.

Abstract

Health management plays an important role in operations of UAV. If there is equipment malfunction on critical components, safe operation of the UAV might possibly be compromised. A technology with particular promise in this arena is equipment prognostics. This technology provides a state assessment of the health

of components of interest, and if a degraded state has been found, it estimates how long it will take before the equipment will reach a failure threshold, conditional on assumptions about future operating conditions and future environmental conditions. This chapter explores the technical underpinnings of how to perform prognostics and shows an implementation on the propulsion of an electric UAV. An accurate run-time battery life prediction algorithm is of critical importance to ensure the safe operation of the vehicle if one wants to maximize in-air time. Current reliability-based techniques turn out to be insufficient to manage the use of such batteries where loads vary frequently in uncertain environments. A Particle Filter is shown as the method of choice in performing state assessment and predicting future degradation. The method is then applied to the batteries that provide power to the propeller motors.

43.1 Introduction

Prognostics Health Management (PHM) is an engineering discipline that aims at maintaining nominal system behavior and function and assuring mission safety and effectiveness under off-nominal conditions. PHM encompasses a set of wide-ranging subdisciplines that address the design, development, operation, and life cycle management of subsystems, vehicles, and other operational systems. Starting with simple time-temperature recorder for the engine hot section on the F-8 aircraft (during deployment in Vietnam), and later the A-7 aircraft engine health monitoring program of the early 1980s, PHM principles found their way in various aircraft. Analysis of vibration and acoustic emissions data from rotorcraft drivetrains has led to breakthroughs in predicting impending failures of complex mechanical systems, resulting in the development of relative mature Health and Usage Monitoring Systems (HUMS) for rotorcraft (Revor and Bechhoefer 2004). Service providers like GE, PW, and Rolls-Royce have employed PHM principles to remotely monitor jet engines around the clock to detect early signs of damage as part of guaranteed uptime service agreements.

43.1.1 Prognostics

Prognostics is a core element of PHM. It is a younger member in the family of health management techniques but has recently received considerable attention due to its game-changing potential. Prognostics is the science of determining the remaining useful life of a component or subsystem given the current degree of wear or damage, the component's load history, and anticipated load and environmental conditions. A quantification of the degree of a component's wear or damage and the estimate of end of life gives decision makers important information about the health of a system. This information can be used on UAV for risk reduction in go/no-go decision, cost reduction through the scheduling of maintenance as needed, and improved asset availability. Prognostics employs techniques that are

often based on a detailed analysis of historical data or an analysis of the fault modes and the modeling of the physics of both the component itself and the attributes that characterize the fault. For the latter, the idea is to model the progression of damage which includes the effects of damage accelerators or stressors (such as load or environmental conditions). Next, algorithms that estimate the remaining life use estimation techniques that propagate the anticipated degradation into the future and provide as output the point where the component does no longer meet its desired functionality. The algorithms use these physics-based models as well as measurements from the system as input. Output of the algorithms is the remaining life estimate. An alternative to physics-based models are data-driven techniques. These synthesize a behavioral representation from a large number of example run-to-failure trajectories via machine learning methods.

Prognostics can be developed for almost any critical component as long as one has either some knowledge about the underlying physics or a sufficient amount of run-to-failure data exists. The efficacy of prognostics has been demonstrated for a wide range of diverse components ranging from mechanical components to electrochemical components to electronics. Specific application areas range from rotating machinery (Marble and Tow 2006) to batteries (Saha et al. 2007), from printed circuit boards (Gu et al. 2007) to solid rocket motors (Luchinsky et al. 2008). In the U.S. military, two significant weapon platforms were designed with a prognostics capability as an integral element of the overall system architecture: the Joint Strike Fighter Program (Hess et al. 2004) and the Future Combat Systems Program (Barton 2007). Prognostic technology is also finding its way into future NASA launch vehicles and spacecraft (Osipov et al. 2007) as well as UAV (Valenti et al. 2007). As the technology matures further, it is expected that prognostics will play an important role in the design and operation of commercial systems such as passenger aircraft, automobiles, ships, the energy infrastructure, and consumer electronics.

43.2 Modeling

Underlying any prediction is a model that describes how the component of interest behaves under nominal conditions and how it will evolve as it experiences wear or a fault condition. To that end, one needs to capture that process in the form of a mathematical model. The model may be derived from laws of physics, captured by empirical relations, or learned from data. Models can also use a combination of these approaches. For example, parts of a component that are well understood may be constructed using physics-based models, with unknown physical parameters learned from data using appropriate system identification techniques.

Modeling of physics can be accomplished at different levels, for example, micro- and macro-levels. At the microlevel, physical models are embodied by a set of dynamic equations that define relationships, at a given time or load cycle, between damage (or degradation) of a component and environmental and operational conditions under which the component is operated. The microlevel models are often referred to as damage propagation model, for example, Yu and Harris's fatigue life

model for ball bearings, which relates the fatigue life of a bearing to the induced stress (Yu and Harris 2001), Paris and Erdogan's crack growth model (Paris and Erdogan 1963) and stochastic defect-propagation model (Li et al. 2000) are other examples of microlevel models. Since measurements of critical damage properties (such as stress or strain of a mechanical component) are rarely available, sensed system parameters have to be used to infer the stress/strain values. Microlevel models need to account in the uncertainty management the assumptions and simplifications, which may pose significant limitations of that approach.

Macro-level models are characterized by a somewhat abridged representation that makes simplifying assumptions, thus reducing the complexity of the model (typically at the expense of accuracy). An example is a lumped parameter model which assumes that the attributes of the component have idealized behavior and the nonideal characteristics are characterized with equivalent elements that suffice for a first-order approximation. When such a system is designed well, it will often (but certainly not always) result in satisfactory results, depending on performance requirements. It should be noted that for complex systems (e.g., a gas turbine engine), even a macro-level model may be rather time-consuming and labor intensive. The resulting simplifications may need to be accounted for via explicit uncertainty management.

43.2.1 Nominal Behavior

The system model describes the characteristics of the system under nominal conditions. Ideally, such a model should be able to factor in the effects of operational and environmental conditions as well as any other conditions that cause different system response under nominal conditions. The model should also be able to adapt to changes of the system that are not considered abnormal. To that end, the system model could learn system behavior from examples, for instance, using machine learning techniques or it could integrate domain expertise and be implemented using rules.

43.2.2 Damage Modeling

A damage propagation model describes how the damage is expected to grow in the future. It should, similar to the system model, account for operational and environmental conditions as well as any other conditions that have an impact on the damage. While one often thinks of damage as a monotonically increasing phenomenon, it is possible for the domain in which damage is evaluated to have non-monotonic attributes. These could be either intrinsic attributes (e.g., recovery effects in batteries or power semiconductors) or extrinsic effects such as partial repair actions. Depending on the fault mode, damage propagation may exhibit different symptoms and it may be necessary to consider dedicated damage propagation models for different fault modes.

43.3 Prognostics Algorithms

The role of the prognostic algorithm is applying the damage propagation model into the future. It needs to ensure that it properly considers the effects of environmental and operational conditions, healing phenomena, as well as how to account for the different sources of uncertainty. Depending on the implementation, the damage propagation model and the prognostic algorithm may not be separable. For the general case, the damage propagation model and the prognostic algorithm will be treated as separate.

43.3.1 Model-Based Algorithms

In order to make a prediction, the current health state of the system must first be known. Determining the current state of the system health is generally known as health state estimation. Given the current state of health, the model-based prediction algorithm propagates this estimate forward in time using damage propagation model equations up to the end-of-life (EOL) threshold. As mentioned earlier, the evolution of the state depends on future stressors. Therefore, these needs to be stated to the degree possible. For many applications, some knowledge about future stressors exists where tasks are scheduled or repeated. In other cases, one has only statistical information about future stressors. The accuracy and precision of the predictions depend on both the quality of the model and the uncertainty of future inputs. The prediction algorithm of choice depends on the type of model used, on what information is needed to describe the EOL (which could be in the form of a distribution), and the amount of computation that may be performed.

This section takes a look at Particle Filters, one of the most prevalent algorithms for model-based prediction.

43.3.2 Particle Filter

Particle methods assume that the state equations can be modeled as a first-order Markov process with additive noise and conditionally independent outputs (Arulampalam et al. 2002). Let

$$\mathbf{x}_k = \mathbf{f}_{k-1}(\mathbf{x}_{k-1}) + \omega_{k-1} \quad (43.1)$$

$$\mathbf{z}_k = \mathbf{h}_k(\mathbf{x}_k) + v_k. \quad (43.2)$$

While there are several flavors of Particle Filters, the focus here is on *Sampling Importance Resampling* (SIR), in which the posterior filtering distribution denoted as $p(\mathbf{x}_k|\mathbf{Z}_k)$ is approximated by a set of N weighted particles $\{\langle x_p^i, w_p^i \rangle; i = 1, \dots, N\}$ sampled from a distribution $q(\mathbf{x})$ that is “similar” to $\pi(\mathbf{x})$, i.e., $\pi(\mathbf{x}) > 0 \Rightarrow q(\mathbf{x}) > 0$ for all $\mathbf{x} \in \mathbb{R}^{n_x}$. The *importance weights* w_k^i are then normalized

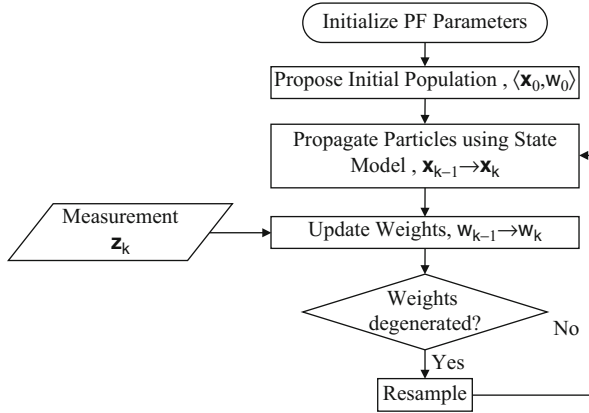

Fig. 43.1 Particle Filtering flowchart

$$w_k^i = \frac{\pi(\mathbf{x}_k^i) / q(\mathbf{x}_k^i)}{\sum_{j=1}^N \pi(\mathbf{x}_k^j) / q(\mathbf{x}_k^j)} \quad (43.3)$$

such that $\sum_i w_k^i = 1$, and the posterior distribution can be approximated as

$$p(\mathbf{x}_k | \mathbf{Z}_k) \approx \sum_{i=1}^N w_k^i \delta(\mathbf{x}_k - \mathbf{x}_k^i). \quad (43.4)$$

Using the model in Eq. (43.1), the prediction step becomes

$$p(\mathbf{x}_k | \mathbf{Z}_{k-1}) \approx \sum_{i=1}^N w_{k-1}^i \mathbf{f}_{k-1}(\mathbf{x}_{k-1}^i). \quad (43.5)$$

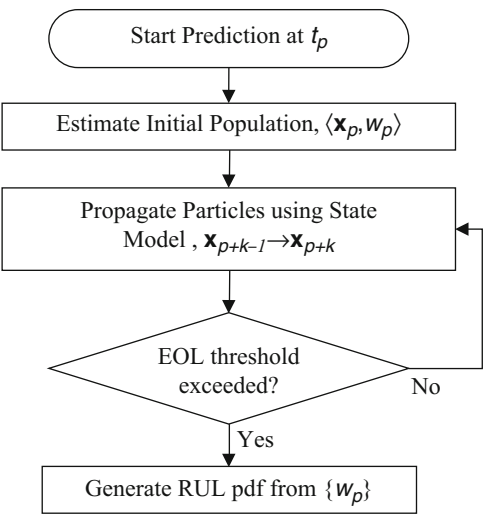

The weights are updated according to the relation

$$\bar{w}_k^i = w_{k-1}^i \frac{p(\mathbf{z}_k | \mathbf{x}_k^i) p(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i)}{q(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i, \mathbf{z}_k)}, \quad (43.6)$$

$$w_k^i = \frac{\bar{w}_k^i}{\sum_{j=1}^N \bar{w}_k^j}. \quad (43.7)$$

It is possible that all but a few of the importance weights degenerate such that they are close to zero. In that case, one has a very poor representation of the system state (and also wastes computing resources on unimportant calculations). To address that, *resampling* of the weights can be used (Saha et al. 2007). The basic logical flowchart is shown in Fig. 43.1.

Fig. 43.2 Prediction flowchart

During prognosis this tracking routine is run until a long-term prediction is required, say at time t_p , at which point Eq.(43.1) will be used to propagate the posterior pdf given by $\left\{ \left\langle x_p^i, w_p^i \right\rangle; i = 1, \dots, N \right\}$ until \mathbf{x}^i fails to meet the system specifications at time t_{EOL}^i . The RUL pdf, i.e., the distribution $p(t_{\text{EOL}}^i - t_p)$, is given by the distribution of w_p^i . Figure 43.2 shows the flow diagram of the prediction process.

43.3.3 Data-Driven Algorithms

As the name implies, data-driven techniques utilize monitored operational data related to system health. Given the availability of data, data-driven approaches are appropriate when the understanding of first principles of system operation is not easy to come by or when the system is sufficiently complex that developing an accurate model is prohibitively expensive. The principal advantage of data-driven approaches is that they can often be deployed quicker and cheaper compared to other approaches and that they can provide system-wide coverage. On the other hand, data-driven approaches require a substantial amount of data for training which is a fundamental limitation for most systems, since full trajectories to failure are not recorded in large numbers for components in high-value systems like aircraft. Data-driven approaches can be further subcategorized into fleet-based statistics and sensor-based conditioning. In addition, data-driven techniques also subsume cycle-counting techniques that may include domain knowledge.

There are two basic data-driven strategies that involve either (1) modeling cumulative damage (or, equivalently, health) and then extrapolating out to a damage (or health) threshold or (2) learning directly from data the remaining useful life.

As mentioned, a principal bottleneck is the difficulty in obtaining run-to-failure data, in particular for new systems, since running systems to failure can be a lengthy and rather costly process. Even where data exist, the efficacy of data-driven approaches is not only dependent on the quantity but also on the quality of system operational data. These data sources may include temperature, pressure, oil debris, currents, voltages, power, vibration and acoustic signal, spectrometric data, as well as calibration and calorimetric data. Features must be extracted from noisy, high-dimensional data.

43.4 Case Study: Prognostics for Batteries Used in Electric UAV

This section will use batteries used for energy storage in electric UAV as an illustrative example to show the principles of prognostics. The section will start with a discussion on battery characteristics, followed by the model chosen and the implementation on the UAV.

43.4.1 Battery Characteristics

Batteries are essentially energy storage devices that facilitate the conversion, or *transduction*, of chemical energy into electrical energy, and vice versa (Huggins 2008). They consist of a pair of *electrodes* (*anode* and *cathode*) immersed in an *electrolyte* and sometimes physically divided by a *separator*. The chemical driving force across the cell is due to the difference in the chemical potentials of its two electrodes, which is determined by the difference between the *standard Gibbs free energies* the products of the reaction and the reactants. The theoretical *open-circuit voltage*, E° , of a battery is measured when all reactants are at 25 °C and at 1 M concentration or 1 atm pressure. However, the voltage during use differs from the theoretical voltage because of various passive components like the electrolyte, the separator, and terminal leads. The voltage drop due to these factors can be mainly categorized into Ohmic drop, activation polarization, and concentration polarization.

Ohmic drop ΔE_{IR} refers to the diffusion process where Li-ions migrate to the cathode via the electrolytic medium. The internal resistance to this ionic diffusion process is also referred to elsewhere as the *IR drop*. For a given load current, this drop usually decreases with time due to the increase in internal temperature that results in increased ion mobility.

Self-discharge is caused by the residual ionic and electronic flow through a cell even when there is no external current being drawn. The resulting drop in voltage has been modeled to represent the *activation polarization* of the battery ΔE_{AP} . All chemical reactions have a certain activation barrier that must be overcome in order

Fig. 43.3 Typical polarization curve of a battery (Saha and Goebel 2009)

to proceed and the energy needed to overcome this barrier leads to the activation polarization voltage drop. The dynamics of this process is described by the Butler–Volmer equation (Bockris and Reddy 1973). This process was represented by an exponential function in Saha and Goebel (2009). However, a log function is a more accurate representation, as abstracted from the Butler–Volmer equation.

The *concentration polarization* ΔE_{CP} represents the voltage loss due to spatial variations in reactant concentration at the electrodes. This is mainly caused when the reactants are consumed by the electrochemical reaction faster than they can diffuse into the porous electrode, as well as due to variations in bulk flow composition. The consumption of Li-ions causes a drop in their concentration along the cell, which in turn causes a drop in the local potential near the cathode. The value of this factor is low during the initial part of the discharge cycle and grows rapidly towards the end of the discharge or when the load current increases.

Figure 43.3 depicts the typical polarization curve of a battery with the contributions of all three of the above factors shown as a function of the current drawn from the cell. The voltage drop usually increases with increasing output current.

The output current plays a prominent role in determining the losses inside a battery and is therefore an important parameter to consider when comparing battery performance. The term most often used to indicate the rate at which a battery is discharged is the *C-Rate* (Huggins 2008). The discharge rate of a battery is expressed as C/r , where r is the number of hours required to completely discharge its nominal capacity. So, a 5 Ah battery discharging at a rate of $C/10$ or 0.5 A would last for 10 h. The terminal voltage of a battery, as also the charge delivered, can vary appreciably with changes in the *C-Rate*. Furthermore, the amount of energy supplied, related to the area under the discharge curve, is also strongly *C-Rate* dependent. Figure 43.4 shows the typical discharge of a battery and its variation

Fig. 43.4 Schematic drawing showing the influence of the current density upon the discharge curve (Reproduced from Fig. 1.14 in Huggins 2008)

with C -Rate. Each curve corresponds to a different C -Rate or C/r value (the lower the r the higher the current) and assumes constant temperature conditions.

43.4.2 Model Adaptation

For many engineered systems, models for nominal operation are available, but damage propagation models like Arrhenius model or Paris' law are comparatively rare. Developing these models may require destructive testing for model validation which may not be possible in many cases. In some cases, testing may be done on subscale systems, but there may be difficulty in generalizing the models learned. Additionally, the parameter values of these models are often system specific and thus need to be relearned for every new application. The PF framework described above can help in these cases by adapting the prognostic/aging model in an online fashion.

One of the key motivating factors for using Particle Filters for prognostics is the ability to include model parameters as part of the state vector to be estimated. This allows *model adaptation* in conjunction with state tracking and, thus, produces a tuned model that can be used for long-term predictions.

Let system health x_k state evolution model \mathbf{f} and measurement model \mathbf{h} with known noise distributions ω and \mathbf{v} , respectively. Additionally, the parameter values of \mathbf{h} are assumed to be known (without lack of generality). The system health state is assumed to be one dimensional. Stationary or (better) non-stationary measurement models can be used to account for progressive degradation in sensors caused by corrosion, fatigue, wear, etc. The parameters of \mathbf{f} , denoted by $\alpha_k = \{\alpha_{j,k}; j = 1, \dots, n_f\}$ $n_f \in N$, are combined with x_k to give the state vector $\mathbf{x}_k = [x_k \ \alpha_k]^T$, where T represents the transpose of a vector or matrix. Equations (43.1) and (43.2) can then be rewritten as

$$x_k = \mathbf{f}(x_{k-1}, \alpha_{k-1}) + \omega_{k-1} \quad (43.8)$$

$$z_k = \mathbf{h}(x_k) + v_k. \quad (43.9)$$

To formulate the state equations for α_k , one can choose a *Gaussian random walk* such that

$$\alpha_{j,k} = \alpha_{j,k-1} + \omega_{j,k-1} \quad (43.10)$$

where $\omega_{j,k-1}$ is drawn from a normal distribution, $\mathcal{N}(0, \sigma_j^2)$, with zero mean and variance σ_j^2 . Given a suitable starting point $\alpha_{j,0}$, and variance σ_j^2 , the PF estimate will converge to the actual parameter value $\bar{\alpha}_j$, according to the *law of large numbers*. In this way, model adaptation has been introduced into the PF framework, adding n_f extra dimensions, yet achieving convergence (and without incurring the curse of dimensionality).

The notion of a good proposal density, though, comes into play in the choice of the values of $\alpha_{j,0}$ and σ_j^2 . If the initial estimate $\alpha_{j,0}$ is far from the actual value and variance σ_j^2 is small, then the filter may take a large number of steps to converge, if at all. The variance value may be chosen to be higher in order to cover more state space, but that can also delay convergence. One way to counter this is to make the noise variance itself a state variable that increases if the associated weight is lower than a preset threshold, i.e., the estimated parameter value is far from the true value, and vice versa. Thus,

$$\begin{aligned} \alpha_{j,k} &= \alpha_{j,k-1} + \omega_{j,k-1}; \quad \omega_{j,k-1} \sim \mathcal{N}(0, \sigma_{j,k-1}^2), \\ \sigma_{j,k} &= c_{j,k} \cdot \sigma_{j,k-1}; \quad \begin{cases} c_{j,k} < 1, & \text{if } w_{k-1} > w_{\text{th}}, \\ c_{j,k} = 1, & \text{if } w_{k-1} = w_{\text{th}}, \\ c_{j,k} > 1, & \text{if } w_{k-1} < w_{\text{th}}. \end{cases} \end{aligned} \quad (43.11)$$

The multiplier $c_{j,k}$ is a positive valued real number, while the threshold w_{th} is some value in the interval $(0, 1)$. The intent is to increase the search space when the error is high and tightening the search when one is close to the target. Note that although this produces a better proposal density, it introduces a further n_f dimensions to the state vector.

It is quickly evident that it is not feasible to take this approach for all the parameters of a sufficiently high-order model. This motivates the use of sensitivity analysis techniques (SA) to determine the more sensitive parameters that need to be estimated online. SA is essentially a methodology for systematically changing parameters in a model to determine the effects on the model output. There are several methods to perform SA like local derivatives (Cacuci 2003), sampling (Helton et al. 2006), and Monte Carlo sampling (Saltelli et al. 2004). Depending upon the form of the system model, any of these methods may be used to assess which parameters to target.

Assuming that the model function \mathbf{f} in Eq.(43.8) is differentiable, i.e., $\partial \mathbf{f} / \partial a_j$ (the time index k dropped for the sake of generality), it can be computed at any

Fig. 43.5 Effect on $f(x) = \alpha_1 \exp(\alpha_2 x)$ due to 10 % variation in parameters α_1 and α_2 (Saha and Goebel 2011)

point in the state space defined by $\mathbf{x}_k = [x_k \ \alpha_k]^T$. If the partial derivative is positive, then the value of the function increases with an increase in the parameter value and vice versa.

The magnitude of the derivative indicates the degree to which the parameter affects the output of \mathbf{f} , as shown in Fig. 43.5. This directs the choice of the parameters to estimate online. If the *posterior error* given by

$$e_k^i = x_k^i - \sum_{i=1}^N w_k^i x_k^i \quad (43.12)$$

is positive, then the parameters that have a positive local partial derivative need to be reduced and those with a negative one need to be increased. The opposite holds true if the error is negative. The amount by which the parameters need to be reduced or increased also depends on the magnitude of the local partial derivative. The higher the magnitude, the smaller the steps needed in order to prevent instability while approaching the true value. This notion can be formalized in the following way (the particle index i has been dropped for the sake of generality):

$$\alpha_{j,k} = \alpha_{j,k-1} + C_{j,k} + \omega_{j,k-1}; \quad \omega_{j,k-1} \sim N(0, \sigma_j^2). \quad (43.13)$$

$$\begin{aligned} C_{j,k} &\propto -e_k, \\ &\propto \left. \frac{\partial \mathbf{f}}{\partial \alpha_{j,k}} \right|_{\mathbf{x}_k}, \\ &= -K \cdot \frac{e_k}{\left. \partial \mathbf{f} / \partial \alpha_{j,k} \right|_{\mathbf{x}_k}}. \end{aligned} \quad (43.14)$$

Note that in this model adaptation scenario, the noise variance parameter is not added to the state vector since the search process is directed and not random as discussed previously.

43.4.3 Battery Model

For the purposes of the electric UAV BHM, the battery model design space is explored at a high level of abstraction with respect to the underlying physics. To predict the end of discharge (EOD), it is required to model the SOC of the battery. For the empirical charge depletion model under consideration here, the output voltage $E(t_k)$ of the cell is expressed in terms of the effects of the changes in the internal parameters (Saha et al. 2011):

$$E(t_k) = E^o - \Delta E_{IR}(t_k) - \Delta E_{AP}(t_k) - \Delta E_{CP}(t_k) \quad (43.15)$$

where E^o is the Gibb's free energy of the cell, ΔE_{IR} is the Ohmic drop, ΔE_{AP} is the drop due to activation polarization, and ΔE_{CP} denotes the voltage drop due to concentration polarization. These individual effects are modeled as

$$\Delta E_{IR}(t_k) = \Delta I_k \alpha_6 (1 - \exp(-\alpha_7 (t_k - t_{\Delta I_k}))) - \alpha_1 t_k \quad (43.16)$$

$$\Delta E_{AP}(t_k) = \alpha_{2,k} \ln(1 + \alpha_{3,k} t_k) \quad (43.17)$$

$$\Delta E_{CP}(t_k) = \alpha_{4,k} \exp(\alpha_{5,k} I_k t_k) \quad (43.18)$$

where ΔI_k is the step change in current at time $t_{\Delta I_k}$ and the α 's represent the set of model parameters to be estimated.

The PF representation of the battery state for predicting EOD is given by

$$\alpha_{j,k} = \alpha_{j,k-1} + \omega_{j,k}, \quad j = 1, \dots, 7 \quad (43.19)$$

$$x_k = E(t_k) + \omega_k \quad (43.20)$$

$$\mathbf{x}_k = [x_k \ \alpha_{j,k}]^T, \quad j = 1, \dots, 7 \quad (43.21)$$

$$z_k = E(t_k) + v_k \quad (43.22)$$

where all but the parameters α_3 and α_5 are learnt from training data, while α_3 and α_5 are estimated by the PF online.

43.4.4 UAV Application

Electric aviation concepts are receiving increasing attention because of their potential benefits for emissions, fuel savings, and possibly noise reduction. While electric propulsion is used in concept manned aircraft, electric UAV is more common due

Fig. 43.6 Edge 540 UAV

to their lighter weight and lower loss consequences (compared to manned flight). However, like ground vehicles, battery-powered electric propulsion in aircraft suffer from uncertainties in estimating the remaining charge and hence most flight plans are highly conservative in nature. Different flight regimes like takeoff/landing and cruise have different power requirements, and a dead stick condition (battery shut off in flight) can have catastrophic consequences. To tackle this issue the battery health management algorithm was designed and implemented on an embedded hardware platform and integrated it into an UAV airframe to provide real-time onboard battery life predictions (Saha et al. 2012).

The particular UAV platform is a COTS 33 % scale model of the Zivko Edge 540T as shown in Fig. 43.6. The UAV is powered by dual tandem mounted electric outrunner motors capable of moving the aircraft up to 85 knots using a 26 in. propeller. The gas engine in the original specification was replaced by two electric outrunner motors which are mounted in tandem to power a single drive shaft. The motors are powered by a set of four Li-Poly rechargeable batteries, each rated at 6,000 mAh. The tandem motors are controlled by separate motor controllers (Quach et al. 2013).

A 12 channel JR radio system is used to control the airplane. The system communicates in the 2.4 GHz band using a proprietary DSM2 protocol. Control surfaces are manipulated by seven actuators.

The airplane is equipped with a number of sensors to collect structure, propulsion, and navigation. The health of the structure is monitored using a series of strain gauges and accelerometers. Navigation data consist of GPS location, ground speed, altitude, true heading, and magnetic heading. Power plant data (such as motor RPMs, currents, battery voltages, and temperatures) help to assess adequacy of the thrust from the motors and 26 in. propeller, the relevant parameters being.

Data from sensors are logged by two separate data systems instantiated in a combination of RCATS and PC104. The RCATS is a turn-key system with proprietary software that creates an ASCII log of connected sensors. It provides telemetry data to a laptop receiver which displays the data for callout to the pilot. It measures flight-related parameters such as motor RPM, motor temperature, airspeed, and z-axis acceleration at 10 Hz and interleaves GPS position and altitude data at 1 Hz. The PC104 stack consists of a CPU board, a DC/DC converter, an IO card, and a signal conditioning card for strain gauges. It runs MathWorks xPC Target

Fig. 43.7 The BHM system installed onboard

operating system. The data are acquired using a Simulink model that is compiled to an xPC target OS. It records strain, accelerometer, battery temperature, and motor current at 200 Hz. It also outputs a 0.5 Hz sine wave to the RCATS system for synchronizing data.

The BHM system is designed to be a relatively low cost analog-to-digital data acquisition system. The design philosophy behind the first BHM system is to use COTS solutions which would have a light weight compact footprint. Figure 43.7 shows the system installed onboard the Edge 540 airframe.

The BHM system itself utilizes several small COTS boards to convert TTL signal voltages into PC RS-232 signal voltages.

43.4.5 Implementation Results

Testing on the Edge 540 UAV platform was initially carried out with the airframe restrained on the ground. The propeller was run through various load regimes indicative of the intended flight profile (takeoff, climb, multiple cruise, turn, and glide segments, descent, and landing) by varying the propeller rotational speed. Figure 43.4 shows the voltages during a typical profile. It is desired to predict when the battery will run out of charge, i.e., the EOD event indicated by the end of the voltage plots after landing.

In order to evaluate the prognostic algorithm, multiple predictions were made at the time instants 13, 15, 17, and 19 min. It is not desired to completely discharge the batteries in flight since there needs to be some time for the UAV pilot to land the aircraft with some safety margin on the remaining battery life (Fig. 43.8).

Fig. 43.8 Predictions (vertical lines) during ground test (Saha et al. 2012)

Fig. 43.9 Battery voltage prediction using Particle Filter during flight test (Saha et al. 2012)

In order to validate the learned prognostic model, several dozen actual flight tests were conducted using the UAV with randomized flight profiles. The prediction performance was accurate to within 2 min, i.e., $|t_{\text{EOD}} - \bar{t}_{\text{RUL},p}| < 2$ min, over multiple flights of durations between 15 and 25 min. Figure 43.9 shows the profile of one such flight.

The blue line indicates the measured voltage, while the green dots indicate the state values of the PF. The grey lines denote the $\mu_{\text{RUL},p}$ values plotted every second, while the amber and red lines represent early alerts for the pilot to land the plane before the dead stick condition.

43.5 Conclusion

This chapter lays out a technique for predicting component degradation as exemplified on a battery used for propulsion of an electric UAV. The approach chosen here is model-based where the form of the model has been linked to the internal processes of the battery and validated using experimental data. The model was used in a PF framework to make predictions of EOD. By profiling the power required for different flight regimes like cruise segments, banked turns, and landings, one can estimate the mission completion probability by calculating the RUL pdf. Since the prediction result is in the form of a pdf, it is easy to integrate the BHM routine into a higher-level decisioning algorithm that can provide advance warning about when to land the aircraft.

Generally, a similar process can be followed for other components where a damage progression model is built for the component at hand. Naturally, the model would be different, if, say, a bearing, an electronics component, or a structural element were the object of interest.

The next step in Prognostics Health Management is to integrate the health information, in this case remaining life, into a decision-making unit that reacts appropriately. Depending on the prognostic horizon, the reaction could be to autonomously change controller settings, reconfigure system resources to ensure primary mission goals (and perhaps extend the life of the stressed component), invoke a replanning or rescheduling routine, or provide the information for later processing in a maintenance setting.

Acknowledgments This work was performed as a cross-center collaboration between NASA Ames and Langley Research Centers (ARC and LaRC) and Dryden Flight Research Center (DFRC). The authors would like to especially thank Patrick Quach, Sixto L. Vazquez, Edward F. Hogge, Thomas H. Strom and Boyd L. Hill at LaRC, and Edwin Koshimoto at DFRC for their contributions. The funding for this work was provided by the NASA System-Wide Safety and Assurance Technologies (SSAT) project under the Aviation Safety Program of the Aeronautics Research Mission Directorate (ARMD).

Abstract

Future unmanned aerial vehicles (UAVs) will be designed to achieve their missions with increased efficiency, safety, and security. To this end, an efficient fault detection and isolation (FDI) system should be capable of monitoring the health status of the aircraft. Fault-tolerant control systems for small and low-cost UAVs should not increase significantly the number of actuators or sensors needed to achieve the safer operation. This chapter is dedicated to actuator fault detection systems for UAVs, with two main requirements: real-time capability and modularity. After defining the terminology employed in this field, this chapter reviews some commonly used techniques in FDI systems. The chapter continues by presenting briefly the mathematical model of a UAV which will serve as a basis for the design of two actuator FDI systems. The first method presents and illustrates the multiple-model approach, whereas the second method presents an FDI system which is based on a single model. Both methods have been enhanced by a mechanism that actively tests actuators in order to efficiently detect and isolate actuator faults and failures. This chapter explains the advantages and drawbacks of each method and discusses issues of robustness against model uncertainties and external perturbation. In addition, aspects of computational load are addressed. Finally, the FDI systems of this chapter are applied to a realistic model of an unmanned aircraft, and the performance of the methods is shown in simulation.

44.1 Introduction

44.1.1 Definition of Fault and Failure

According to the definition found in Isermann (2006), “a fault is an unpermitted deviation of at least one characteristic property or feature of the system from the acceptable, usual, standard condition.” Based on this definition, a fault corresponds to an abnormal behavior of the system, which may not affect the overall functioning of the system but may eventually lead to a failure (defined below). Moreover, a fault may be small or hidden and therefore difficult to detect and estimate.

For example, consider the temperature of an engine. If this temperature exceeds a certain accepted limit, say 100°C, there is a fault in the system. Although this

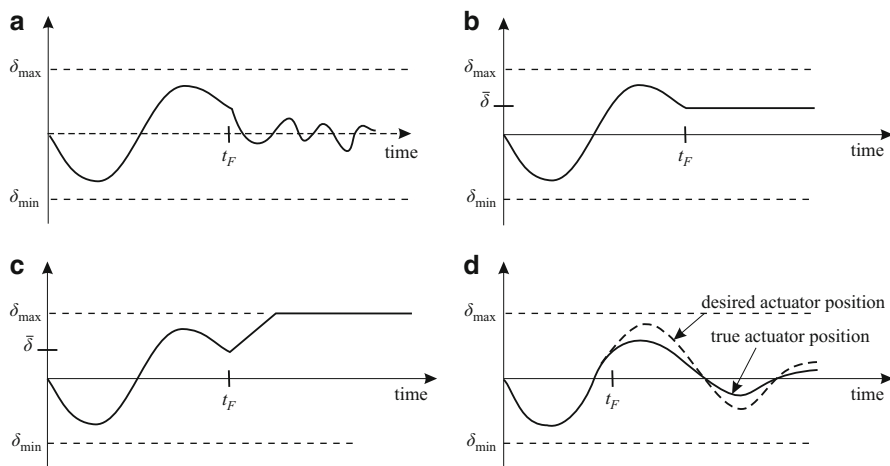

Fig. 44.1 Several types of actuator failures: (a) floating around trim, (b) locked-in-place, (c) hard-over, and (d) loss of effectiveness (actuator fault occurring after t_F)

excessive temperature does not prevent the engine from working properly for a while, it may eventually damage components of the engine and possibly lead to its breaking down.

In this chapter, an actuator fault corresponds to any abnormal behavior. This includes bias or loss of effectiveness as shown in Fig. 44.1d.

A failure is a permanent interruption of a system's ability to perform a required function under specified operating conditions. (Isermann 2006)

Resulting from one or more faults, a failure is therefore an event that terminates the functioning of a unit in the system. On an aircraft, actuators are used to deflect control surfaces such as ailerons, elevators, and rudders, and also to actuate the engine throttle or the landing-gear mechanism. An actuator is declared failed when it can no longer be used in a controlled manner.

For a control surface, there are two major types of failures (Boskovic and Mehra 2003). As shown in Fig. 44.1a, the control surface may become ineffective and float at the zero-moment position. The control surface can also be locked at any arbitrary intermediate position (Fig. 44.1b) or reach and stay at the saturation position as shown in Fig. 44.1c.

Mechanical failures may also happen. This is the case when the mechanical link between the control surface and its corresponding actuator or servo breaks. The engine may also fail.

Finally, there are other sources of possible irreversible damage to the aircraft that may be classified as *structural failures*. They correspond to the scenarios where a piece of the aircraft is missing, such as an aileron, a tail rudder, an elevator, or part of a wing.

44.1.2 Different Approaches for FDI Systems

In the context of reconfigurable flight control using an explicit online fault detection and isolation system (FDI), results from the FDI are used to modify the control system's structure, laws, parameters, or even the trajectory of the aircraft.

There are two families of FDI systems, namely, passive and active FDI systems. Passive FDI systems “wait” until a fault or failure occurs (Maybeck and Stevens 1991; Maybeck 1999), whereas active FDI systems will artificially excite the aircraft, either by flying health-check maneuvers (Azam et al. 2005; Elgersma et al. 1998) or by injecting test signals in the actuator commands and then assessing the individual health status of actuators and sensors.

Very few papers have discussed this technique so far. The work published by Honeywell in 1998 (Elgersma et al. 1998) and 2001 (Elgersma and Glavaski 2001) is among the first occurrences of using artificial exciting signals for FDI purposes. Test signals are injected into the null space of the inputs using redundant control surfaces such that these signals (ideally) cancel one another and thereby do not excite aircraft motion (Elgersma and Glavaski 2001) but contribute to better fault diagnosis; see also Buffington et al. (1999).

The use of artificial signals was demonstrated to improve significantly the performance of an FDI system based on the extended multiple model adaptive estimation (EMMAE) method (Ducard and Geering 2006, 2008). This method is described in Chap. 4 of this book (Ducard 2009). In 2007, the authors of Boskovic et al. (2007) suggested an adaptive fault-tolerant controller with self fault-diagnosis actuators. This is done by generating high-frequency signals for actuators with suspected failures and minimizing the effects of those signals on the system state using the remaining healthy actuators. In Bateman et al. (2011), the isolation procedure between redundant actuators is inspired from the excitation mechanism from Ducard and Geering (2006). Latest contributions in active FDI are reported in Ducard and Geering (2010) and extended in the second part of this chapter.

Table 44.1 provides a list of common and recent techniques that are encountered in the literature for the design of FDI systems.

44.1.2.1 Trends in Filter Design for FDI System

In the mid-1990s, several implementations of recursive least-squares (RLS) algorithms were used in FDI systems and successfully flight tested. For example, the work by Ward et al. (1998) describes a computationally efficient real-time parameter identification and reconfigurable control algorithm. The identification algorithm is based on a modified sequential least-squares (MSLS) found in Ward and Barron (1995), the recursive version of which is found in Bodson (1995). The MSLS parameter identification algorithm is based on RLS techniques and incorporates additional constraints to take into account a priori information and to adjust the size of the data window used in the regressor of the filter (Ward et al. 1994).

Many FDI filters have also been designed using mathematical models of the system being monitored. Model-based FDI methods have been enhanced using

Table 44.1 List of some recent and popular techniques used to design FDI systems for flight applications

| Technique | Example of recent books/papers using this technique (ordered chronologically) |

robust FDI techniques as defined in Chen and Patton (1999). It consists of incorporating during the design of FDI systems the effects of disturbance signals, model uncertainties, and measurement noise (Patton et al. 2000). It is often the case that several model-based filters are organized in a bank in which one filter is sensitive to a specified failure but the other filters remain insensitive to that failure. A recent example of this technique can be found in Patton et al. (2008), where a robust fault diagnosis for a spacecraft attitude control system is designed.

Many different variants of Kalman filters (KFs) have been constructed for detecting and isolating faults or for state estimation and state reconstruction. The use of extended Kalman filters (EKFs) applied to nonlinear systems for FDI purposes has also gained recent interest in Ducard and Geering (2008). A recent paper presented a method that uses EKFs to estimate online the aircraft's aerodynamic parameters and the components of the wind velocity. These estimates are used to update the parameters of the flight controller (Tanaka et al. 2006).

The unscented Kalman filter (UKF) is among the latest extensions of Kalman-type filters and seems to provide remarkable results for systems that are particularly nonlinear. The paper by Campbell et al. (2007) discusses the implementation of a sigma point filter (SPF) which was originally introduced as the UKF (Julier et al. 2000), where the distributions are approximated by a finite set of points. It is used to estimate aircraft states and aerodynamic derivatives in real time. This is a nonlinear estimation algorithm that can be performed online, which possesses robustness properties against parameter uncertainties, against filter tuning, and against initial conditions.

The discussion in Julier et al. (2000) explains that the SPF has similar performance to a truncated second-order EKF but without the need to calculate the Jacobian matrices. A comparison between EKF and SPF can also be found in Brunke and Campbell (2002). The main results of this chapter indicate that the SPF filter has equal or better performance than an EKF for real-time estimation application for the following reasons: the SPF is more robust against initial uncertainties and against jumps in the data, is less sensitive to tuning of the process noise, is less susceptible to divergence, is more accurate from one time step to the next, and, finally, requires equivalent computational load. Recent contributions in Perea and Eloegui (2008) focused on a new formulation for the state update equation of the filter for improved accuracy.

Recently, linear parameter-varying (LPV) filters gained the attention of some researchers in the fault-tolerant control community. For example, a design of LPV-based FDI filters is found in Szaszi et al. (2005). An example of an H_∞ control law that minimizes command tracking errors under actuator fault occurrence combined with an FDI filter based on an affine LPV model of a Boeing 747 is found in Shin et al. (2006).

44.1.2.2 Challenges of Designing Reliable FDI Systems

A reliable FDI system provides accurate information about the health status of the aircraft. In order to achieve such a result, the FDI system needs to be robust against external disturbances, model uncertainties, and sensor noise. In addition, the FDI system should not trigger false alarms and should still be sufficiently sensitive to detect the faults. Therefore, robustness is a fundamental issue in the performance of FDI systems and reconfigurable flight controller. FDI systems may experience significant performance reduction if the model uncertainties are not properly considered. A robustness analysis framework for failure detection and accommodation is provided in Chen and Patton (1999), Zhang and Jiang (2000), and Belcastro and Chang (2002).

44.1.3 Interaction Between Flight Controllers and FDI Systems

It is often the case that a reconfigurable flight control system incorporates an FDI system and a flight controller. The FDI system monitors the aircraft's behavior and identifies relevant parameters that are usually used by the flight controller to

synthesize the control commands. Therefore, the performance of the flight controller is dependent on the results provided by the FDI system and vice versa. Thus, the interactions between these two systems should be rigorously investigated.

The following observation is made in Shin et al. (2006): “it is fairly common for integration of failure detection and accommodation systems to be problematic if they are designed separately.”

Challenges exist when some aircraft parameters need to be identified during the flight in real time and under feedback control (Ward et al. 1998). This task is even more difficult and delicate when an actuator or a sensor fault happens. Moreover, the robustness of the flight controller can mask some aircraft faults and failures and make the detection problem more difficult.

There exist already many examples of integrated fault-tolerant control, sometimes referred to as IFTC (Zhang and Jiang 2000; Schierman et al. 2004; Boskovic et al. 2005; Shin et al. 2006).

New generations of reconfigurable flight control systems will not only rely on a fault-tolerant controller but will include complete and integrated systems that reconfigure the flight controllers, adapt the guidance system, and reshape online the vehicle trajectories (Schierman et al. 2004).

44.1.4 Other Practical Challenges

Usually, the flight control system relies on some nominal values for the mass, the moments of inertia, and the aerodynamic coefficients to generate the control signals. When the aircraft experiences an actuator failure or airframe damage, the aircraft becomes asymmetric. It is thus not trivial to determine which of these parameters need to be (online) reestimated to keep good flying performance.

It is often the case that the available onboard processing power is limited, in particular for small or micro UAVs. The design of a reconfigurable flight controller is therefore a trade-off between performance, complexity, and available processing power.

Finally, challenges are many when the fault diagnostic, the reconfiguration of the control system, and the reconfiguration of the path plan or of the mission are to be done autonomously under limited or no human supervision.

44.2 Aircraft Configuration and Dynamics

This section presents the mathematical model of an unmanned aircraft, whose actuators are to be monitored by an FDI system. This model has been constructed, validated, and identified through real flight tests of an aerobatic UAV and is reported in Möckli (2006). This model will serve as a basis for the design of the different filters created for the FDI systems of the subsequent sections. The numerical values of the aircraft model parameters are found in the Appendix.

Fig. 44.2 Aircraft configuration

44.2.1 Aircraft Configuration

The five control surfaces of the aircraft under consideration are one left aileron, one right aileron, one left elevator, one right elevator, and one rudder, as shown in Fig. 44.2. All actuators are fully independent, which means that ailerons (or elevators) can individually move up or down. This configuration permits some pitch torque to be produced with ailerons or some roll torque to be produced with elevators. The control vector of the aircraft involving only actuator deflections is $\delta = [\delta_{a_1} \delta_{a_2} \delta_{e_1} \delta_{e_2} \delta_r]^T$.

44.2.2 Aircraft Dynamics

Among the nonlinear equations which describe the dynamics of an aircraft, those involving the turn rates are of primary interest. Indeed, as soon as any control surface exhibits a faulty behavior, the aerodynamic moments applied to the airframe are altered. The fault detection system constructed in this chapter is based on a simplified aircraft model that gives the explicit relationship between turn rates (p, q, r) , the inertia matrix \mathbf{I}^b , and the torques applied to the aircraft, that is, $[L \ M \ N]^T$, expressed in the body-axes frame (x_b, y_b, z_b) of the aircraft:

$$\begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} = (\mathbf{I}^b)^{-1} \left(\begin{bmatrix} L \\ M \\ N \end{bmatrix}^b - \begin{bmatrix} p \\ q \\ r \end{bmatrix} \times \mathbf{I}^b \begin{bmatrix} p \\ q \\ r \end{bmatrix} \right). \quad (44.1)$$

In the context of this work, the aircraft is a small UAV for which the aerodynamic moments have been modeled as follows (see Stevens and Lewis (2003), Stengel (2004), Möckli (2006), and Ducard (2009)):

$$\begin{aligned} L &= \bar{q} S b C_L(\delta_{a1}, \delta_{a2}, \delta_{e1}, \delta_{e2}, p, r, \beta), \\ M &= \bar{q} S \bar{c} C_M(\delta_{a1}, \delta_{a2}, \delta_{e1}, \delta_{e2}, \alpha, q), \\ N &= \bar{q} S b C_N(\delta_{a1}, \delta_{a2}, \delta_{e1}, \delta_{e2}, \delta_r, r, \beta), \end{aligned} \quad (44.2)$$

where the dynamic pressure is $\bar{q} = \frac{\rho V_T^2}{2}$, the total airspeed of the aircraft is V_T , the air density is ρ , the wing total surface is S , the wing span is b , and the mean aerodynamic wing chord is \bar{c} .

The aerodynamic derivatives are expressed as a linear combination of the state elements and control inputs as

$$\begin{aligned} C_L &= C_{L_{a1}} \delta_{a1} + C_{L_{a2}} \delta_{a2} + C_{L_{e1}} \delta_{e1} + C_{L_{e2}} \delta_{e2} + C_{L_{\bar{p}}} \bar{\bar{p}} + C_{L_{\bar{r}}} \bar{\bar{r}} + C_{L_{\beta}} \beta, \\ C_M &= C_{M1} + C_{M_{a1}} \delta_{a1} + C_{M_{a2}} \delta_{a2} + C_{M_{e1}} \delta_{e1} + C_{M_{e2}} \delta_{e2} + C_{M_{\bar{q}}} \bar{\bar{q}} + C_{M_{\alpha}} \alpha, \\ C_N &= C_{N_{\delta_r}} \delta_r + C_{N_{\bar{r}}} \bar{\bar{r}} + C_{N_{\beta}} \beta, \end{aligned} \quad (44.3)$$

with the dimensionless angular rates $\bar{\bar{p}} = \frac{bp}{2V_T}$, $\bar{\bar{q}} = \frac{\bar{c}q}{2V_T}$, $\bar{\bar{r}} = \frac{br}{2V_T}$. The last two differential equations concern the angle of attack α and the sideslip angle β as follows (see Ducard (2009) for the derivation of the following two formulae):

$$\begin{aligned} \dot{\alpha} &\approx q + \frac{g}{V_T} \left\{ 1 + \frac{\bar{q} S}{mg} ([C_{X1} + C_{Z\alpha}] \alpha + C_{Z1}) \right\}, \\ \dot{\beta} &\approx -r + \frac{\bar{q} S C_{Y1}}{m V_T} \beta, \end{aligned} \quad (44.4)$$

with the drag derivative C_{X1} , the side force derivative C_{Y1} , and the lift derivatives C_{Z1} , $C_{Z\alpha}$ being constant terms.

Finally, the inertia matrix expressed in the body-fixed frame is $\mathbf{I}^b = \begin{bmatrix} I_{xx} & 0 & I_{xz} \\ 0 & I_{yy} & 0 \\ I_{zx} & 0 & I_{zz} \end{bmatrix}$, with $I_{xz} = I_{zx}$. The numerical values of the parameters of the aircraft model used throughout this chapter are summarized in Table 44.2 in Appendix.

44.3 Residual Generator

In this chapter, the detection of a fault in the system is achieved by monitoring a signal that is within certain limits in normal conditions and that goes beyond these limits in faulty situations. This is the reason why a mathematical model has

been developed to describe the behavior of the aircraft. This model and the real aircraft receive the same actuator commands issued by the flight controller. The real aircraft dynamics are measured by sensors mounted aboard the vehicle. They will be compared with the predicted aircraft dynamics that are computed with the aircraft model. The difference between the real and predicted dynamics constitutes signals that are called residuals.

However, the mathematical model of the aircraft will never be perfect, leaving many effects unmodeled. Also, this model will only be approximated by the computer implementation. Furthermore, several parameters of the model will not be known exactly, and the sensor measurement data will be corrupted by noise and biases. For all these reasons, Kalman filtering techniques are employed in this work to take into account such system dynamics and measurement noise, errors, and uncertainties.

Kalman filters (KF) are well suited when the real world can be described by linear differential equations expressed in state space form and when the measurements are linear functions of the states. However, in most realistic problems, the real world is described by nonlinear differential equations. In order to take into account these nonlinearities, the residual generator of the FDI systems presented in this chapter uses extended Kalman filters (EKF), which are recalled below.

44.3.1 EKF Equations

The EKFs are designed based on a set of continuous nonlinear differential equations that describe the plant under consideration as follows (see Zarchan and Musoff (2005)):

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) + \mathbf{w}, \quad (44.5)$$

where the state vector is \mathbf{x} , the control input vector is \mathbf{u} , the set of nonlinear functions of the state and control vectors is $\mathbf{f}(\mathbf{x}, \mathbf{u})$, and the random zero-mean process noise vector is \mathbf{w} .

The continuous process noise covariance matrix describing the random process \mathbf{w} is given by

$$\mathbf{R}_w = E\{\mathbf{w}\mathbf{w}^T\}. \quad (44.6)$$

Equation 44.5 is first linearized around the current operating point and then discretized using the Euler integration method. Note that the Euler integration method is also used for the simulations presented in the following sections. The discretized form of (44.5) is expressed in state space form as

$$\mathbf{x}_{k+1} = \phi_k \mathbf{x}_k + \mathbf{G}_k \mathbf{u}_k + \mathbf{w}_k, \quad (44.7)$$

where the state vector is evaluated at the discrete-time instant $t_k = kT_s$, with the constant T_s being the sampling period of the system. The control input vector at time step k is \mathbf{u}_k , and the discrete random zero-mean process noise \mathbf{w}_k is used to describe uncertainties in the model.

Finally, the discrete form of the measurement equation, either a linear or a nonlinear function of the states, is

$$\mathbf{y}_k = \mathbf{h}(\mathbf{x}_k) + \mathbf{v}_k, \quad (44.8)$$

where the discrete zero-mean random noise \mathbf{v}_k is described by the measurement noise covariance matrix $\mathbf{R}_{v,k} = E\{\mathbf{v}_k \mathbf{v}_k^T\}$ and consists of the variances of each of the measurement noise sources.

The discrete transition matrix ϕ_k is approximated by

$$\phi_k \approx \mathbf{I} + \mathbf{F}(k)T_s, \quad (44.9)$$

where the continuous system dynamics matrix $\mathbf{F}(k)$ is obtained by linearizing the continuous nonlinear equations and is evaluated at the latest available state estimate $\hat{\mathbf{x}}_{k|k}$ according to

$$\mathbf{F}(k) = \left. \frac{\partial \mathbf{f}(\mathbf{x}, \mathbf{u})}{\partial \mathbf{x}} \right|_{\mathbf{x}=\hat{\mathbf{x}}_{k|k}, \mathbf{u}=\mathbf{u}_k}. \quad (44.10)$$

Similarly, the continuous measurement matrix $\mathbf{H}(k)$ is computed by linearizing the (possibly nonlinear) measurement equation $\mathbf{h}(\mathbf{x})$ and is successively evaluated at the latest available state estimate $\hat{\mathbf{x}}_{k|k}$ (see mechanization shown in Fig. 44.3) according to

$$\mathbf{H}(k) = \mathbf{H}_k = \left. \frac{\partial \mathbf{h}(\mathbf{x})}{\partial \mathbf{x}} \right|_{\mathbf{x}=\hat{\mathbf{x}}_{k|k}}. \quad (44.11)$$

The equations used in the EKF are described below (Kalman 1960; Brown and Hwang 1997; Zarchan and Musoff 2005). The schematic overview of the computation steps is shown in Fig. 44.3.

44.3.2 Filter's Equations

The equations used in the filter are as follows:

1. The Kalman gain matrix \mathbf{L}_k is computed as

$$\mathbf{L}_k = \Sigma_{k|k-1} \mathbf{H}_k^T [\mathbf{H}_k \Sigma_{k|k-1} \mathbf{H}_k^T + \mathbf{R}_{v,k}]^{-1} \quad (44.12)$$

and is a function of the last-propagated state error covariance matrix $\Sigma_{k|k-1}$ and of the measurement noise covariance matrix $\mathbf{R}_{v,k}$.

2. The measurement update of the state estimate is as follows:

$$\hat{\mathbf{x}}_{k|k} = \hat{\mathbf{x}}_{k|k-1} + \mathbf{L}_k [\mathbf{y}_k - \mathbf{h}(\hat{\mathbf{x}}_{k|k-1})], \quad (44.13)$$

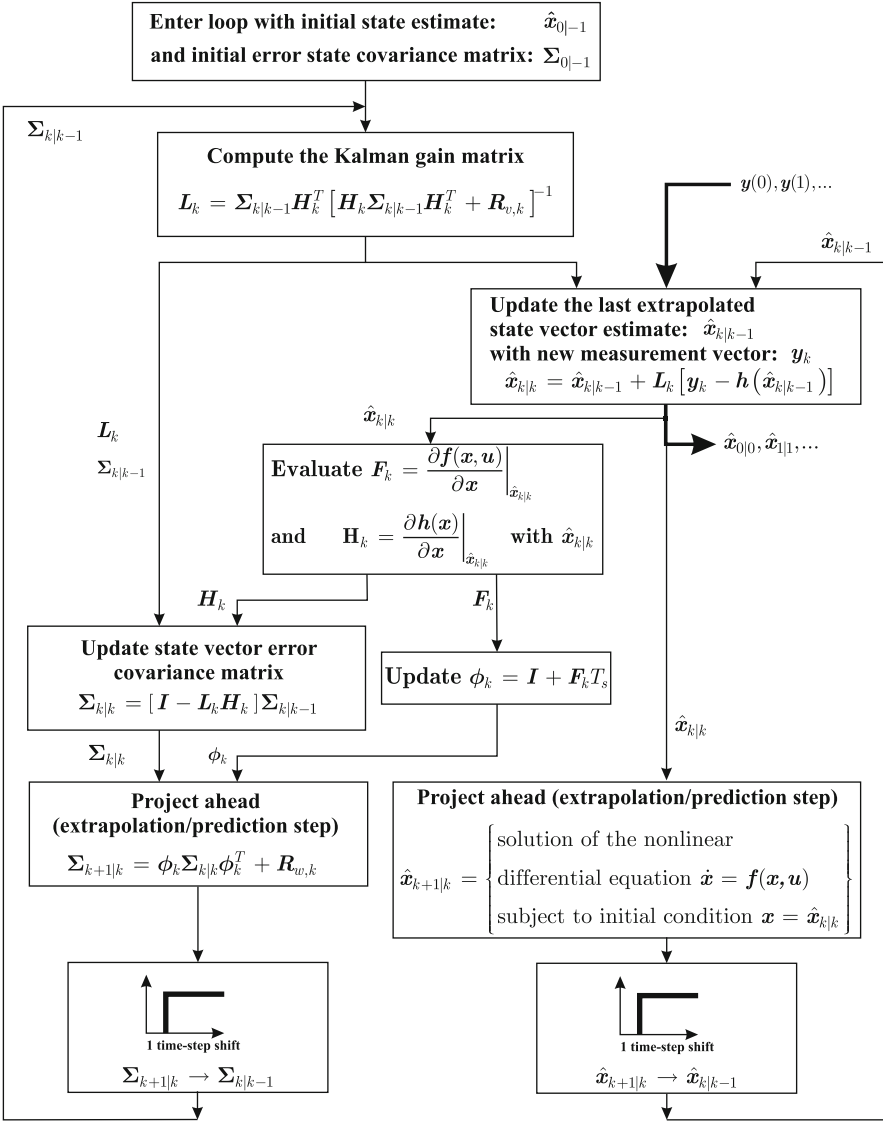

Fig. 44.3 EKF mechanization

where the last extrapolated state estimate is $\hat{\mathbf{x}}_{k|k-1}$, the measurement vector is \mathbf{y}_k , and the estimated measurement vector is $\mathbf{h}(\hat{\mathbf{x}}_{k|k-1})$. The set of continuous nonlinear measurement equations is $\mathbf{h}(\cdot)$.

- The third step concerns the update of the state error covariance matrix $\Sigma_{k|k} = \mathbf{E}\{\mathbf{e}_{k|k} \mathbf{e}_{k|k}^T\}$ with $\mathbf{e}_{k|k} = \mathbf{x}(k) - \hat{\mathbf{x}}_{k|k}$, where $\mathbf{x}(k)$ is the true (unknown) value of the state vector at the discrete instant k . The matrix $\Sigma_{k|k}$ is recursively computed

as a function of the last predicted state error covariance matrix $\Sigma_{k|k-1}$ and the last computed Kalman gain matrix \mathbf{L}_k as follows:

$$\Sigma_{k|k} = [\mathbf{I} - \mathbf{L}_k \mathbf{H}_k] \Sigma_{k|k-1}. \quad (44.14)$$

4. The forward propagation of the state error covariance matrix is

$$\Sigma_{k+1|k} = \phi_k \Sigma_{k|k} \phi_k^T + \mathbf{R}_{w,k}, \quad (44.15)$$

where the matrix $\mathbf{R}_{w,k}$ represents the covariance of the discrete process noise acting on the elements of the state vector. The value of $\mathbf{R}_{w,k}$ is found from the continuous process noise covariance matrix \mathbf{R}_w and the continuous transition matrix ϕ according to

$$\mathbf{R}_{w,k} = \int_0^{T_s} \phi(\tau) \mathbf{R}_w \phi^T(\tau) d\tau, \quad (44.16)$$

where the matrix $\phi(t)$ is defined as follows:

$$\phi(t) = \mathbf{I} + \mathbf{F}(k)t. \quad (44.17)$$

There is an alternative solution of introducing process noise into the system through the control input matrix. Indeed, if the plant is described by the following equation:

$$\mathbf{x}_{k+1} = \phi_k \mathbf{x}_k + \mathbf{G}_k \mathbf{u}_k + \mathbf{G}_k \mathbf{w}_k, \quad (44.18)$$

then the process noise covariance matrix is defined by

$$\mathbf{R}_{w,k} = \mathbf{G}_k \mathbf{R}_w \mathbf{G}_k^T, \quad (44.19)$$

where the covariance matrix of the discrete process noise acting on the elements of the state vector is $\mathbf{R}_{w,k}$, and the discrete control input matrix is $\mathbf{G}_k =$

$$T_s \left. \frac{\partial \mathbf{f}}{\partial \mathbf{u}} \right|_{V_T(k)}.$$

5. The propagation forward of the state estimate does not have to be done with the discrete transition matrix ϕ_k , but rather it is done directly by integrating the actual nonlinear differential equations forward at each sampling interval. If the Euler integration technique is used, the extrapolated state estimate is computed with

$$\hat{\mathbf{x}}_{k+1|k} = \hat{\mathbf{x}}_{k|k} + \dot{\hat{\mathbf{x}}}_{k|k} T_s, \quad (44.20)$$

where the state time derivative is obtained from

$$\dot{\hat{\mathbf{x}}}_{k|k} = \mathbf{f}(\hat{\mathbf{x}}_{k|k}, \mathbf{u}_k). \quad (44.21)$$

Remarks:

- Note that the EKF presented in this section keeps track of the total estimates and not of the incremental ones (deviation from a nominal trajectory) as would be the case in a linearized KF. Indeed, the residuals are built from the difference between the true measurement vector and the predicted measurement vector using the set of nonlinear measurement equations acting on the total state estimate $\mathbf{h}(\hat{\mathbf{x}}_{k|k-1})$.
- Moreover, the measurement update of the state estimate is done using the total estimate $\hat{\mathbf{x}}(k|k-1)$, and the propagation forward of the total state estimate is achieved using the set of nonlinear differential equations acting on the total state estimate $\mathbf{f}(\hat{\mathbf{x}}_{k|k}, \mathbf{u}_k)$ instead of using the discrete transition matrix acting on incremental state quantities.
- Nevertheless, the computation of the Kalman gains and state error covariance matrices makes use of the recursively updated linear model through ϕ_k , \mathbf{H}_k , and $\mathbf{R}_{w,k}$.
- The schematic overview shown in Fig. 44.3 clarifies the mechanization of the EKF implemented in this work.

44.4 Multiple Model Approaches for FDI Systems

One popular approach to detect and isolate actuator or sensor faults is the multiple model adaptive estimation (MMAE) method (Magill 1965; Maybeck and Stevens 1991) as depicted in Fig. 44.4. It is based on a bank of parallel Kalman filters (KF), each of which is matching a particular fault status of the system. A hypothesis

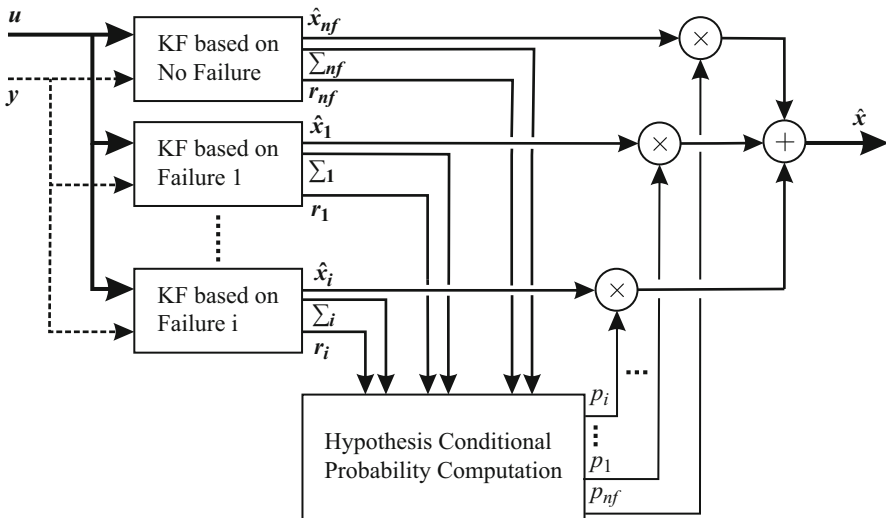

Fig. 44.4 Classical MMAE scheme

testing algorithm uses the vector of residuals \mathbf{r}_i and state error covariance matrix Σ_i from each KF to assign a conditional probability to each fault hypothesis. Several papers have demonstrated how the MMAE method can be used in the context of FDI systems for aircraft (Maybeck and Stevens 1991; Eide and Maybeck 1996; Maybeck 1999) and underwater vehicles (Ni 2001).

The main advantage of the MMAE method lies in its responsiveness to parameter variations, potentially leading to faster fault isolation than that obtained by other methods without a multiple model structure.

However, the MMAE method possesses three limitations to its successful application as explained in Ducard and Geering (2008). The first limitation concerns the number of filters that must be designed in order to span the range of possible fault scenarios, which must be limited due to computational load. The second limitation appears when an actuator is locked at an arbitrary nonzero position that biases the residuals of the KFs, leading to inaccurate fault detection and state estimation. Third, most of the implementations of an MMAE method only work efficiently around predefined operating conditions. This chapter shows how the MMAE method is modified to compensate the three limitations of the classical MMAE implementation by employing extended Kalman filters (EKF) to estimate the deflection of a faulty control surface (or actuator). The resulting method is called thus “extended multiple model adaptive estimation” (EMMAE), and its architecture is shown in Fig. 44.6 (Rupp et al. 2005).

44.4.1 Modeling Actuator Faults

A lock-in-place or floating actuator fault in the system can be seen as if the desired control input δ_j was disconnected and replaced by a faulty control signal $\bar{\delta}_j$ that takes control over the plant, as shown in Fig. 44.5. In a concise manner (Tao et al. 2004), the true input of the plant can be written as

$$u_i(t) = \delta_i(t) + \sigma_{A_i}(\bar{\delta}_i(t) - \delta_i(t)). \quad (44.22)$$

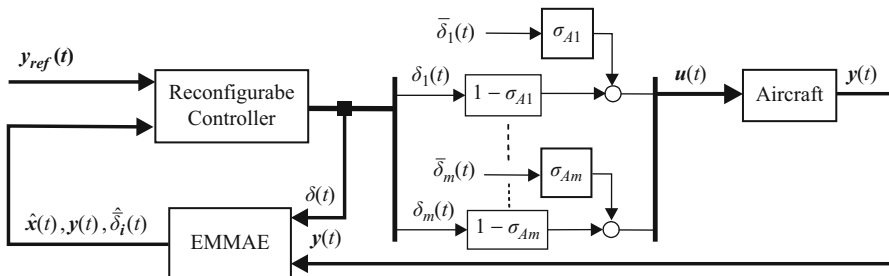

Fig. 44.5 Modeling of actuator faults

In the case of actuator failure(s), the vector of the (unknown) inputs is

$$\bar{\delta}(t) = [\bar{\delta}_1(t) \ \bar{\delta}_2(t) \ \dots \ \bar{\delta}_m(t)]^T, \quad (44.23)$$

with $\sigma = \text{diag}\{\sigma_{A1} \ \sigma_{A2} \ \dots \ \sigma_{Am}\}$, where

$$\sigma_{Aj} = \begin{cases} 1, & \text{if the } j\text{th actuator fails} \\ 0, & \text{otherwise} \end{cases}. \quad (44.24)$$

In the method presented below, the unknown parameters $\bar{\delta}_j$ are constantly estimated by their respective EKF. The conditional fault-hypothesis probabilities p_j assign the value for σ_{Aj} .

44.4.2 The EMMAE Method

The MMAE method is to be made applicable for any arbitrary lock-in-place faults or uncontrolled varying faults and at all flying conditions. Therefore, the original MMAE algorithm is modified by replacing the linear KFs by EKFs used as nonlinear estimators of the state vector and a fault parameter, namely, the deflection of a faulty control surface (or actuator) $\bar{\delta}_j$. The implementation of the EMMAE is depicted in Fig. 44.6. Contrary to the FDI designs with

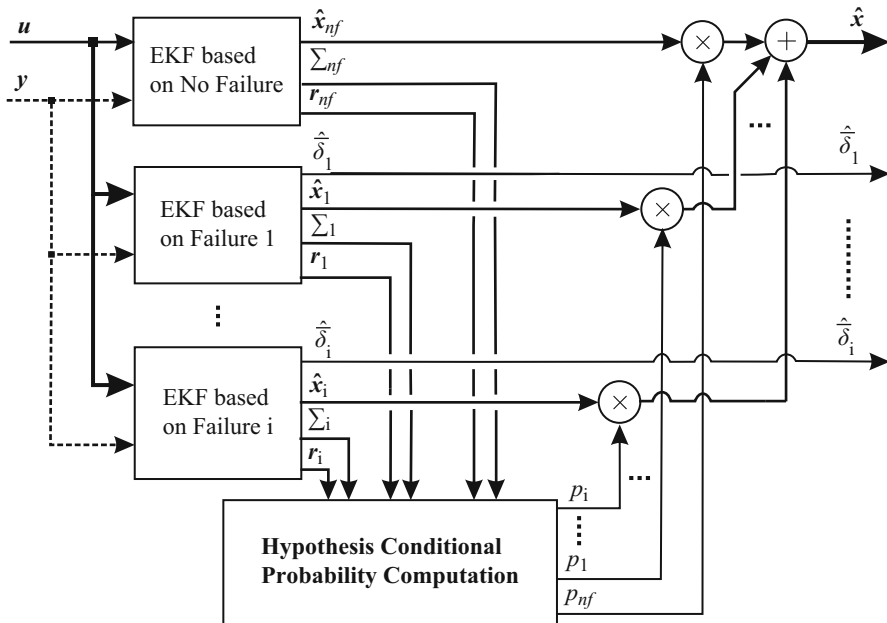

Fig. 44.6 EMMAE-FDI scheme: each EKF monitors its assigned actuator

the classical MMAE method where several KFs are designed for several faulty deflections for one actuator, in the EMMAE method, only one EKF is responsible for completely monitoring one actuator's health. Therefore, the EMMAE method drastically reduces the number of filters required for actuator health monitoring.

The addition of the actuator deflection estimate in the system state vector enables the EMMAE method to work for all the possible positions where an actuator can be locked or floating. In order to better illustrate the difference between the EMMAE and MMAE methods, Eqs. (44.25) and (44.26) recall how the models are defined in the regular MMAE method (Eide and Maybeck 1996; Maybeck 1999; Maybeck and Stevens 1991; Ni 2001) for an actuator or a sensor failure. The MMAE scheme considers a bank of linear models of the form

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{Ax} + \mathbf{Bu}, \\ \mathbf{y} &= \mathbf{Cx} + \mathbf{Du},\end{aligned}\tag{44.25}$$

where each model matches a fault scenario.

For example, the model that describes a failure of the j th actuator will have its \mathbf{B} matrix modified such that the j th column of the \mathbf{B} matrix is replaced by the very same column times a factor λ_j that varies from zero (complete loss of the actuator) to one (fully functioning actuator), see (44.26). Any intermediate value of λ_j indicates a reduction in the effectiveness of the j th actuator to modify the dynamics of the aircraft as shown in (44.26):

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{Ax} + \mathbf{B}_j \mathbf{u}, \\ \dot{\mathbf{x}} &= \mathbf{Ax} + \begin{bmatrix} b_{11} & \cdots & b_{1j}\lambda_j & \cdots & b_{1N} \\ \vdots & \cdots & \vdots & \cdots & \vdots \\ b_{l1} & \cdots & b_{lj}\lambda_j & \cdots & b_{lN} \\ \vdots & \cdots & \vdots & \cdots & \vdots \\ b_{p1} & \cdots & b_{pj}\lambda_j & \cdots & b_{pN} \end{bmatrix} \begin{bmatrix} u_1 \\ \vdots \\ u_j \\ \vdots \\ u_N \end{bmatrix}.\end{aligned}\tag{44.26}$$

However, this kind of approach for the modeling of actuator failure is very restrictive. Indeed, in the case of a total loss of the j th actuator, the factor λ_j equals zero. This means that whatever control input the controller generates for the j th actuator, it has no influence on the dynamics of the aircraft, and the faulty actuator deflection is considered to be zero. Note that if the j th actuator is actually locked at a nonzero deflection angle, the faulty actuator deflection has an influence on the dynamics of the aircraft. This condition results in an unknown bias term that will prevent the j th KF in the MMAE method from working properly. Therefore, the residuals will be biased, and the state estimation and the computation of the probabilities will be incorrect as well.

In the EMMAE method, both the control input matrix and the dynamics matrix are modified. Indeed, in order to define a model that describes a failure of the j th actuator, the j th column of the control input matrix is zeroed and the state vector is augmented with the j th actuator deflection $\bar{\delta}_j$. The dynamics matrix is also augmented with the original j th column of the control input matrix. In this way, the control inputs from the controller to the j th actuator are totally ignored, but the faulty deflection $\bar{\delta}_j$ that is constantly estimated ($\hat{\bar{\delta}}_j$) in the state vector contributes to modifying the dynamics of the aircraft model of the j th filter. It yields residuals that are the smallest for the filter matching the occurring fault. The next section illustrates how the filters in the EMMAE are constructed in practice.

44.4.3 Designing the EKF for the No-Fault Scenario

In the EMMAE method, the residuals $\mathbf{r}(k)$ are obtained as follows:

$$\mathbf{r}(k) = \mathbf{y}(k) - \hat{\mathbf{x}}_{k|k-1}, \quad (44.27)$$

where the filter's last-propagated state estimate vector is $\hat{\mathbf{x}}_{k|k-1} = [\hat{p} \ \hat{q} \ \hat{r} \ \hat{\alpha} \ \hat{\beta}]_{(k|k-1)}^T$ and the measurement vector is $\mathbf{y}(k) = [p, q, r, \alpha, \beta]_{(k)}^T$.

The continuous system dynamics matrix for the no-fault filter $\mathbf{F}_{nf}(k)$ evaluated at time step k can be explicitly derived from the nonlinear model detailed in Sect. 44.2 as

$$\mathbf{F}_{nf}(k) = \begin{bmatrix} 0 & \frac{Sb[I_{zz}C_{L\bar{\beta}} - I_{xz}C_{N\bar{\beta}}]}{D_1}\bar{q} \\ \mathbf{F}_1 & \frac{S\bar{c}C_{M\alpha}}{I_{yy}}\bar{q} & 0 \\ 0 & 0 & \frac{Sb[I_{xx}C_{N\bar{\beta}} - I_{xz}C_{L\bar{\beta}}]}{D_1}\bar{q} \\ 0 & 1 & 0 & \frac{\rho V_T S C_{Z\alpha}}{2m} & 0 \\ 0 & 0 & -1 & 0 & \frac{\rho V_T S C_{Y1}}{2m} \end{bmatrix} \hat{\mathbf{x}}_{nf}(k|k), \bar{q}(k) \quad (44.28)$$

with the submatrix \mathbf{F}_1 defined as

$$\mathbf{F}_1 = \begin{bmatrix} \frac{I_{zz}Sb^2C_{L\bar{\beta}}}{2D_1V_T}\bar{q} - \frac{N_1}{D_1}q & -\frac{N_1}{D_1}p + \frac{N_2}{D_1}r & \frac{(I_{zz}C_{L\bar{\beta}} - I_{xz}C_{N\bar{\beta}})Sb^2}{2D_1V_T}\bar{q} + \frac{N_2}{D_1}q \\ -\frac{I_{xx} - I_{zz}}{I_{yy}}r + 2\frac{I_{xz}}{I_{yy}}p & \frac{S\bar{c}^2C_{M\bar{q}}}{2V_T I_{yy}}\bar{q} & -\frac{I_{xx} - I_{zz}}{I_{yy}}p - \frac{2I_{xz}}{I_{yy}}r \\ -\frac{Sb^2C_{L\bar{\beta}}I_{xz}}{2D_1V_T}\bar{q} + \frac{N_3}{D_1}q & \frac{N_3}{D_1}p + \frac{N_1}{D_1}r & \frac{Sb^2[-I_{xz}C_{L\bar{\beta}} + I_{xx}C_{N\bar{\beta}}]}{2D_1V_T}\bar{q} + \frac{N_1}{D_1}q \end{bmatrix}, \quad (44.29)$$

where $N_1 = I_{xz}(I_{xx} - I_{yy} + I_{zz})$, $N_2 = I_{yy}I_{zz} - I_{xz}^2 - I_{zz}^2$, $N_3 = I_{xz}^2 - I_{xx}I_{yy} + I_{xx}^2$ and $D_1 = I_{xx}I_{zz} - I_{xz}^2$.

The discrete transition matrix for the no-fault filter is calculated with $\phi_{nf,k} = \mathbf{I} + \mathbf{F}_{nf}(k)T_s$. The control input matrix of the no-fault filter $\mathbf{G}_{nf}(k)$ is computed as follows:

$$\mathbf{G}_{nf}(k) = \bar{q}_k \begin{bmatrix} \frac{SbI_{zz}CLa_1}{D_1} & \frac{SbI_{zz}CLa_2}{D_1} & \frac{SbI_{zz}CLe_1}{D_1} & \frac{SbI_{zz}CLe_2}{D_1} & \frac{-SbI_{xz}CN_{\delta r}}{D_1} \\ \frac{S\tilde{c}C_{Ma1}}{I_{yy}} & \frac{S\tilde{c}C_{Ma2}}{I_{yy}} & \frac{S\tilde{c}C_{Me1}}{I_{yy}} & \frac{S\tilde{c}C_{Me2}}{I_{yy}} & 0 \\ \frac{-SbI_{xz}CLa_1}{D_1} & \frac{-SbI_{xz}CLa_2}{D_1} & \frac{-SbI_{xz}CLe_1}{D_1} & \frac{-SbI_{xz}CLe_2}{D_1} & \frac{SbI_{xx}CN_{\delta r}}{D_1} \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}. \quad (44.30)$$

The discrete control input matrix for the no-fault filter is $\mathbf{G}_{nf,k} = \mathbf{G}_{nf}(k)T_s$.

44.4.4 Augmenting the State Vector with the Faulty Actuator Parameter δ_i

The state vector of the i th filter is augmented to monitor the occurrence of the i th actuator fault. The deflection of the failed actuator is included in the state vector in a way to be estimated by the EKF. Therefore, the state vector for each filter i is

$$\mathbf{z}_i = \begin{bmatrix} \mathbf{x} \\ \bar{\delta}_i \end{bmatrix}. \quad (44.31)$$

The augmented state vector leads to the following state space equations for each filter i :

$$\begin{aligned} \mathbf{z}_i(k+1) &= \mathbf{f}_{z_i}(\mathbf{z}_i(k), \delta(k)) + \mathbf{w}_k, \\ \mathbf{y}_i(k) &= \mathbf{h}(\mathbf{z}_i(k)) + \mathbf{v}_k, \end{aligned} \quad (44.32)$$

Using the above equations, the linearized system evaluated at each sampling time can be written as

$$\begin{aligned} \begin{bmatrix} \mathbf{x}(k+1) \\ \bar{\delta}_i(k+1) \end{bmatrix} &= \begin{bmatrix} \mathbf{F}(k) & \mathbf{G}^i(k) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{x}(k) \\ \bar{\delta}_i(k) \end{bmatrix} + \begin{bmatrix} \mathbf{G}^{(0,i)}(k) \\ 0 \end{bmatrix} \delta(k), \\ \mathbf{y}(k) &= [\mathbf{H} \quad 0] \begin{bmatrix} \mathbf{x}(k) \\ \bar{\delta}_i(k) \end{bmatrix}. \end{aligned} \quad (44.33)$$

where $\mathbf{G}^{(i)}$ represents the i th column of \mathbf{G} and $\mathbf{G}^{(0,i)}$ represents the matrix \mathbf{G} with its i th column set to zero.

44.4.5 Designing the EKF for the Case of a Failure on Aileron 1

This section provides an example of how to derive the matrices for the EKF corresponding to the scenario of a lock-in-place or floating actuator failure. Aileron 1 is taken as an example.

The system dynamics matrix for the aileron1-fault filter $\mathbf{F}_{\delta a1}(k)$ is explicitly derived from the nonlinear model as

$$\mathbf{F}_{\delta a1}(k) = \begin{bmatrix} 0 & \frac{Sb[I_{zz}C_{L\beta} - I_{xz}C_{N\beta}]}{D_1}\bar{q} & \frac{SbI_{zz}C_{La1}}{D_1}\bar{q} \\ \mathbf{F}_1 & \frac{S\bar{c}C_{Ma}}{I_{yy}}\bar{q} & 0 & \frac{S\bar{c}C_{Ma1}}{I_{yy}}\bar{q} \\ 0 & \frac{Sb[I_{xx}C_{N\beta} - I_{xz}C_{L\beta}]}{D_1}\bar{q} & \frac{-SbI_{xz}C_{La1}}{D_1}\bar{q} \\ 0 & 1 & 0 & \frac{\rho V_T S C_{Z\alpha}}{2m} & 0 \\ 0 & 0 & -1 & 0 & \frac{\rho V_T S C_{Y1}}{2m} & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \hat{\mathbf{z}}_1(k|k) \quad (44.34)$$

The discrete transition matrix for the aileron1-fault filter is calculated with $\phi_{k,\delta a1} = \mathbf{I} + \mathbf{F}_{\delta a1}(k)T_s$. The control input matrix of the no-fault filter $\mathbf{G}_{\delta a1}(k)$ is computed as follows:

$$\mathbf{G}_{\delta a1}(k) = \begin{bmatrix} 0 & \frac{SbI_{zz}C_{La2}}{D_1}\bar{q} & \frac{SbI_{zz}C_{Le1}}{D_1}\bar{q} & \frac{SbI_{zz}C_{Le2}}{D_1}\bar{q} & \frac{-SbI_{xz}C_{N\delta r}}{D_1}\bar{q} \\ 0 & \frac{S\bar{c}C_{Ma2}}{I_{yy}}\bar{q} & \frac{S\bar{c}C_{Me1}}{I_{yy}}\bar{q} & \frac{S\bar{c}C_{Me2}}{I_{yy}}\bar{q} & 0 \\ 0 & \frac{-SbI_{xz}C_{La2}}{D_1}\bar{q} & \frac{-SbI_{xz}C_{Le1}}{D_1}\bar{q} & \frac{-SbI_{xz}C_{Le2}}{D_1}\bar{q} & \frac{SbI_{xx}C_{N\delta r}}{D_1}\bar{q} \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \bar{q}(k) \quad (44.35)$$

The discrete control input matrix for the aileron1-fault filter is $\mathbf{G}_{\delta a1,k} = \mathbf{G}_{\delta a1}(k)T_s$. All the other filters monitoring the other actuators are designed in a similar way.

44.4.6 Actuator Fault Isolation

44.4.6.1 Hypothesis Testing

A hypothesis testing algorithm uses the residuals and the state error covariance matrix from each EKF to assign a conditional probability to each fault scenario.

The estimated state vector of the system is the sum of the state vector of each EKF weighted by its corresponding probability

$$\hat{\mathbf{x}}[k] = \sum_i \hat{\mathbf{x}}_i[k] \cdot p_i[k], \quad (44.36)$$

where $\hat{\mathbf{x}}_i[k]$ is the state estimate computed by the EKF that assumes the fault scenario θ_i . The index i covers all the fault scenarios implemented, including the no-fault case. The term $p_i[k]$ denotes the probability that the i th fault scenario is occurring. Now, the main difficulty lies in the online computation of the probability $p_i[k]$. In order to determine which fault scenario the actual plant is the closest to, it is needed to consider the measurement data from the sensors. The last available measurement vector is $\mathbf{y}[k]$, sometimes also written \mathbf{y}_k in the following. The sequence of the last measurement vectors is defined as $\mathbf{Y}_k = \{\mathbf{y}_k, \mathbf{y}_{k-1}, \mathbf{y}_{k-2}, \dots, \mathbf{y}_0\}$. The fault probability $p_i[k]$ can be expressed as the a posteriori conditional probability $p_i[k] = p(\theta = \theta_i | \mathbf{Y}_k)$, that is, the probability that the actual plant can be categorized in the scenario θ_i given the sequence of the last measurements \mathbf{Y}_k . The Bayes' law states that

$$p_i[k] = p(\theta = \theta_i | \mathbf{Y}_k) = \frac{p[\mathbf{Y}_k | \theta = \theta_i] p[\theta = \theta_i]}{p[\mathbf{Y}_k]}, \quad (44.37)$$

where the probability $p[\mathbf{Y}_k]$ can be decomposed as

$$\begin{aligned} p[\mathbf{Y}_k] &= p[\mathbf{Y}_k | \theta = \theta_1] \cdot p[\theta = \theta_1] + \dots + p[\mathbf{Y}_k | \theta = \theta_N] \cdot p[\theta = \theta_N], \\ &= \sum_{j=0}^N p[\mathbf{Y}_k | \theta = \theta_j] \cdot p[\theta = \theta_j]. \end{aligned} \quad (44.38)$$

Combining (Eq. 44.37) and (Eq. 44.38) yields

$$p_i[k] = p[\theta = \theta_i | \mathbf{Y}_k] = \frac{p[\mathbf{Y}_k | \theta = \theta_i] p[\theta = \theta_i]}{\sum_{j=0}^N p[\mathbf{Y}_k | \theta = \theta_j] \cdot p[\theta = \theta_j]}, \quad (44.39)$$

with N being the number of different scenarios under consideration. In order to make a recursive form appear in the probabilities, the measurement data sequence \mathbf{Y}_k is rewritten as the sequence $\{\mathbf{y}_k, \mathbf{Y}_{k-1}\}$:

$$\begin{aligned} p[\mathbf{Y}_k | (\theta = \theta_j)] &= p[\mathbf{y}_k, \mathbf{Y}_{k-1} | (\theta = \theta_j)] \\ &= p[\mathbf{y}_k | (\mathbf{Y}_{k-1}, \theta = \theta_j)] \cdot p[\mathbf{Y}_{k-1} | (\theta = \theta_j)] \\ &= p[\mathbf{y}_k | (\theta = \theta_j, \mathbf{Y}_{k-1})] \cdot p[(\theta = \theta_j) | \mathbf{Y}_{k-1}] \\ &= p[\mathbf{y}_k | (\theta = \theta_j, \mathbf{Y}_{k-1})] \cdot p_j[k-1]. \end{aligned} \quad (44.40)$$

Using the result (Eq. 44.40) in (Eq. 44.39) yields

$$p_i[k] = p[(\theta = \theta_i) | \mathbf{Y}_k] = \frac{p[\mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})] \cdot p_i[k-1] \cdot p[\theta = \theta_i]}{\sum_{j=0}^N p[\mathbf{y}_k | (\theta = \theta_j, \mathbf{Y}_{k-1})] \cdot p_j[k-1] \cdot p[\theta = \theta_j]}. \quad (44.41)$$

Since a fault may occur at any time, regardless of which actuator may fail, the same probability is assigned to all the scenarios, that is, $p[\theta = \theta_j] = 1/N$ for $j = 1, \dots, N$. Therefore, the equation above simplifies to the following recursive expression:

$$p_i[k] = p[\theta = \theta_i | \mathbf{Y}_k] = \frac{p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})] \cdot p_i[k-1]}{\sum_{j=0}^N p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_j, \mathbf{Y}_{k-1})] \cdot p_j[k-1]}. \quad (44.42)$$

Remarks:

- By examining the probabilities, the “health status” of the system can be determined. It is either the no-fault case or a case where an actuator is locked-in-place or floating. An actuator fault is declared valid if the corresponding fault probability exceeds 90 % for a certain amount of time. A fault is declared removed when the corresponding fault probability is below 5 % for a certain amount of time.
- One may notice that the denominator of (Eq. 44.42) corresponds to the sum of each scenario probability’s numerator, such that fault probabilities add up to one.
- In practice, in order to prevent the possibility that the recursive computation of the fault probability in (Eq. 44.42) stays at zero forever as soon as the probability reaches zero, the lower bound of each probability is set to 0.001.
- This method that uses probabilities for fault isolation is sometimes called a Bayes classifier (see Isermann (2006), Chap. 16).

44.4.6.2 Gaussian Conditional Probability Density

This section provides an explicit formula for the term $p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})]$, which corresponds to the probability of obtaining the measurement data $\mathbf{y}[k]$ at time $t_k = kT_s$, assuming the scenario θ_i exists and given the sequence of the last measurements \mathbf{Y}_{k-1} .

The probability density is chosen to be a Gaussian function (Maybeck 1994) with its characteristic bell-shaped curve according to the following formula:

$$p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})] = \lambda_i[k] e^{-\mathbf{r}_i[k]^T \Sigma_i^{-1}[k] \mathbf{r}_i[k]/2}, \quad (44.43)$$

with $\lambda_i[k] = \frac{1}{(2\pi)^{m/2} |\Sigma_i[k]|^{1/2}}$, where $|\dots|$ denotes the determinant of the matrix, m represents the measurement dimension, and $\Sigma_i[k]$ is the residual covariance matrix calculated at time step k by the i th EKF. The term $\mathbf{r}_i[k]$ corresponds to the residuals of the i th EKF, when the measurement update step occurs according to $\mathbf{r}_i[k] = \mathbf{y}_k - \mathbf{h}(\hat{\mathbf{x}}_i(k|k-1))$.

Fig. 44.7 Conditional probability density in the scalar case

Intuitive Explanation of the Probability Density

In the case of a single-input single-output problem, in which the state and measurement vectors reduce to scalars, the measurement data $h(\hat{x}_i(k|k-1))$ that are expected according to the model can be seen as the mean value of the measurement data computed by the i th EKF, that is, $\hat{y}_i[k]$ in Fig. 44.7.

The width of the conditional Gaussian density is governed only by the covariance term $\Sigma_i[k]$. Figure 44.8 shows the shapes of the Gaussian function for several standard deviations $\sigma^2 = \Sigma(j,j)$. The residual $r_i[k]$ determines the relative position of the peak of the probability density with the actual measurement y_k .

In the multivariable case, which applies in this FDI system, the fault probability

$$p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})] \quad (44.44)$$

is given by $\mathbf{f}(\mathbf{r}_i = \mathbf{r}_i[k] | (\theta = \theta_i, \mathbf{Y}_{k-1}))$, with the probability density defined as a function of the residual \mathbf{r}_i with

$$f(\mathbf{r}_i | (\theta = \theta_i, \mathbf{Y}_{k-1})) = \frac{1}{(2\pi)^{m/2} |\Sigma_i[k]|^{1/2}} \cdot e^{-\mathbf{r}_i^T \Sigma_i^{-1}[k] \mathbf{r}_i / 2}. \quad (44.45)$$

Therefore, the filter that corresponds to the fault scenario produces an estimate for the measurement vector $\hat{\mathbf{y}}_i[k] = \mathbf{h}(\hat{\mathbf{x}}_i(k|k-1))$ very close (apart from noise) to the actual value of the measurement data vector $\mathbf{y}[k]$. The residual $\mathbf{r}_i[k] = \mathbf{y}_k - \mathbf{h}(\hat{\mathbf{x}}_i(k|k-1))$ will be small and close to zero. This means that the corresponding probability $p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})]$ is the highest for the filter matching the fault scenario.

Fig. 44.8 Gaussian functions for zero-mean value and several standard deviations σ

By examining the probabilities computed with (Eq. 44.46), the health status of the system is determined; it is either the no-fault case or actuator-failure case:

$$p_i[k] = p[\theta = \theta_i | \mathbf{Y}_k] = \frac{p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_i, \mathbf{Y}_{k-1})] \cdot p_i[k-1]}{\sum_{j=0}^N p[\mathbf{y} = \mathbf{y}_k | (\theta = \theta_j, \mathbf{Y}_{k-1})] \cdot p_j[k-1]}. \quad (44.46)$$

Remarks:

- The hypothesis testing uses a Gaussian density function, which assumes that the residuals from the EKF are Gaussian distributed. When this is not the case, there is a little inconsistency with the application of the theory. However, the assumption that these residuals are Gaussian distributed is still reasonable, especially when the aircraft dynamics are slow.
- The reason why a Gaussian distribution is used to describe the probability density of the current measurement to take on the value y_k based on the fault hypothesis θ_i and the previous measurements \mathbf{Y}_{k-1} is to make the mathematics tractable. As mentioned in the book by Maybeck (1994), “the Kalman filter, which propagates the first and second-order statistics [mean and variance of a process], includes all information contained in the [Gaussian] conditional probability density, rather than only some of it, as would be the case with a different form of density.” If another probability density function was known, then (Eq. 44.45) could be changed accordingly.

44.4.7 Simulation Results of the EMMAE-FDI with No Supervision System

44.4.7.1 Simulation Conditions

In order to obtain realistic simulations, the sensor measurement data are corrupted on purpose with zero-mean white Gaussian noise corresponding to typical specifications of low-cost sensors. For the turn rate sensors, the standard deviation is $\sigma_{p,q,r} = 5^\circ/\text{s} = 0.0873 \text{ rad/s}$, which corresponds to a noise covariance of $\Sigma_{p,q,r} = 0.0076 \times I_3 \text{ (rad}^2/\text{s}^2\text{)}$. For the airflow angle sensors, the noise standard deviation is $\sigma_{\alpha,\beta} = 2^\circ = 0.0349 \text{ rad}$ ($\Sigma_{\alpha,\beta} = 0.0012 \times I_2 \text{ [rad}^2\text{]}$). The airspeed sensor noise has a standard deviation of $\sigma_{V_T} = 1 \text{ m/s}$ ($\Sigma_{V_T} = 1 \text{ m}^2/\text{s}^2$). Poor sensor quality adversely affects the FDI reliability.

When there is little excitation and when the faulty actuator deflection is close to the trim conditions, an actuator failure becomes even more difficult to detect. Indeed, due to large sensor noise, the control signals (see Fig. 44.9) become noisy as well, which reduces the difference between the actual faulty actuator deflection and its corresponding control signal. The larger this difference, the easier it is to detect the fault.

The EKF process noise covariance matrix and the sensor noise covariance matrix are selected as follows: $\mathbf{R}_w = 0.002 \times \mathbf{I}_5$ and $\mathbf{R}_v = \text{diag}[0.1 \times \mathbf{I}_3 \quad 0.02 \times \mathbf{I}_2]$.

44.4.7.2 Scenario

The scenario to test the fault detection method is chosen to put the FDI in the most difficult conditions, which are those of minimum excitation of the system. This is achieved when the aircraft is flying straight and level (no maneuvers, no wind) at a constant speed of 30 m/s.

The actuator faults are simulated by blocking the control surfaces close to the trim deflections corresponding to straight level flight conditions, because those faults are harder to detect and to estimate. For example, the ailerons and the rudder are intentionally made to fail close to the neutral deflection (0°), and the elevators are made to fail close to -2° . Fault detection with the EMMAE method is tested on a 6 degree-of-freedom nonlinear aircraft model of a UAV used in Möckli (2006) and Ducard (2009).

Simulations were performed in MATLAB®/Simulink® on closed-loop control architecture, with a nonlinear autopilot which regulates the speed, altitude, and the attitude of the aircraft. The actuator configuration of the aircraft is depicted in Fig. 44.2. The EMMAE-FDI system is therefore composed of six EKFs, one for monitoring the no-fault case, two for monitoring each aileron (one on each wing), two EKFs for monitoring each of the two independent elevators, and one EKF for the rudder.

As depicted in Fig. 44.9, a sequence of consecutive faults is generated. From $t = 10 \dots 40 \text{ s}$, aileron 1 fails and is locked at -1° deflection; for $t = 70 \dots 100 \text{ s}$, aileron 2 fails and is “floating” between the two positions -1° and 1° in a square-wave fashion. For $t = 130 \dots 160 \text{ s}$, the rudder fails and is locked at -1° .

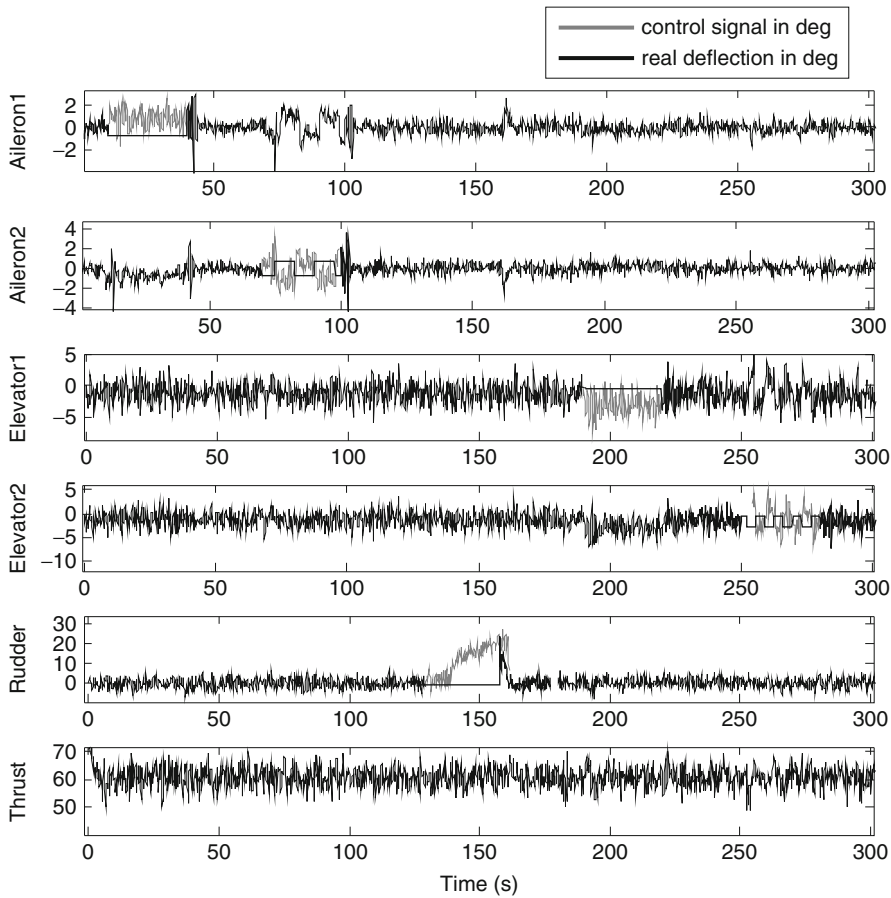

Fig. 44.9 Control signals and actual actuator deflections

For $t = 190 \dots 220$ s, elevator 1 gets locked at -0.5° , and finally, for $t = 250 \dots 280$ s, elevator 2 is floating between two uncontrolled positions -1° and -3° in a square-wave fashion. After this sequence of faults, the aircraft continues to fly straight and level, and no more faults are introduced.

44.4.7.3 Comments on the Simulation Results

Figure 44.10 shows the results obtained by the FDI system after the sequence of faults. The top plot labeled “no fault” has a probability of 1 when the EMMAE-FDI system does not detect any fault in the aircraft. An actuator fault is declared valid if the corresponding fault probability exceeds 90 % for a certain amount of time. A fault is declared removed when the corresponding fault probability is below 5 % for a certain amount of time. When aileron 1 fails at $t = 10$ s, the “No-Fault” filter needs about 6 s for its probability to go down to almost 0, which means that a failure

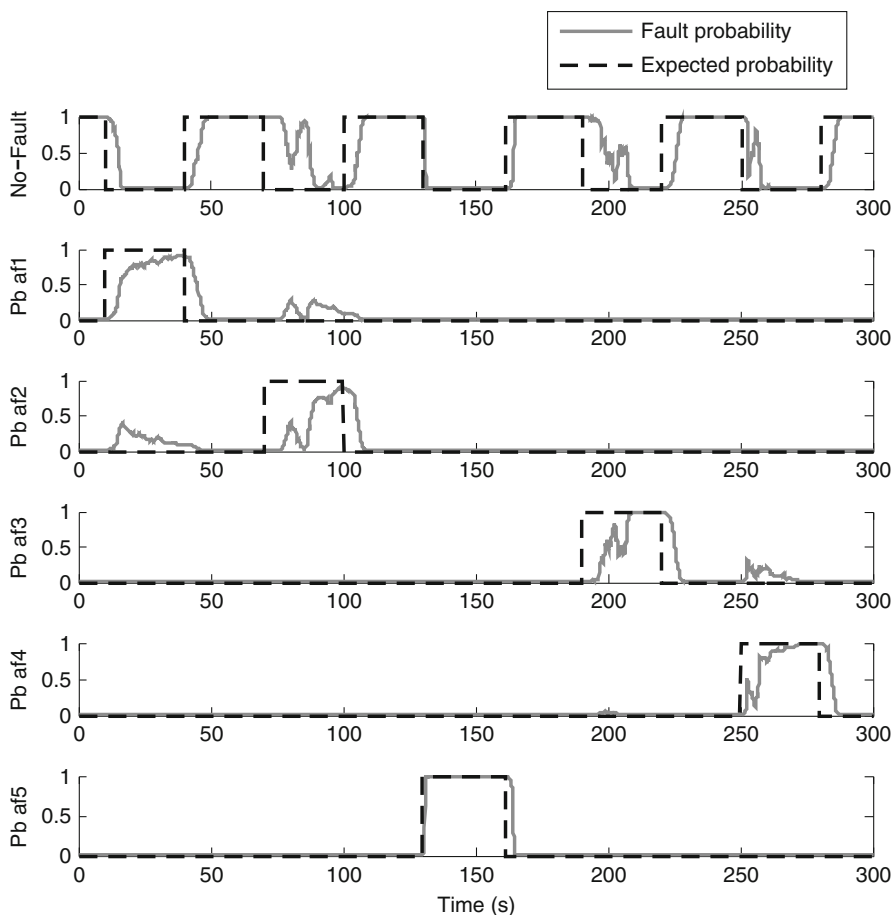

Fig. 44.10 Probabilities from each filter of the EMMAE-FDI after a sequence of faults (no supervision system)

occurred somewhere. After the aileron 1 fault is introduced, both probabilities for aileron 1 and 2 to fail ($Pbaf1$, $Pbaf2$) start rising at $t = 11.5$ s. At $t = 17$ s, the FDI system begins to distinguish between the two ailerons which one has failed, and $Pbaf2$ returns to zero while $Pbaf1$ rises up to 90 % at $t = 34$ s. Therefore, it took 24 s for the FDI system to indicate that aileron 1 experiences a failure. At $t = 40$ s, the fault of aileron 1 is removed, and the actuator behaves normally again. Figure 44.10 shows that the probability $Pbaf1$, indicating whether aileron 1 fails, decreases slowly and reaches 0 again after 10 s, while the “No-Fault” probability rises accordingly. It thus takes 10 s for the FDI system to indicate that the fault has been removed.

As Fig. 44.9 shows, at $t = 70$ s, aileron 2 fails and has an uncontrolled square-wave motion between -1° and 1° . Figure 44.10 shows that the FDI system takes 20 s to detect such a failure. An ambiguity exists between the two ailerons for a few

seconds before the probability P_{baf2} finally reaches 90 % at $t = 90$ s. At $t = 100$ s, the fault of aileron 2 is removed, and this actuator behaves normally again. However, the FDI system is not capable of detecting quickly that the fault has been removed. It takes about 8 s to do so.

For the rudder, the fault is introduced at $t = 130$ s and is isolated by the FDI system at $t = 131$ s when P_{baf5} exceeds 90 %. The fault removal is detected in less than 5 s. It takes less time to isolate a rudder fault and to detect its removal because there is only one rudder, unlike the other actuators which are redundant (two ailerons, two elevators). Therefore, a malfunctioning rudder cannot be compensated by a redundant rudder, thus resulting in no actuator-fault ambiguity.

The introduction of the elevator 1 fault at $t = 190$ s is isolated by its corresponding filter (probability signal P_{baf3} exceeding 90 %) at $t = 208$ s. After the fault removal, the FDI system takes 8 s to indicate the fault removed. The behavior of elevator 2 is similar to the behavior of elevator 1. Finally, after the last fault has been removed, 5 s are needed by the FDI system to slowly build up probability in the “No-Fault” filter to indicate that no more faults are present in the system.

44.4.8 Remarks on the First Attempt to Use the EMMAE-FDI System

- The results plotted in Fig. 44.10 indicate that the current implementation of the method is able to detect the fact that a failure occurred, even in a very low-excitation case, but it could not tell quickly and reliably which actuator experienced the fault. In cases of redundant actuators having the same influence on the aircraft aerodynamics, the EMMAE method has difficulty quickly resolving ambiguities between redundant actuators when they cannot be properly excited.
- It appears that failures of actuators near trim deflection are more difficult to detect and isolate.
- Moreover, whenever a fault is removed, the EMMAE method alone requires a long time to detect that fact. It is critical, however, that the FDI quickly detects the removal of a failure or quickly recognizes that a false alarm has been triggered due to possible external perturbations, such as strong wind gusts.
- Finally, it is critical that the probabilities quickly reach the “expected values” which correctly describe the fault scenario. Indeed, the estimated state vector of the system, which is the sum of the state vector of each EKF weighted by its corresponding probability, must be sufficiently correct and accurate if this state estimate is fed back to the controller.

44.4.9 Techniques to Improve Actuator Fault Diagnosis

This section describes some techniques added to enhance the performance of the FDI system, when there is very low excitation of the system, particularly during steady level flight. In order to improve the speed and the accuracy of the fault isolation, a supervision module is designed whose tasks are detailed below.

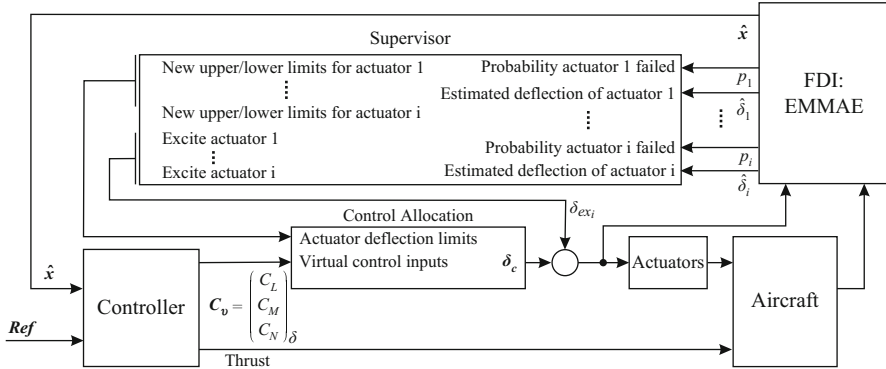

Fig. 44.11 EMMAE-FDI system in a reconfigurable flight control system

44.4.9.1 Design of an Active Supervision Module (Supervisor)

The supervision module shown in Fig. 44.11 is designed to monitor probability signals from the FDI. If an actuator-failure probability exceeds a certain threshold for some time, then the supervisor is designed to superimpose an artificial control signal on the corresponding actuator. If an actuator fails, the additional signal will have no effect on the aircraft dynamics, but it will help the FDI confirm more quickly the failure of this actuator. On the other hand, if the actuator has not actually failed, the aircraft will respond according to the additional signal, and the FDI will then remove the fault assigned to this actuator. If the corresponding fault probability falls below a certain threshold for a defined period of time, the supervisor removes the superimposed signal.

The excitation signals can also be adaptively controlled within certain limits, for example, from 1° to 4° , with the function $\delta_{ex,i}(t) = [1^\circ + 3^\circ(1 - p_i(t))] \cos(2\pi f_i t)$, see Fig. 44.12.

Note that an actuator is only excited when its corresponding fault probability p_i exceeds 5%. Most of the time, only one actuator is excited. If several actuators are to be excited simultaneously, better detection performance may be expected if the excitation signals to each actuator are independent and uncorrelated. The frequency of the signal is to be chosen within the range of the aircraft bandwidth; in the case of this chapter, $f_i = 1$ Hz.

The excitation signal has an adaptive amplitude dependent on the probability p_i of actuator i to have failed. In this way, when the probability p_i is low, the excitation amplitude is large and vice versa. Simulation results show that this adaptive amplitude for the excitation signal efficiently improves the accuracy and speed for fault isolation compared with a fixed amplitude excitation signal. This adaptive amplitude ensures that the actuator is excited as little as possible, but still enough to isolate the fault or to remove a false alarm. Figure 44.12 shows the practical implementation of the excitation signal generator and provides an example for aileron 1.

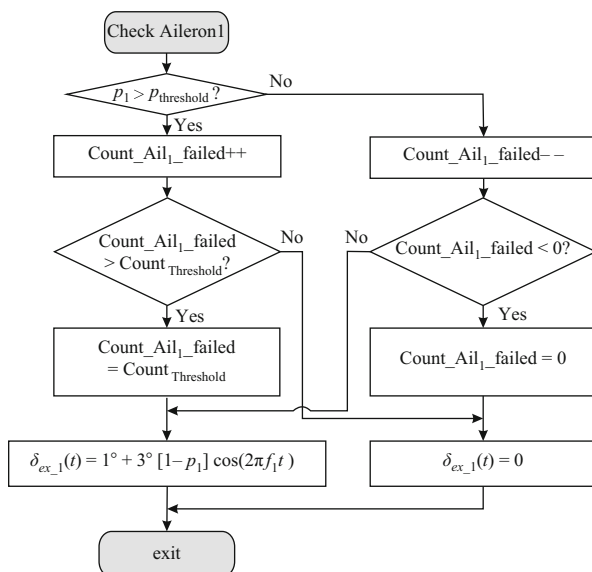

Fig. 44.12 Generation of the actuator excitation signal (example for aileron 1)

This method is therefore a systematic way of testing each triggered failure alarm, to confirm it or to remove it, hence making the FDI more robust. Whereas other proposed schemes (Ni 2001; Azam et al. 2005) suggest having the aircraft perform a “health-check maneuver” or “diagnostic maneuver” as soon as a failure is detected, in the method presented in this chapter, the actuator is directly excited by the supervision module rather than by the aircraft autopilot, yielding much faster and more accurate fault isolation.

44.4.9.2 Fault Detection Performance of the EMMAE-FDI with the Supervision System

Figure 44.13 shows how the aileron faults are accurately detected and isolated in less than 5 s. The rudder fault is isolated after 1 s. The elevator faults take longer (about 9 s) to be isolated. However, the removal of all the faults is detected in less than 5 s. Furthermore, there is no more ambiguity or false detection among the actuator faults. The results shown in Fig. 44.13 compared to those of Fig. 44.10 indicate that the performance and the robustness of the EMMAE-FDI system have greatly improved due to the supervision module.

It is recalled that these results are obtained in the most difficult conditions for the FDI system. Indeed, there is no external disturbance such as wind gusts, the aircraft flies straight and level, and the actuators fail close to their trim deflection.

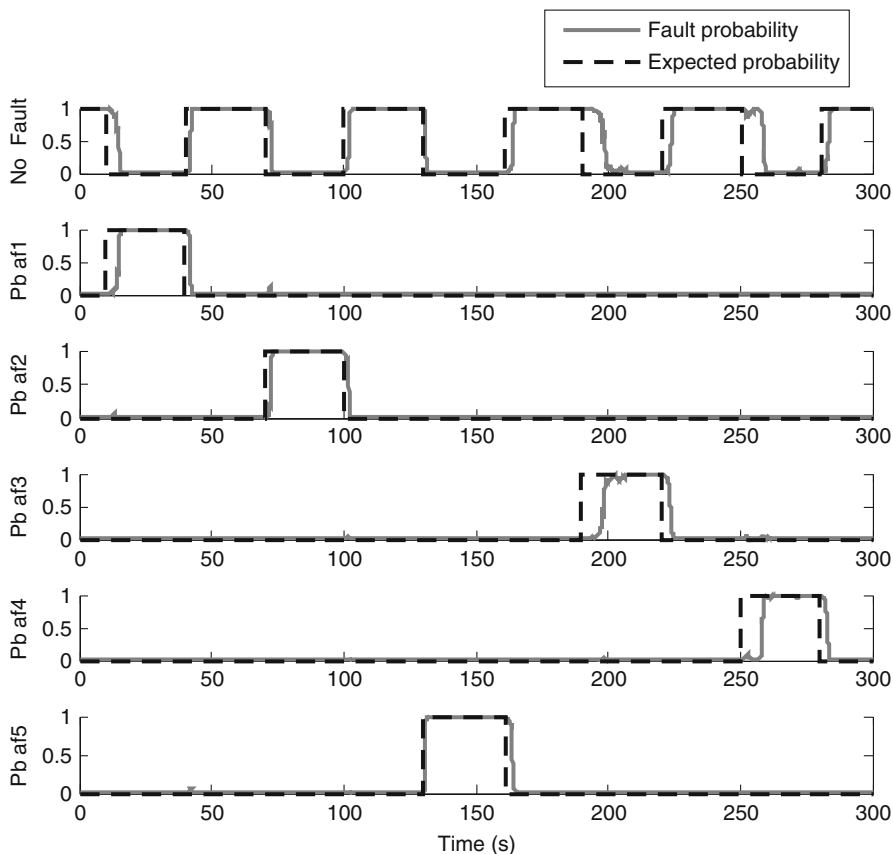

Fig. 44.13 Probabilities from each filter of the EMMAE-FDI after a sequence of faults (with the supervisor)

44.4.10 Computational Complexity of the EMMAE-FDI

Let us denote by N the number of actuators that are monitored by an FDI system. In the classical implementation of an MMAE-FDI, for each actuator, k filters are to be designed for k different possible positions of the failed actuator. Therefore, $kN + 1$ KFs are required (+1 refers to the no-fault filter). If the appearance of a second fault is to be checked as well, a new bank of KFs has to be reloaded, based on the knowledge of the first fault that occurred. In total $Nk + 1 + (N - 1)kN = N^2k + 1$, KFs must be designed.

One major advantage of the EMMAE-FDI method presented in this chapter over classical MMAE schemes is that it requires only one filter to completely monitor one actuator. Any possible actuator-fault scenario is taken into account by only one filter. Therefore, for the monitoring of a single actuator fault, only $N + 1$ filters are

required with the EMMAE-FDI method. For the monitoring of a second actuator fault with the EMMAE-FDI method, no other bank of filters has to be loaded. Indeed, if actuator i fails, it suffices to feed all the other filters with the estimate of the faulty control surface deflection $\hat{\delta}_i$ instead of the input δ_i . Thus, again only $N + 1$ filters are needed with the EMMAE-FDI system to detect and isolate a second fault after a first actuator fault has been introduced.

As a simple example, the UAV described in Sect. 44.2 is equipped with five actuators. A classical MMAE scheme designed for 3 possible faulty deflections per actuator requires 16 filters, whereas the EMMAE method needs only 6 filters for any lock-in-place and floating actuator fault scenarios.

Finally, compared to other works (e.g., Ducard and Geering (2006)) with larger state vectors, the choice of the state vector $\mathbf{x} = [p \ q \ r \ \alpha \ \beta \ \delta]^T$ minimizes the number of relevant state elements for the satisfactory operation of the filters, thus limiting the number of computations required for the EKFs.

44.4.11 Realistic Flight Scenario and Conclusions

More simulation results are reported in Ducard (2009), where the EMMAE FDI system is tested in a realistic flight scenario, in which the UAV takes off, tracks a predefined trajectory, and follows an altitude and a speed reference profile. First, the simulation is done without wind, and in a second phase, Dryden Wind turbulences are included in the simulation to test the behavior of the FDI system in the presence of external disturbances. The speed profile is chosen to cover a significant range of the aircraft speed in order to test the performance of the fault detection system at different operating conditions. The measured airspeed V_T is corrupted by noise, like all the other measurement signals defined in Sect. 44.4.7.1 that are used in the FDI system. Also, the altitude reference signal is chosen such that the aircraft has a typical vertical motion during a short mission.

The results show that the EMMAE-FDI algorithm, combined with an active supervision module, offers fast and accurate fault detection and isolation. Moreover, the addition of the estimation of the faulty control surface deflection in the state vector makes the method applicable for actuator failures such as frozen or floating at an arbitrary position. Only one filter is needed to monitor the health of one actuator. The filters used in the EMMAE-FDI are EKFs, which provide nonlinear state estimations at any flight-operating condition. An active FDI technique is developed, which generates appropriate artificial excitation of the aircraft when needed. In Ducard (2009), an additional filtering stage for the fault-probability signals has been designed to enhance the robustness of the diagnosis, even in the event of severe wind turbulence. The whole system has been demonstrated using nonlinear simulations of a realistic flight scenario. The FDI system was shown to be capable of handling two simultaneous actuator failures without increasing the computational load. Finally, when a fault is clearly isolated, the faulty actuator deflection estimate

can be advantageously used to modify online the settings of a control allocator, making the whole system suitable for flight control reconfiguration without any change in the initial controller and any additional actuator position sensor.

44.5 A Single Model Active (SMAC) FDI System

In both the MMAE and EMMAE methods, actuator fault detection and isolation is done through the computation of fault probabilities. Although the EMMAE is more computationally efficient and reliable than the MMAE method, it still requires a bank of EKF, where each EKF monitors one actuator in the system.

This section presents an FDI system which is single model based and thus does not employ a bank of filters. This FDI system employs a single EKF to generate residuals, which indicate the deviation of the monitored system from its normal behavior (fault detection). The residuals are further used to assess the origin of the system's behavior discrepancy. In order to isolate which actuator experiences a fault, an innovative mechanism that artificially excites actuators has been designed. The method presented next has been named single model active fault detection and isolation (SMAC-FDI) system (Ducard and Geering 2010).

This section is organized in order to (1) present an innovative architecture of an FDI system based on a single filter for the generation of residuals independently on the fault scenario; (2) describe an active strategy that searches in the residuals of this single filter the signature of an actuator fault and to test the actuators in a systematic way; (3) show a new procedure to isolate actuator fault that is not based on residuals manipulations but on the observation of control signals only; (4) show that the SMAC-FDI method is highly computationally efficient and, therefore, can run on microcontrollers with low computational resources; and (5) demonstrate the performance of this simple method in simulation.

Figure 44.14 shows the architecture of the SMAC-FDI system. It is composed of five main subsystems: a residual generator, a fault detector, an excitation signals generator (ESG), an actuator health evaluator (AHE), and a fault isolator. Each of these subsystems is described in the following:

44.5.1 Residual Generator

The residual generator monitors the control signals sent to actuators and the behavior of the aircraft through the reading of selected measurement of the aircraft's dynamics. In the SMAC-FDI system, the turn rates p , q , and r are measured and compared to the expected turn rates \hat{p} , \hat{q} , and \hat{r} , which are obtained using a model of the aircraft. This model receives the same actuator commands as the real aircraft. A filter is used to take into account model uncertainties and sensor measurement data noise. This filter is an EKF, whose useful output – for FDI purpose – is the vector of residuals $\tilde{\omega}_k$ defined as follows:

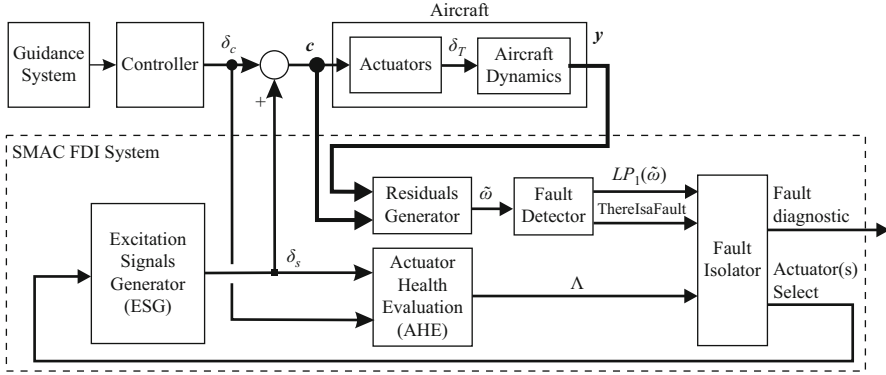

Fig. 44.14 Architecture of the SMAC-FDI system

$$\tilde{\omega}_k = \mathbf{y}_k - \hat{\mathbf{x}}_{k|k-1} = \begin{bmatrix} \tilde{p} \\ \tilde{q} \\ \tilde{r} \end{bmatrix} = \begin{bmatrix} p - \hat{p}_{(k|k-1)} \\ q - \hat{q}_{(k|k-1)} \\ r - \hat{r}_{(k|k-1)} \end{bmatrix}, \quad (44.47)$$

where the measurement vector at the discrete-time instant k is $\mathbf{y}_k = [p \ q \ r]^T$ and the filter's state vector is the estimate of the turn rates. These residuals indicate whether the aircraft has dynamics that deviate from the model-expected dynamics. If the residual values are higher than a certain threshold, it is most likely that an actuator fault is present in the system.

The EKF used in this residual generator has the structure described in Sect. 44.3. The matrices and vectors involved in this filter are described next.

44.5.1.1 Discrete Transition Matrix for the SMAC-FDI System

The discrete transition matrix ϕ_k is computed as $\phi_k = \mathbf{I}_3 + \mathbf{F}(k)T_s$. The continuous transition matrix $\mathbf{F}(k) \in \Re^{3 \times 3}$ is obtained using the model of the aircraft described in Sect. 44.2 and updated at each sample time by the estimates of the turn rates $\hat{p}_{(k|k)}$, $\hat{q}_{(k|k)}$, $\hat{r}_{(k|k)}$ and with the measurement data for the airspeed V_T involved in the dynamic pressure $\bar{q} = \frac{1}{2}\rho V_T^2$ as follows:

$$\mathbf{F}(k) = \begin{bmatrix} A_{11\bar{q}} \bar{q} + A_{11q} q & A_{12p} p + A_{12r} r & A_{13\bar{q}} \bar{q} + A_{13q} q \\ A_{21p} p + A_{21r} r & A_{22\bar{q}} \bar{q} & A_{23p} p + A_{23r} r \\ A_{31\bar{q}} \bar{q} + A_{31q} q & A_{32p} p + A_{32r} r & A_{33\bar{q}} \bar{q} + A_{33q} q \end{bmatrix} \begin{cases} p = \hat{p}_{(k|k)} \\ q = \hat{q}_{(k|k)} \\ r = \hat{r}_{(k|k)} \\ \bar{q} = \bar{q}_{(k)} \end{cases} \quad (44.48)$$

with the terms of the transition matrix defined as

$$\begin{aligned}
 A_{11\bar{q}} &= \frac{I_{zz} S b^2 C_{L\bar{p}}}{2D_1 V_T} & A_{11q} &= A_{12p} = \frac{-N_1}{D_1} & A_{12r} &= A_{13q} = \frac{I_{yy} I_{zz} - I_{xz}^2 - I_{zz}^2}{D_1} \\
 A_{13\bar{q}} &= \frac{S b^2 [I_{zz} C_{L\bar{p}} - I_{xz} C_{N\bar{p}}]}{2D_1 V_T} & A_{21r} &= A_{23p} = \frac{I_{zz} - I_{xx}}{I_{yy}} & A_{21p} &= -A_{23r} = \frac{2I_{xz}}{I_{yy}} \\
 A_{22\bar{q}} &= \frac{S \bar{c}^2 C_{M\bar{q}}}{2V_T I_{yy}} & A_{31q} &= A_{32p} = \frac{I_{xx}^2 - I_{xx} I_{yy} + I_{xz}^2}{D_1} & A_{31\bar{q}} &= -\frac{I_{xz} S b^2 C_{L\bar{p}}}{2D_1 V_T} \\
 A_{32r} &= A_{33q} = \frac{N_1}{D_1} & A_{33\bar{q}} &= \frac{S b^2 [I_{xx} C_{N\bar{p}} - I_{xz} C_{L\bar{p}}]}{2D_1 V_T}
 \end{aligned} \tag{44.49}$$

using the auxiliary constants $D_1 = I_{xx} I_{zz} - I_{xz}^2$ and $N_1 = I_{xz}(I_{xx} - I_{yy} + I_{zz})$.

Remark: In the above equations, the constant terms have been written taking into account the fact that $I_{xz} = I_{zx}$.

44.5.1.2 Process Noise Covariance Matrix for the SMAC-FDI System

The value of $\mathbf{R}_{w,k}$ is found from the continuous process noise covariance matrix \mathbf{R}_w and the continuous transition matrix ϕ as defined in Eq. 44.17, according to

$$\mathbf{R}_{w,k} = \int_0^{T_s} \phi(\tau) \mathbf{R}_w \phi^T(\tau) d\tau \tag{44.50}$$

$$\mathbf{R}_w = E(\mathbf{w}\mathbf{w}^T) = \text{diag}(w_1^2, w_2^2, w_3^2) \tag{44.51}$$

$$\mathbf{w} = [w_1, w_2, w_3]^T, E(w_i w_j) = 0, \forall i \neq j. \tag{44.52}$$

The matrix $\mathbf{R}_{w,k} \in \Re^{3 \times 3}$ is symmetric, and the lower-triangle terms are obtained as follows:

$$\begin{aligned}
 \mathbf{R}_{w,k}(1, 1) &= w_1^2 T_s \left[1 + \phi(1, 1) T_s + \phi(1, 1)^2 \frac{T_s^2}{3} \right] \\
 &\quad + \frac{T_s^3}{3} \left[w_2^2 \phi(1, 2)^2 + w_3^2 \phi(1, 3)^2 \right] \\
 \mathbf{R}_{w,k}(2, 2) &= w_2^2 T_s \left[1 + \phi(2, 2) T_s + \phi(2, 2)^2 \frac{T_s^2}{3} \right] \\
 &\quad + \frac{T_s^3}{3} \left[w_1^2 \phi(2, 1)^2 + w_3^2 \phi(2, 3)^2 \right] \\
 \mathbf{R}_{w,k}(3, 3) &= w_3^2 T_s \left[1 + \phi(3, 3) T_s + \phi(3, 3)^2 \frac{T_s^2}{3} \right] \\
 &\quad + \frac{T_s^3}{3} \left[w_1^2 \phi(3, 1)^2 + w_2^2 \phi(3, 2)^2 \right]
 \end{aligned}$$

$$\begin{aligned}
\mathbf{R}_{w,k}(2, 1) &= A_1\phi(2, 1) + A_2\phi(1, 2) + w_3^2 \frac{T_s^3}{3} \phi(1, 3)\phi(2, 3) \\
\mathbf{R}_{w,k}(3, 1) &= A_1\phi(3, 1) + A_3\phi(1, 3) + w_2^2 \frac{T_s^3}{3} \phi(1, 2)\phi(3, 2) \\
\mathbf{R}_{w,k}(3, 2) &= A_2\phi(2, 1) + A_3\phi(2, 3) + w_1^2 \frac{T_s^3}{3} \phi(2, 1)\phi(3, 1) \quad (44.53)
\end{aligned}$$

with the constants

$$\begin{aligned}
A_1 &= w_1^2 \frac{T_s^2}{2} \left[1 + \frac{2}{3} T_s \phi(1, 1) \right], \quad A_2 = w_2^2 \frac{T_s^2}{2} \left[1 + \frac{2}{3} T_s \phi(2, 2) \right], \\
A_3 &= w_3^2 \frac{T_s^2}{2} \left[1 + \frac{2}{3} T_s \phi(3, 3) \right] \quad (44.54)
\end{aligned}$$

where $\phi(i, j)$ and $\mathbf{R}_{w,k}(i, j)$ designate the term found at the i th line and j th column of the matrix ϕ and matrix $\mathbf{R}_{w,k}$, respectively.

44.5.1.3 State Estimate Propagation Step

The state estimate propagation step is done with $\hat{\mathbf{x}}_{k+1|k} = \hat{\mathbf{x}}_{k|k} + \dot{\hat{\mathbf{x}}}_{k|k} T_s$, where time derivative of the state $\dot{\hat{\mathbf{x}}}_{k|k} = \mathbf{f}(\hat{\mathbf{x}}_{k|k}, \mathbf{u}_k)$ is obtained by direct calculation of (Eq. 44.1).

44.5.1.4 Sensor Noise and Filter Tuning

The measurement vector involved in the EKF of the SMAC-FDI system is $\mathbf{y} = [p, q, r]^T$, where the body-axis turn rates p, q , and r are measured by gyroscopes. The measurement noise is assumed to be Gaussian distributed with zero mean. The noise standard deviations are $\sigma_{pqr} = 0.08$ (rad/s) (variance $\Sigma_{pqr} = 0.0064$ [rad/s]²) for the turn rates; $\sigma_{\alpha, \beta} = 0.0349$ (rad) for the angles α and β ; and $\sigma_{V_T} = 5$ (m/s) for the airspeed measurement.

The EKF is tuned by selecting the measurement noise covariance matrix $\mathbf{R}_v = 0.1 \times \mathbf{I}_3$ (rad/s)² and the process noise covariance matrix $\mathbf{R}_w = 2 \times \mathbf{I}_3$ (rad/s)². The filter is initialized with the initial state estimate $\hat{\mathbf{x}}_{0|-1} = [0 \ 0 \ 0]^T$ and initial state error covariance matrix $\Sigma_{0|-1} = \mathbf{I}_3$.

44.5.2 Fault Detector

44.5.2.1 Architecture of the Fault Detector

The architecture of the fault detector is shown in Fig. 44.15. First, the vector of turn-rate residuals $\tilde{\omega}$ coming from the EKF is filtered by a first-order low-pass filter LP_1 with a cutoff frequency f_1 . Second, the residuals are assembled as follows:

$$\Gamma_1 = |LP_1(\tilde{p})| + |LP_1(\tilde{q})| + |LP_1(\tilde{r})|. \quad (44.55)$$

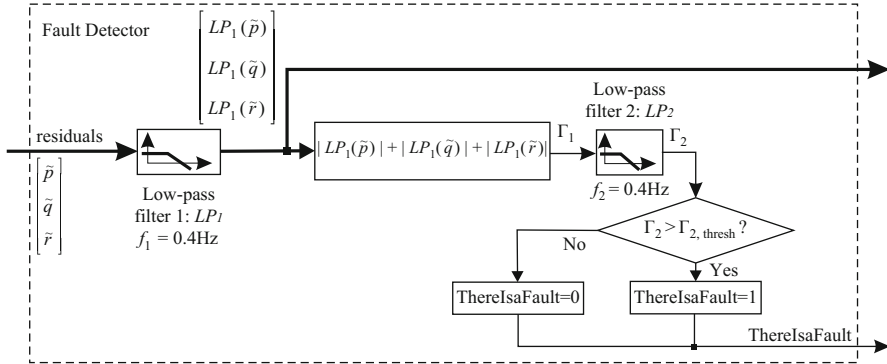

Fig. 44.15 Architecture of the fault detector subsystem

Third, the first-order low-pass filter with cut-off frequency f_2 is used to transform the signal Γ_1 into the signal Γ_2 . Fourth, if the signal Γ_2 exceeds the threshold value $\Gamma_{2, \text{Thresh}}$, the fault detector indicates that there is a fault somewhere in the system by setting to one the output signal labeled “ThereIsaFault” shown in Fig. 44.15. The origin of the fault is not known at this stage. It is the task of the fault isolator subsystem – described below – to investigate the origin of the fault.

Remark: The fault isolator is disabled when the flag $\text{ThereIsaFault}=0$ and enabled when $\text{ThereIsaFault}=1$, thus keeping the total amount of computational load required by the SMAC-FDI system to the minimum needed, as opposed to an MMAE or EMMAE structure in which the whole bank of filters is permanently running.

44.5.2.2 Selection of the Cutoff Frequencies

Since the excitation signals have a fixed frequency of 1 Hz and that the purpose of the low-pass filters is to attenuate these sinusoidal signals in the residuals, the cutoff frequencies f_1 and f_2 are both chosen in the range $]0, 1[\text{ Hz}$. In this work, the chosen value is $f_1 = f_2 = 0.4 \text{ Hz}$, which provides a trade-off between smoothing and delaying the residual signals.

44.5.2.3 Determination of the Threshold Value $\Gamma_{2, \text{thresh}}$

The success of fault detection is dependent on the possibility to create relevant signals that deviate from a nominal value in the case of a fault. In this work, the residuals of the Kalman filter are used and assembled as shown in Fig. 44.15. As soon as the signal named Γ_2 exceeds a certain threshold $\Gamma_{2, \text{thresh}}$, this indicates that a fault is present somewhere in the system.

In order to build these residuals, the Kalman filter is using a model of the aircraft’s turn-rate dynamics. However, this model contains parameters which are uncertain. In order to cope with uncertainties, the Kalman filter possesses intrinsically a mechanism to compute the observer gain matrix L in (Eq. 44.12) that mitigates the confidence level between the quality of the model (through the process

noise covariance matrix \mathbf{R}_w) and the quality of the measurement data (through the measurement noise covariance matrix \mathbf{R}_v).

For the determination of a suitable value for $\Gamma_{2,\text{thresh}}$, a linear SISO model is constructed for the roll, pitch, and yaw axis as follows:

$$\dot{\chi} = (\hat{a}_\chi + \Delta a_\chi) \chi + (\hat{b}_\chi + \Delta b_\chi) \delta_\chi, \quad (44.56)$$

where the variable χ is p, q, r , respectively, and the real control input to the system δ_χ – that may include a fault – is $\delta_a, \delta_e, \delta_r$, respectively. Note that (Eq. 44.56) is used as a template for three different equations.

The terms \hat{a}_χ and \hat{b}_χ represent the uncertain model parameters in use in the FDI system. They are made of the sum of the true value a_χ, b_χ and the uncertainty part Δa_χ and Δb_χ , respectively, as follows:

$$a_\chi = \hat{a}_\chi + \Delta a_\chi \quad b_\chi = \hat{b}_\chi + \Delta b_\chi. \quad (44.57)$$

For analysis purpose, let us consider a linear Kalman-type estimator of the form:

$$\dot{\hat{\chi}} = \hat{a}_\chi \hat{\chi} + \hat{b}_\chi \delta_{\chi,c} + L_\chi (\chi - \hat{\chi}), \quad (44.58)$$

where the Kalman gain is L_χ and the control signal generated by the flight controller is $\delta_{\chi,c}$. By subtracting (Eq. 44.58) to (Eq. 44.56), the differential equation for the residuals of turn-rate dynamics is obtained as follows:

$$\dot{\tilde{\chi}} = -(L_\chi - \hat{a}_\chi) \tilde{\chi} + \hat{b}_\chi \Delta \delta_\chi + \Delta \epsilon(\chi(t), x(t)), \quad (44.59)$$

where the term $\Delta \delta_\chi = \delta_\chi - \delta_{\chi,c}$ is the deviation between a true actuator position and its commanded value. All of the uncertainty contributions are regrouped in the term $\Delta \epsilon(\chi(t), x(t))$, which may be dependent on the turn rate itself $\chi(t)$ and other state elements, such as angle of attack α , sideslip angle β , and aircraft total airspeed V_T .

The stability of the filter is obtained if the condition

$$L_\chi - \hat{a}_\chi > 0 \quad (44.60)$$

is satisfied, in which case the residual $\tilde{\chi}$ converges to a certain value if the system approaches steady-state conditions. The condition in (Eq. 44.60) is fulfilled by choosing the terms in the process noise covariance matrix \mathbf{R}_w sufficiently large.

In the presence of model uncertainties or actuator fault, the residuals will no longer be zero-mean centered. This is precisely what will trigger the detection of a fault in the system. It is therefore necessary to be able to assess the amount of bias in the residuals that is due to model uncertainties that are not zero-mean centered.

To this end, suppose that an actuator failure occurs, the flight controller will compensate by actuating the remaining actuators in order to stabilize the turn rates of the vehicle, that is, $p = q = r = 0$. Moreover, if the vehicle is flying straight,

level and at constant speed, the terms $\Delta\delta_\chi$ and $\Delta\epsilon$ will reach a constant value $\Delta\delta_{\chi,ss}$ and $\Delta\epsilon_{ss}$. Therefore, the residual in (Eq. 44.59) reaches the following steady-state value:

$$\tilde{\chi}_{ss} = \frac{\hat{b}_\chi \Delta\delta_{\chi,ss} + \Delta\epsilon_{ss}}{L_\chi - \hat{a}_\chi} = \frac{\hat{b}_\chi (\Delta\delta_{\chi,ss} + \Delta\gamma_{ss})}{L_\chi - \hat{a}_\chi}, \quad \text{with } \Delta\gamma_{ss} = \frac{\Delta\epsilon_{ss}}{\hat{b}_\chi}. \quad (44.61)$$

Once the maximum amount of uncertainty in the model, $\sup |\Delta\epsilon|$, is specified, the threshold value of Γ_2 is chosen according to the following inequality:

$$\frac{\hat{b}_\chi \sup |\Delta\gamma|}{L_\chi - \hat{a}_\chi} < \Gamma_{2, \text{thresh}} < \frac{\hat{b}_\chi (|\Delta\delta_{\chi, \min}| - \sup |\Delta\gamma|)}{L_\chi - \hat{a}_\chi}. \quad (44.62)$$

Remarks:

- The results shown in Sect. 44.5.6 are obtained with the value of $\Gamma_{2, \text{thresh}} = 0.05$ rad/s. But note that a value of $\Gamma_{2, \text{thresh}}$ can be computed online and therefore be adapted to the current flight conditions.
- If the value of the true model term b_χ is known within some uncertainty bounds $\hat{b}_\chi = b_\chi \pm \Delta b_\chi$, it is better to choose in the FDI system an overestimated value for \hat{b}_χ , that is, $\hat{b}_\chi = b_\chi + |\Delta b_\chi|$ as this tends to increase the detectable fault level to uncertainty level ratio.

44.5.2.4 Effect of Uncertainties on Actuator Fault Detection Performance

The effect of model uncertainties on the minimum detectable value of the actuator fault $\Delta\delta_{\chi, \min}$ is visible in (Eq. 44.62), where it appears that a lower bound for $\Delta\delta_{\chi, \min}$ given the maximum uncertainty level $\sup |\Delta\gamma|$ is

$$|\Delta\delta_{\chi, \min}| > 2 \sup |\Delta\gamma|. \quad (44.63)$$

Clearly, the less uncertainty there is in the model, the smaller the fault that can be detected.

44.5.3 Excitation Signals Generator (ESG)

As shown in Fig. 44.14, the ESG “listens” to the fault isolator that selects which actuator to test. The ESG superimposes on that actuator’s command an artificial excitation signal of the form:

$$\delta_s(t) = A \sin(\omega t). \quad (44.64)$$

The frequency ω has to be chosen within the bandwidth of the aircraft under consideration. Indeed, as explained in Sect. 44.5.4, the excitation signal must be

of sufficiently low frequency such that the aircraft dynamics get disturbed by this excitation signal. As a result, the flight controller will generate actuator commands to compensate this perturbation. If the presence of this excitation signal is visible in the actuator control signals, it means the tested actuator has actually not failed, and vice versa.

In order to discuss a suitable value for the amplitude A , let us consider the dynamics of the residuals when the signal δ_s is applied to a failed actuator. The dynamics of the residual vector $\tilde{\chi}$ is as follows:

$$\dot{\tilde{\chi}} = -(L_\chi - \hat{a}_\chi)\tilde{\chi} + \hat{b}_\chi (\Delta\delta_\chi - A \sin \omega t + \Delta\gamma). \quad (44.65)$$

It can be shown that the asymptotic solution to (Eq. 44.65) is

$$\tilde{\chi}_\infty = C_1 - C_2 \sin(\omega t - \phi_0), \quad (44.66)$$

with the terms $C_1 = \frac{\hat{b}_\chi}{L_\chi - \hat{a}_\chi} (\Delta\delta_\chi + \Delta\gamma)$, $C_2 = \frac{\hat{b}_\chi A}{\sqrt{\omega^2 + (L_\chi - \hat{a}_\chi)^2}}$, and $\phi_0 = \tan^{-1} \left(\frac{\omega}{L_\chi - \hat{a}_\chi} \right)$.

In the presence of an actuator fault in the system, it is shown in Fig. 44.15 that the signal Γ_2 must exceed a certain threshold $\Gamma_{2,\text{thresh}}$ for the fault to be detected. The signal Γ_2 is obtained by low-pass filtering the signal Γ_1 . In order to simplify a bit the discussion, let us assume that the signal $\Gamma_1 = |\tilde{\chi}|$, which is the case when the residuals build up dominantly on a certain aircraft axis.

In view of (Eq. 44.66), it can be shown that the mean value of Γ_2 is mostly given by the “constant” part of $|\tilde{\chi}|$, that is, C_1 . As soon as the excitation signal is triggered, additional calculations show that whatever the amplitude of C_2 compared to C_1 , ($C_2 > C_1$ or $C_2 < C_1$), the condition $\Gamma_2 > \Gamma_{2,\text{thresh}}$ which triggered the excitation signal still remains satisfied after the addition of excitation signals. In fact, if the term C_1 is smaller than C_2 , the excitation term has the positive effect of contributing to an higher value of Γ_2 .

Therefore, the amplitude A is chosen as a compromise between (1) a value of A as large as possible such that the fault isolation explained in Sect. 44.5.4 can maximize the amplitude of the isolation signals Λ_i , despite the possible presence of external perturbation, such as wind gusts or aircraft maneuvers, thus improving FDI robustness; and (2) a value of A sufficiently small, not to unnecessarily destabilize the aircraft as it flies, if the excitation signal is applied to a non-failed actuator.

Remark: In Sect. 44.5.6, the results shown are obtained with a frequency $\omega = 2\pi$ (rad/s) and an amplitude $A = 2 \frac{\pi}{180}$ (rad).

44.5.4 Actuator Health Evaluator (AHE)

The actuator health evaluator (AHE) subsystem is responsible for assessing whether a selected actuator δ_i is properly functioning or not. As shown in Fig. 44.14,

the AHE module receives the control signals $\delta_c = [\delta_{c,1} \dots \delta_{c,n}]$ of n actuators generated by the flight controller and the excitation signals $\delta_s = [\delta_{s,1} \dots \delta_{s,n}]$ generated by the ESG module.

For the i th actuator, the output of the AHE is given by the following equation:

$$\Lambda_i(k) = LP_{i2} \left(|\delta_{s,i}(k - \lambda T_s) + [\delta_{c,i} - \bar{\delta}_{c,i}](k)| \right), \quad (44.67)$$

where $LP_{i2}(X)$ means that the signal X is filtered through a first-order low-pass filter $\frac{1}{1+\tau_{i2}s}$ with cutoff frequency $f_{i2} = \frac{1}{2\pi\tau_{i2}}$ (Hz). The choice of the frequency f_{i2} is not really important. This low-pass filter is only meant to attenuate the noise level of its incoming signal. In steady-state conditions, the signal $\bar{\delta}_{c,i}$ equals the mean value of $\delta_{c,i}$. The excitation signal $\delta_{s,i}$ is delayed by an integer number of sampling periods λT_s , $\lambda \in N^+$, such that the signals $[\delta_{c,i} - \bar{\delta}_{c,i}](k)$ and $\delta_{s,i}(k - \lambda T_s)$ are in opposite phase when actuator i is non-failed. The delay λ is determined experimentally and corresponds to the delay of the flight controller to react to the disturbance caused by $\delta_{s,i}$ superimposed onto actuator i when non-failed.

44.5.4.1 Case 1: Testing a Failed Actuator

If the actuator i being tested has really failed, the excitation signal $\delta_{s,i}$ has no effect on the control signal $\delta_{c,i}$ but has an effect on the residuals generated by the residual generator. The AHE detects the nonresponse of the flight controller to the excitation $\delta_{s,i}$ and thus generates the signal Λ_i whose amplitude is compared to a threshold value (Ail1FaultThresh, Ail2FaultThresh, Elev1FaultThresh, Elev2FaultThresh, and RuddFaultThresh, respectively) inside the fault isolator module. If Λ_i is above the threshold value, the actuator i is declared faulty, as shown in Figs. 44.21 and 44.19.

44.5.4.2 Case 2: Testing a Non-failed Actuator

If the actuator i has actually not failed, the superimposed excitation signal $\delta_{s,i}$ has an influence of the aircraft dynamics, and the flight controller will try to compensate the disturbance input signal. However, there is a small delay in the controller response. The term $\delta_{s,i}$ is delayed in such a way to be in opposite phase with the term $[\delta_{c,i} - \bar{\delta}_{c,i}]$. Therefore, their sum Λ_i is close to zero and below the threshold value (Ail1FaultThresh, Ail2FaultThresh, Elev1FaultThresh, Elev2FaultThresh, and RuddFaultThresh, respectively) in the fault isolator module. The actuator i is thus declared non-faulty, as shown in Figs. 44.21 and 44.19.

44.5.4.3 Tuning of the AHE

The tuning of the AHE subsystem consists in finding the appropriate cutoff frequency noted f_{i1} as shown in Fig. 44.16. The frequency f_{i1} is chosen in such a way that the term $\bar{\delta}_{c,i}$ converges to the mean value of $\delta_{c,i}$: $E(\delta_{c,i})$ after a time interval ΔT :

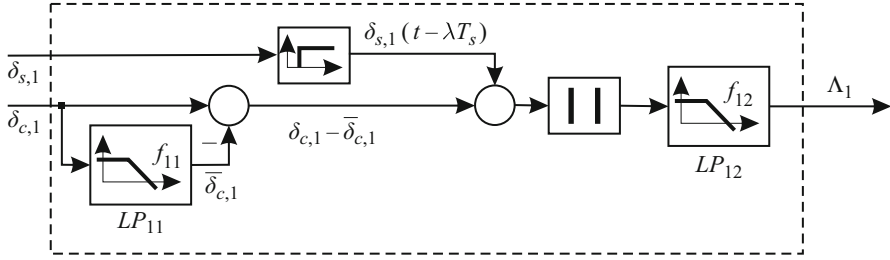

Fig. 44.16 Architecture of the actuator health evaluator, AHE subsystem (example of actuator 1)

$$\left| \frac{E(\delta_{c,i}) - \bar{\delta}_{c,i}(t > \Delta T)}{E(\delta_{c,i})} \right| < \epsilon, \quad (44.68)$$

with the relative error $\epsilon = 5\%$, for example. The frequency f_{i1} is chosen as

$$f_{i1} > \frac{\ln(1/\epsilon)}{2\pi\Delta T}. \quad (44.69)$$

44.5.4.4 Selection of the Threshold Values for Actuator Fault Diagnosis

The threshold values (Ail1FaultThresh, Ail2FaultThresh, Elev1FaultThresh, Elev2FaultThresh, RuddFaultThresh) are used inside the fault isolator module to declare an actuator to have failed.

The signal Λ_i at the output of the i th AHE subsystem has a value close to zero in the non-fault case and a maximum value of

$$\Lambda_{i,\max} = \frac{2A}{\pi}, \quad (44.70)$$

if actuator i experiences a complete failure case. If actuator i experiences a fault, such as loss of effectiveness, the signal Λ_i takes an intermediate value within the range $0 < \Lambda_i < \frac{2A}{\pi}$.

Example: The simulations provided in Sect. 44.5.6 have been performed with $A = 2\frac{\pi}{180}$ (rad). According to (Eq. 44.70), during the complete failure of aileron1 and aileron2, the values of Λ_1 and Λ_2 should be 0.022 (rad), which is confirmed by the results shown in Fig. 44.21. Therefore, the threshold values for actuator fault diagnosis have been chosen to be $\Lambda_{i,\text{thresh}} = 0.01$ (rad).

44.5.5 Fault Isolator

The complete architecture of the fault isolator is shown in Fig. 44.17. It manipulates the residuals in order to choose which actuator group to test (aileron group, elevator group, or rudder group). In each of these groups, the fault isolator selects an

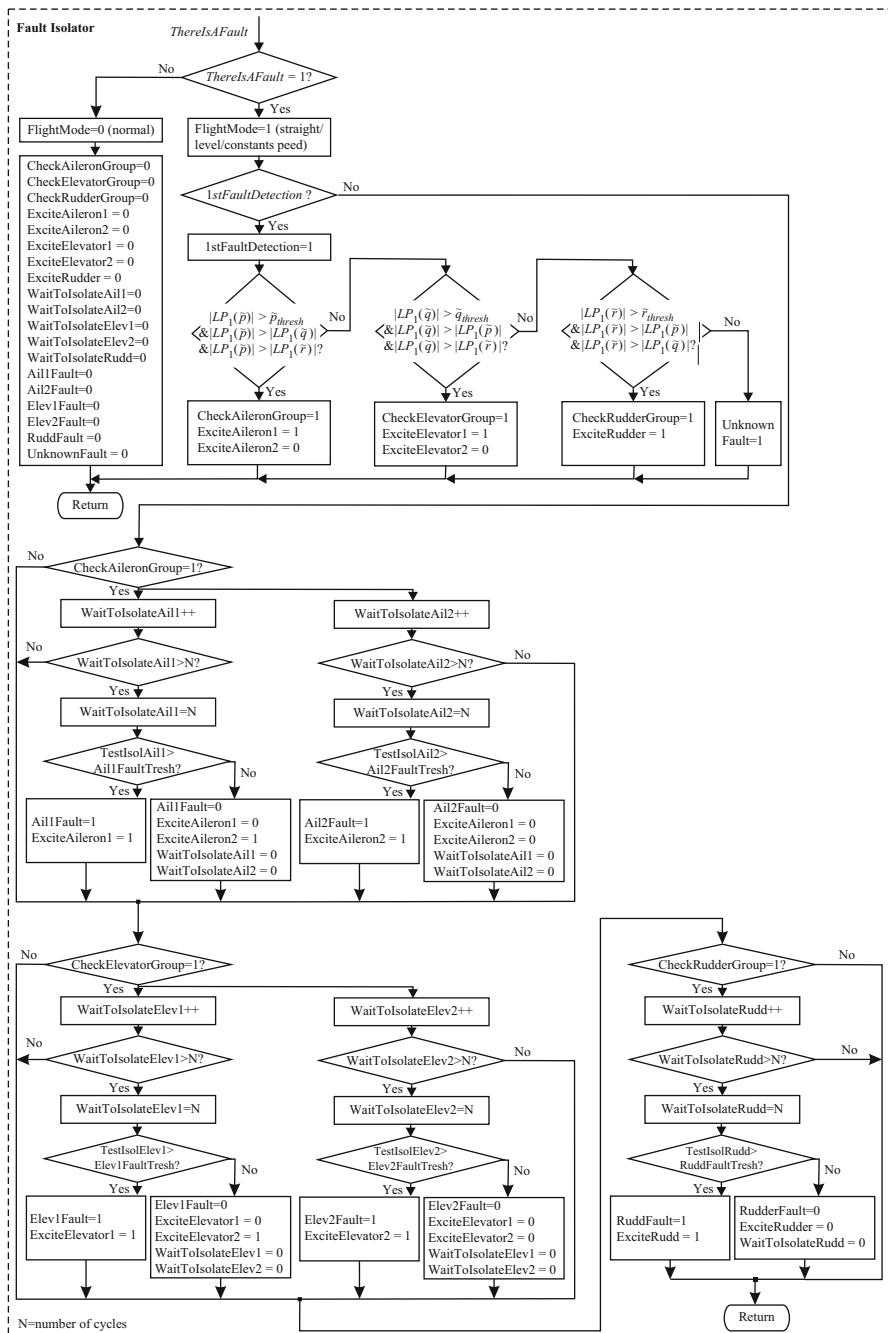

Fig. 44.17 Architecture of the fault isolator subsystem

actuator to test. It is the responsibility of the ESG subsystem shown in Fig. 44.14 to generate the artificial excitation signals to superimpose on the selected actuator. The threshold values $\tilde{p}_{\text{thresh}}$, $\tilde{q}_{\text{thresh}}$, and $\tilde{r}_{\text{thresh}}$ that appear in Fig. 44.17 are chosen according to (Eq. 44.62) for each axis.

44.5.6 Simulations

The simulations are done in Matlab/Simulink using a nonlinear 6 degree-of-freedom model of an aircraft controlled by its autopilot described in Ducard (2009). The aircraft is flying straight, level, and at a constant speed of 30 m/s. These conditions correspond to difficult circumstances for an FDI system due to the lack of excitation. The actuator fault scenario consists of the failure of aileron 1 at a small deflection of 1° during the time interval [25 ... 50 s], the failure of aileron 2 that gets stuck at 2° deg during [75 ... 100 s], and finally aileron 1 is stuck again at 1 deg during [125 ... 175 s].

Simulations are carried out with Gaussian sensor noise with zero mean and a standard deviation of (1) $\sigma_{pqr} = 0.08$ (rad/s) for the body-axis turn rates p , q , and r ; (2) $\sigma_{V_T} = 5$ (m/s) for the aircraft total airspeed V_T ; and (3) $\sigma_\alpha = \sigma_\beta = 0.0349$ (rad/s) for the measurement data of the angle of attack α and the sideslip angle β . Moreover, uncertainties – in the aircraft model used in the prediction step of the EKF in the SMAC-FDI system – have been introduced in the form of reducing by 25 % the values of the torque vector $[L, M, N]^T$ involved in (Eq. 44.2). This is similar to taking an underestimated value of the model input coefficient \hat{b}_χ used in Sect. 44.5.2.3, and it corresponds to a worse case scenario in terms of FDI performance than if the coefficient \hat{b}_χ had been overestimated, as explained in the Remarks of Sect. 44.5.2.3.

This simulation scenario is chosen to show the capability of the SMAC-FDI system to (1) detect actuator failure even if the angle of the stuck control surface is very small and (2) distinguish the precise location of an actuator failure despite the ambiguity that may arise due to actuator redundancies in the system. It is indeed shown in Ducard and Geering (2008) how, for example, an MMAE or EMMAE-FDI scheme performs poorly to isolate a failed actuator between two actuators having the same aerodynamic effect on the aircraft.

The SMAC-FDI is run in simulation at a rate of 50 Hz; therefore, the strategy shown in Fig. 44.17 has a cycle period of 20 ms. Figure 44.18 shows that the SMAC-FDI detects the presence of the fault after 1 s. Figures 44.19 shows that the isolation of a faulty actuator takes about 1.8 s and the detection of a fault removal is detected in both cases in less than 1.2 s. Figure 44.20 and 44.21 show the actuator control signals and results of the AHE subsystem, respectively.

Note that real external perturbations, like wind gusts, may shortly contribute to generate residuals and potentially could trigger a false alarm. However, the SMAC-FDI is architected to systematically excite the actuator – thought to have failed – and eventually conclude whether it has really failed.

44.5.7 Properties of the SMAC-FDI System

The benefits of the SMAC-FDI system are the following:

- It is able to detect the presence of an actuator fault.
- Only 1 EKF for residual generation is used with only three-state elements p, q, r . It is therefore of low computational load (no need for a bank of KFs or EKFs).
- The fault isolation is based on an active and systematic actuator-testing procedure, thus reducing isolation latencies, removing isolation ambiguities among equivalent actuators, and increasing the robustness of this FDI method against external perturbations and model uncertainties.
- The SMAC-FDI system is scalable to a larger number of actuators and can deal with simultaneous faults.
- It is easy to tune.
- It does not require any additional sensor.
- The algorithm does not disturb the flight (the aircraft is not destabilized during actuator testing, failed or not).
- The isolation process is insensitive to the control signals amplitude, contrary to methods based on residuals.
- The isolation process is insensitive to model uncertainties, since it is not model based.
- The SMAC-FDI system can also track a fault once detected even with low natural excitation of the aircraft.
- The SMAC-FDI system is capable of detecting and isolating multiple actuator failures, provided that the logic in the fault isolator is slightly modified to search for the presence of a subsequent fault in the system.

44.5.8 Computational Load Requirements

The SMAC-FDI algorithm automatically reduces to the minimum amount of computation required, since parts of the algorithm are only activated if the presence of a fault has been detected. With the EMMAE method described in Ducard and Geering (2008), a bank of $N + 1$ EKF with at least six states is constantly running to monitor N actuators. The MMAE method is even more computationally intense. In the SMAC-FDI, the computational load is considerably reduced since only one EKF with only three states is constantly running. Therefore, the SMAC-FDI is a very fast method and well suited for a small microcontroller.

44.5.9 Conclusions About the SMAC-FDI System

The SMAC-FDI system is a computationally efficient system to detect and isolate actuator fault (FDI system) with application to an aircraft. This FDI system is based on a single-model-based filter that generates residuals as soon as the behavior of the aircraft deviates from expected. If a fault is detected, the guidance system of the aircraft is reconfigured to fly the aircraft straight and level. A procedure is

engaged to systematically excite each suspected actuator and decide whether it is failed. The residuals of a three-state only EKF are used to detect the presence of a fault in the system, whereas the isolation process is done by observing the control signals. The system is simple to implement and tune, is robust against model uncertainties and external perturbation, does not require additional sensor, and shows good performance in simulation.

44.6 Chapter General Conclusion

In this chapter, some concepts of fault detection and isolation with application to unmanned aircraft have been presented. The fundamental part in an FDI system is the generation of signal(s) that indicate the presence of a fault in the system.

This chapter focused on using residuals calculated by Kalman-type filters that predict the dynamics of the aircraft through a model. The mathematical aircraft model used and the equations of extended kalman filters have been recalled. Two FDI systems have been detailed. The first uses a multiple-model approach and estimates the position of a faulty actuator. The second approach is less computationally intense as it relies on a unique filter to generate residuals for fault detection, and fault isolation is carried out with an actuator-testing procedure. The chapter contains discussions about dealing with model uncertainties, techniques to enhance the robustness of the fault diagnosis, and finally about computational load.

Appendix

Table 44.2 Aircraft model parameters

| Parameter | Value | Unit | Definition |
|----------------------|--|----------------------|-------------------------|
| I^b | $I^b = \begin{bmatrix} 2.56 & 0 & 0.5 \\ 0 & 10.9 & 0 \\ 0.5 & 0 & 11.3 \end{bmatrix}$ | [kg·m ²] | Airplane inertia matrix |
| S | 1.80 | [m ²] | Wing surface |
| \bar{c} | 0.58 | [m] | Mean aerodynamic Chord |
| b | 3.1 | [m] | Wing span |
| C_{Z1} | 1.29×10^{-2} | [—] | Lift derivative |
| $C_{Z\alpha}$ | −3.25 | [—] | Lift derivative |
| C_{X1} | -2.12×10^{-2} | [—] | Drag derivative |
| $C_{X\alpha}$ | -2.66×10^{-2} | [—] | Drag derivative |
| C_{Y1} | -3.79×10^{-1} | [—] | Side force derivative |
| $C_{La1} = -C_{La2}$ | -3.395×10^{-2} | [—] | Roll derivative |
| $C_{Le1} = -C_{Le2}$ | -0.485×10^{-2} | [—] | Roll derivative |
| $C_{L\beta}$ | -1.30×10^{-2} | [—] | Roll derivative |

Table 44.2 (continued)

| Parameter | Value | Unit | Definition |
|---------------------|------------------------|------|------------------|
| $C_{L\bar{p}}$ | -1.92×10^{-1} | [-] | Roll derivative |
| $C_{L\bar{r}}$ | 3.61×10^{-2} | [-] | Roll derivative |
| C_{M1} | 2.08×10^{-2} | [-] | Pitch derivative |
| C_{Me} | 5.45×10^{-1} | [-] | Pitch derivative |
| $C_{Me1} = C_{Me2}$ | 2.725×10^{-1} | [-] | Pitch derivative |
| $C_{Ma1} = C_{Ma2}$ | 0.389×10^{-1} | [-] | Pitch derivative |
| $C_{M\alpha}$ | -9.03×10^{-2} | [-] | Pitch derivative |
| $C_{M\bar{q}}$ | -9.83 | [-] | Pitch derivative |

Abstract

This chapter investigates the problems of fault detection, diagnosis, and fault-tolerant control for unmanned aerial vehicles (UAVs). It presents first a detailed overview on the existing experimental works considering these problems in the literature. The existing works consider fixed-wing as well as rotorcraft UAVs including the single-rotor and the multi-rotor helicopters (also known as quadrotors). Later on, the chapter discusses three Kalman filters employed for actuator fault detection and diagnosis, namely, the unscented Kalman filter, the two-stage Kalman filter, and the adaptive two-stage Kalman filter. The three

filters are experimentally applied to a quadrotor helicopter UAV test bed at the Department of Mechanical and Industrial Engineering of Concordia University. The obtained results are shown, compared, and discussed.

45.1 Introduction

Unmanned aerial vehicles are being incorporated in an increasing variety of operations such as surveillance, remote sensing, search, geographic studies, as well as various military and security applications. This expansion will bring UAVs into difficult new situations such as flight in urban environments where reliability is particularly critical. The poor reliability of current unmanned vehicles presents a roadblock to their success in demanding new flight environments (Drozeski et al. 2005). The Office of the Secretary of Defense acknowledges this shortcoming in the UAV Roadmap 2002–2027 (Office of the Secretary of Defense 2002). It identifies the development of self-repairing, smart flight-control systems as a crucial step in the overall advancement of UAV autonomy: “Improving UAV reliability is the single most immediate and long-reaching need to ensure their success.” Damage tolerance capability is also crucial for UAVs such as unmanned combat aircraft systems operating in extremely hazardous environments. The technology for this damage tolerance would need to provide virtually instantaneous, autonomous assessment of damage incurred, followed by an immediate response that alters the flight-control system to compensate for the effects of that damage. A survey on fault diagnosis and fault-tolerant control for UAVs can be found in Qi and Han (2007) and Sadeghzadeh and Zhang (2011). This chapter will only focus on research works with experimental application of fault detection, diagnosis, and fault-tolerant control in the presence of actuator, control surface faults, and structural damages.

In the context of the Joint Unmanned Combat Aircraft Systems (J-UCAS) program sponsored by the Defense Advanced Research Projects Agency (DARPA), Rockwell Collins developed a new approach to autonomously mitigate the effects of physical damage to aircraft in an air combat environment. The efforts focused on airborne demonstrations of autonomous damage detection, recovery, and the subsequent real-time reconfiguration of the control laws needed to maintain vehicle stability. These adjustments enable air vehicles to complete their missions after incurring battle damage and allow them to safely return home. The developed technology is based on a unique, software-based approach to vehicle control called automatic supervisory adaptive control (ASAC) system. Many flight demonstration videos have been released for damage-tolerant flight control and autonomous landing capabilities on an unmanned subscale F/A-18 and the RQ-7B Shadow unmanned aircraft system (Fig. 45.1). Battle damage and in-flight failure is simulated in Rockwell Collins (2008) by ejecting more than 60 % of the subscale F/A-18’s right wing. Upon ejection, the ASAC system reacts to the airplane’s new vehicle configuration, automatically regains baseline performance, and continues to fly. The airplane successfully lands automatically despite the wing damage. An in-flight comparison is provided in Rockwell Collins (2009) where the ASAC system

Fig. 45.1 The UAVs used by Rockwell Collins for the ASAC flight demonstration. (a) The unmanned subscale F/A-18. (b) The RQ-7B Shadow UAV

is activated and deactivated in the presence of a wing damage. A more severe fault is considered in Rockwell Collins (2010b) where the damage tolerance flight test involved ejecting 80 % of the F/A-18's right wing. In that flight, the ASAC technology quickly brings the aircraft back to trimmed flight after damage, and the vehicle continues to fly its mission before completing its flight with an autonomous landing. The technology also shows to be efficient in the presence of multiple surface damages: in Rockwell Collins (2010a), ASAC is shown to recover the aircraft from damage in the right wing, the right horizontal stabilizer, and the right vertical stabilizer. After the F/A-18 completes its takeoff, 60 % of its right wing and 30 % of its right vertical stabilizer are ejected simultaneously. The aircraft violently rolls over 100° before ASAC brings the wings back to level position and the vehicle continues to fly its mission. Later in the flight, 30 % of the right horizontal stabilizer is ejected. The UAV performs then an autonomous landing with its damaged airframe. Later on, the DARPA, the U.S. Army, and Rockwell Collins demonstrated damage-tolerance control on the RQ-7B Shadow unmanned aircraft system (Fig. 45.1), marking the first time that the technology has been tested on a fielded platform. The tests included ejecting 20 in. of the Shadow's wing during flight (Rockwell Collins 2010c). Despite the damage sustained by the Shadow, it remains steady in-flight and lands successfully.

Similar in-flight wing damage scenarios have been carried out at the Mechanical Engineering Department, University of Utah, in 2001–2002 using the Twinstar radio-controlled model aircraft (Shore and Bodson 2004). In this latter work, four in-flight failures were planned: frozen left elevator, frozen left aileron, left or right engine failure, and separation of left stabilizer/elevator. A recursive parameter identification is then employed to track the effects of the failures, such as reduced effectiveness of pitch commands due to a locked elevator or roll and sideslip due to engine failure. For the fault-tolerant flight control, a continuously adaptive approach is used where the gains of the control law are computed from the estimated parameters, and no attempt is made to categorize the health or failure state of the aircraft. The reconfigurable control algorithm can be viewed as a special case of

Fig. 45.2 The Twinstar by Multiplex

model reference adaptive control. The Twinstar UAV shown in Fig. 45.2 has been also considered at the School of Aerospace Engineering of Georgia Institute of Technology. The Twinstar, produced by Multiplex, is a commercially available multi-engine model-scale aircraft. It is made from highly resilient Styrofoam material and is an ideal candidate for fault-tolerant control work (Chowdhary et al. 2011). This vehicle has the capability to easily produce in-flight fault scenarios such as control surface failures, structural damage, and wing breakage. The vehicle has been equipped with the AFI FCS-20 onboard flight computer system (Adaptive Flight online). The AFI FCS-20 is a complete autopilot with a reliable navigation solution, fusing outputs from multiple embedded sensors to provide high-fidelity measurements of aircraft velocity. Two videos in Georgia Tech (2009a,b) show the Twinstar with 50 % in-flight right-wing ejection along with complete loss of right aileron functionality. Although that there is no information if autonomous landing is performed, one can see that the aircraft is still capable to autonomously track a predefined trajectory in spite of the severe structural damage. It should be noted that a baseline nonadaptive controller is employed in fault-free and fault conditions, and thus oscillations in angle of attack and roll are observed, which result in oscillations in altitude. In future works, adaptive control algorithms will be augmented to the baseline control algorithm to mitigate the observed oscillations and enable safe landing in the presence of significant structural faults.

As for fault-tolerant control approaches, several neural networks (NN) techniques have been applied to many aircrafts in the presence of actuator faults. The NASA/Boeing X-36 (Fig. 45.3) Tailless Fighter Agility Research Aircraft program successfully demonstrated the tailless fighter design using advanced technologies to improve the maneuverability and survivability of possible future fighter aircraft (RESTORE online). In a follow-on effort, the Air Force Research Laboratory (AFRL), Wright-Patterson Air Force Base, Ohio, contracted with Boeing to fly AFRL's Reconfigurable Control for Tailless Fighter Aircraft (RESTORE) software as a demonstration of the adaptability of NN techniques to compensate for in-flight damage/malfunction of flaps, ailerons, and rudders. Two RESTORE research

Fig. 45.3 The X-36 tailless fighter

flights were flown in December 1998, proving the viability of the software approach. The NN was developed to adaptively regulate the inversion error between the pre-estimated aircraft model and the true aircraft dynamics. The inversion error can be caused by the model uncertainty, actuator failure, or aircraft damage. A control allocation module was used to distribute the desired control response from the control algorithms to the remaining “healthy” control actuators. A system identification module uses a least-squares algorithm to estimate aerodynamic parameters. Null-space injection is used to briefly excite control surfaces to obtain these estimates without significant performance degradation. Another project using the NN is the Intelligent Flight Control System (IFCS) research project (IFCS online) at NASA Dryden Flight Research Center. The IFCS project was established to design aircraft flight controls that can optimize aircraft performance in both normal and failure conditions. IFCS was designed to incorporate self-learning NN concepts with different purposes and levels of criticality into the flight-control software. This enables a pilot to maintain control and safely land an aircraft that has suffered a major systems failure and/or combat damage. The test-bed aircraft for the IFCS project is the NASA NF-15B. This aircraft has been highly modified from a standard F-15 (Fig. 45.4) configuration to include canard control surfaces, thrust vectoring nozzles, and a digital fly-by-wire flight-control system. Later on, West Virginia University (WVU) has been involved in the IFCS controller design and flight testing as well as the design of a “safety monitor” scheme to allow smooth and safe transitions from conventional to research control laws and from research control laws at nominal conditions to failure conditions (Gu 2004; Napolitano 2002). Furthermore, one of the WVU YF-22 Research Aircraft Models (Fig. 45.5) is used to test a set of IFCS control laws as a scaled-down version of the IFCS flight-testing program. A recent video (FTC 2011) shows a fault-tolerant flight control and safe landing for a model-scale aircraft in the presence of 20 % wing ejection using neural networks.

The quadrotor helicopter system has been also considered in the context of fault-tolerant control. The quadrotor UAV is a relatively simple, affordable, and easy

Fig. 45.4 The F-15 aircraft

Fig. 45.5 The YF-22 Research Aircraft Models of Flight Control Systems Laboratory of WVU

to fly system, and thus it has been widely used to develop, implement, and test-fly methods in control, fault diagnosis, fault-tolerant control as well as multiagent based technologies in formation flight, cooperative control, distributed control, mobile wireless networks, and communications. Few research laboratories are carrying out advanced theoretical and experimental works on the system. Among others, one may cite, for example, the UAV SWARM health management project of the Aerospace Controls Laboratory at MIT (SWARM online) supported by Boeing Phantom Works, the Stanford Testbed of Autonomous Rotorcraft for Multi-Agent Control project (STARMAC online), and the Micro Autonomous Systems Technologies project (MAST online). The Active Adaptive Control Laboratory (AACLAB online) at MIT considered the fault-tolerant control problem for the quadrotor UAV using the Draganflyer V Ti Pro (see Fig. 45.6): a video in Dydek (2010b) shows a three-way comparison between nominal (nonadaptive), model reference adaptive control (MRAC), and combined/composite model reference adaptive control (CMRAC) in the presence of 30 % thrust loss. In Dydek (2010a), a video shows a comparison of nominal (nonadaptive) and adaptive controllers in response to a sudden loss of thrust due to one of the propellers being cut mid-flight. A team of researchers at

Fig. 45.6 The Draganflyer V Ti Pro

the Department of Mechanical and Industrial Engineering of Concordia University has been working on a research and development project on fault-diagnosis, fault-tolerant, and cooperative control of multiple UAVs since 2007 (see the Networked Autonomous Vehicles laboratory (NAV online)). This work is financially supported by NSERC (Natural Sciences and Engineering Research Council of Canada) through a Strategic Project Grant and a Discovery Project Grant and three Canadian-based industrial partners (Quanser Inc., Opal-RT Technologies Inc., and Numerica Technologies Inc.) as well as Defence Research and Development Canada (DRDC) and Laval University. In addition to the work that has been carried out for the multi-vehicles case, many fault-tolerant control (FTC) strategies have been developed and applied to the single-vehicle quadrotor UAV system. The objective is to consider actuator faults and to propose FTC methods to accommodate as much as possible the fault effects on the system performance. Detailed information about the group activities can be found in Zhang and Chamseddine (2011). The proposed methods have been tested either in simulation, experimental, or both frameworks where the experimental implementation has been carried out using a cutting-edge quadrotor UAV test bed known as Qball-X4. The developed approaches include the gain-scheduled PID (GS-PID), model reference adaptive control (MRAC), sliding mode control (SMC), backstepping control (BSC), model predictive control (MPC), and flatness-based trajectory planning/replanning (FTPR). As an example of the work carried out at Concordia University, a comparison is shown in Chamseddine (2011a,b) between the linear quadratic regulator (LQR) and the conventional MRAC in the presence of a mid-flight propeller damage of 12 and 16 %, respectively. In Chamseddine and Sadeghzadeh (2011), the quadrotor X4 (4 motors) unmanned aerial helicopter is modified to an X6 (6 motors) helicopter, and the control reallocation technique is used to maintain the helicopter stability in the presence of 70 % and up to 100 % propeller damage.

Some of the above FTC methods require information about the time of occurrence, the location, and the amplitude of faults whereas others do not. In the former

Fig. 45.7 The MARVIN helicopter

case, a fault detection and diagnosis (FDD) module is needed to detect, isolate, and identify the occurred faults. In Heredia et al. (2008), the authors investigate the FDD problem for unmanned rotorcraft systems in the presence of actuator faults. The system that has been considered is the MARVIN helicopter (Fig. 45.7) where stuck-type faults has been produced in the main and tail rotors in different flight conditions (near hover, forward flight at different velocities, etc.). An input-output model of the helicopter system is identified for output prediction then linear observers are used for fault detection. A fault-tolerant control architecture that couples techniques for fault detection and identification with reconfigurable flight control is developed at Georgia Institute of Technology (Drozeski et al. 2005; Drozeski 2005). Neural networks are employed for fault detection and identification, and an adaptive neural network feedback linearization technique is employed to stabilize the vehicle after fault detection. Actual flight test results are carried out on the Yamaha GTMax helicopter shown in Fig. 45.8 to support the validity of the approach. The fault-tolerant control architecture is tested in the presence of several actuator faults such as faults in the swashplate and the collective rotor. The Shenyang Institute of Automation, Chinese Academy of Sciences, has been focusing its research on rotorcraft UAV for several years now (Qi et al. 2009). Several experimental platforms are designed for advanced control algorithm research demonstration including navigation, advanced flight control, 3D path planning, and fault-tolerant control. Among these platforms, the ServoHeli-20 is a model class platform which has 20 kg takeoff weight. The ServoHeli-40 and ServoHeli-120 (Fig. 45.9) are engineering class platforms for highway patrol, electrical line patrol, and photography. They have 40 and 120 kg takeoff weight and have performed fully autonomous flight-control experimental demonstration. In the recent research of Qi et al. (2009), a novel adaptive unscented Kalman filter (AUKF) is proposed for onboard failure coefficient estimation and a new fault-tolerant control method is designed against the actuator failure of the ServoHeli series rotorcraft UAVs. The filter method with adaptability to statistical characteristic of noise is presented to improve the estimation accuracy of traditional UKF. The algorithm with the adaptability to statistical characteristic of noise, named Kalman filter (KF)-based adaptive UKF,

Fig. 45.8 The Yamaha GTMax helicopter

Fig. 45.9 The ServoHeli-40 and ServoHeli-120 rotorcraft UAV systems. (a) The ServoHeli-40. (b) The ServoHeli-120

is proposed to improve the UKF performance. By introducing the actuator health coefficients (AHCs) into the dynamics equation of a rotorcraft UAV, the proposed AUKF is utilized to online estimate both the flight states and the AHCs. A fault adaptive control is further designed based on the estimated states and AHCs.

The subsequent sections of this chapter present some experimental results on the actuator FDD problem applied to a quadrotor helicopter test bed. Three Kalman filters are considered: the unscented Kalman filter, the two-stage Kalman filter, and the adaptive two-stage Kalman filter. The quadrotor helicopter test bed is first presented in the next section before proceeding with the FDD problem.

45.2 Description and Dynamics of the Quadrotor UAV System

The Qball-X4 test bed developed by Quanser Inc. through the above-mentioned NSERC-SPG project is shown in Fig. 45.10a. It is enclosed within a protective carbon fiber round cage (therefore a name of Qball-X4) to ensure safe operation of the vehicle and protection to the personnel who is working with the vehicle in an indoor

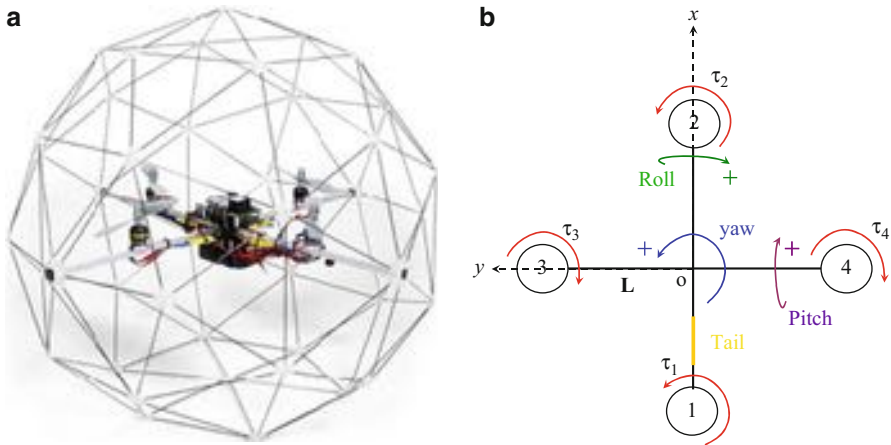

Fig. 45.10 The Quanser Qball-X4 quadrotor UAV and its schematic representation. **(a)** The Quanser Qball-X4 quadrotor UAV, **(b)** Qball-X4 schematic representation

research and development environment. It uses four 10-in. propellers and standard motors and speed controllers. It is equipped with the Quanser embedded control module (QECM), which is comprised of a Quanser HiQ aero data acquisition card and a QuaRC-powered Gumstix single-board embedded computer where QuaRC is Quanser's real-time control software. The Quanser HiQ provides high-resolution accelerometer, gyroscope, and magnetometer IMU sensors as well as servo outputs to drive four motors. The onboard Gumstix computer runs QuaRC, which allows to rapidly develop and deploy controllers designed in MATLAB/Simulink environment to real-time control of the Qball-X4. The controllers run onboard the vehicle itself, and runtime sensors measurement, data logging, and parameter tuning are supported between the ground host computer and the target vehicle (Quanser 2010).

The block diagram of the entire UAV system is illustrated in Fig. 45.11. It is composed of three main parts:

- The first part represents the electronic speed controllers (ESCs), the motors, and the propellers in a set of four. The input to this part is $u = [u_1 \ u_2 \ u_3 \ u_4]^T$ which are pulse-width modulation (PWM) signals. The output is the thrust vector $T = [T_1 \ T_2 \ T_3 \ T_4]^T$ generated by four individually controlled motor-driven propellers.
- The second part is the geometry that relates the generated thrusts to the applied lift and torques to the system. This geometry corresponds to the position and orientation of the propellers with respect to the system's center of mass.
- The third part is the dynamics that relate the applied lift and torques to the position P , velocity V , and acceleration A of the Qball-X4.

The subsequent sections describe the corresponding mathematical model for each of the blocks in Fig. 45.11.

Fig. 45.11 The UAV system block diagram

45.2.1 Dynamics

The Qball-X4 dynamics in a hybrid coordinate system are given hereafter where the position dynamics are expressed in the inertial frame and the angular dynamics are expressed in the body frame (Bresciani 2008):

$$\begin{aligned}
 m\ddot{x} &= u_z (\cos \phi \sin \theta \cos \psi + \sin \phi \sin \psi) - k_x \dot{x} \\
 m\ddot{y} &= u_z (\cos \phi \sin \theta \sin \psi - \sin \phi \cos \psi) - k_y \dot{y} \\
 m\ddot{z} &= u_z (\cos \phi \cos \theta) - mg - k_z \dot{z} \\
 J_x \dot{p} &= u_p + (J_y - J_z) qr - J_T q \Omega - k_p p \\
 J_y \dot{q} &= u_q + (J_z - J_x) pr - J_T p \Omega - k_q q \\
 J_z \dot{r} &= u_r + (J_x - J_y) pq - k_r r
 \end{aligned} \tag{45.1}$$

where x , y , and z are the coordinates of the quadrotor UAV center of mass in the inertial frame. m is the system mass and J_x , J_y , and J_z are the moments of inertia along y , x , and z directions, respectively. θ , ϕ , and ψ are the pitch, roll, and yaw Euler angles and p , q , and r are the angular velocities in the body-fixed frame. k_x , k_y , k_z , k_p , k_q , and k_r are drag coefficients and are constant. J_T is the moment of inertia for each motor, and Ω is the overall speed of propellers:

$$\Omega = -\Omega_1 - \Omega_2 + \Omega_3 + \Omega_4 \tag{45.2}$$

where Ω_i is the i th propeller speed.

The angular velocities in the inertial frame (Euler rates) can be related to those in the body frame as follows:

$$\begin{bmatrix} p \\ q \\ r \end{bmatrix} = \begin{bmatrix} 1 & 0 & -\sin \theta \\ 0 & \cos \phi & \cos \theta \sin \phi \\ 0 & -\sin \phi & \cos \theta \cos \phi \end{bmatrix} = \begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} \tag{45.3}$$

Close to hovering conditions, the matrix in the above equation is close to identity matrix, and therefore the angular velocities in the body frame can be seen as the angular velocities in the inertial frame. The model (45.1) can then be written as

$$\begin{aligned}
m\ddot{x} &= u_z (\cos \phi \sin \theta \cos \psi + \sin \phi \sin \psi) - k_x \dot{x} \\
m\ddot{y} &= u_z (\cos \phi \sin \theta \sin \psi - \sin \phi \cos \psi) - k_y \dot{y} \\
m\ddot{z} &= u_z (\cos \phi \cos \theta) - mg - k_z \dot{z} \\
J_x \ddot{\theta} &= u_\theta + (J_y - J_z) \dot{\phi} \dot{\psi} - J_T \dot{\phi} \Omega - k_\theta \dot{\theta} \\
J_y \ddot{\phi} &= u_\phi + (J_z - J_x) \dot{\theta} \dot{\psi} - J_T \dot{\theta} \Omega - k_\phi \dot{\phi} \\
J_z \ddot{\psi} &= u_\psi + (J_x - J_y) \dot{\theta} \dot{\phi} - k_\psi \dot{\psi}
\end{aligned} \tag{45.4}$$

where u_p , u_q , u_r , k_p , k_q , and k_r have been respectively changed to u_θ , u_ϕ , u_ψ , k_θ , k_ϕ , and k_ψ for notation convenience. At low speeds, one can obtain a simplified nonlinear model of (45.4) by neglecting drag terms and gyroscopic and Coriolis-centripetal effects:

$$\begin{aligned}
m\ddot{x} &= u_z (\cos \phi \sin \theta \cos \psi + \sin \phi \sin \psi) \\
m\ddot{y} &= u_z (\cos \phi \sin \theta \sin \psi - \sin \phi \cos \psi) \\
m\ddot{z} &= u_z (\cos \phi \cos \theta) - mg \\
J_x \ddot{\theta} &= u_\theta \\
J_y \ddot{\phi} &= u_\phi \\
J_z \ddot{\psi} &= u_\psi
\end{aligned} \tag{45.5}$$

A further simplified linear model can be obtained by assuming hovering conditions ($u_z \approx mg$ in the x and y directions) with no yawing ($\psi = 0$) and small roll and pitch angles:

$$\begin{aligned}
\ddot{x} &= \theta g; & J_x \ddot{\theta} &= u_\theta \\
\ddot{y} &= -\phi g; & J_y \ddot{\phi} &= u_\phi \\
\ddot{z} &= u_z/m - g; & J_z \ddot{\psi} &= u_\psi
\end{aligned} \tag{45.6}$$

The nonlinear model (45.5) will be used later for the unscented Kalman filter design whereas the simplified model (45.6) will be used for the two-stage and adaptive two-stage Kalman filters.

45.2.2 ESCs, Motors, and Propellers

The motors of the Qball-X4 are outrunner brushless motors. The generated thrust T_i of the i th motor is related to the i th PWM input u_i by a first-order linear transfer function:

$$T_i = K \frac{\omega}{s + \omega} u_i ; i = 1, \dots, 4 \quad (45.7)$$

where K is a positive gain and ω is the motor bandwidth. K and ω are theoretically the same for the four motors, but this may not be the case in practice, and therefore this can be one of sources of modeling errors/uncertainties for the FDD schemes.

45.2.3 Geometry

A schematic representation of the Qball-X4 is given in Fig. 45.10b. The motors and propellers are configured in such a way that the back and front (1 and 2) motors spin clockwise and the left and right (3 and 4) motors spin counterclockwise. Each motor is located at a distance L from the center of mass o , and when spinning, a motor produces a torque τ_i . The origin of the body-fixed frame is the system's center of mass o with the x -axis pointing from back to front and the y -axis pointing from right to left. The thrust T_i generated by the i th propeller is always pointing upward in the z -direction in parallel to the motor's rotation axis. The thrusts T_i and the torques τ_i result in a lift in the z -direction (body-fixed frame) and torques about the x , y , and z axes. The relations between the lift/torques and the thrusts are

$$\begin{aligned} u_z &= T_1 + T_2 + T_3 + T_4 \\ u_\theta &= L(T_1 - T_2) \\ u_\phi &= L(T_3 - T_4) \\ u_\psi &= \tau_1 + \tau_2 - \tau_3 - \tau_4 \end{aligned} \quad (45.8)$$

The torque τ_i produced by the i th motor is directly related to the thrust T_i via the relation of $\tau_i = K_\psi T_i$ with K_ψ as a constant. In addition, by setting $T_i \approx K u_i$ from (45.7), the relation (45.8) reads

$$\begin{aligned} u_z &= K(u_1 + u_2 + u_3 + u_4) \\ u_\theta &= KL(u_1 - u_2) \\ u_\phi &= KL(u_3 - u_4) \\ u_\psi &= KK_\psi(u_1 + u_2 - u_3 - u_4) \end{aligned} \quad (45.9)$$

where u_z is the total lift generated by the four propellers and applied to the quadrotor UAV in the z -direction (body-fixed frame). u_θ , u_ϕ , and u_ψ are, respectively, the applied torques in θ , ϕ , and ψ directions (see Fig. 45.10b).

45.3 Fault Detection and Diagnosis for the Quadrotor Helicopter

Fault detection and diagnosis (FDD) aims to detect abnormal behaviors of a process due to a component failure and eventually isolate the exact location of the failed component and identify the failure type and its severity. This problem has been extensively considered in the literature (see, e.g., Ding 2008; Isermann 2006; Zhang and Jiang 2008 and the references therein) since a better knowledge of the failure location, type, and amplitude greatly helps in minimizing the fault effects on the process behavior. This is particularly important for safe operation and/or fault-tolerant control of safety-critical systems, such as aircrafts, spacecrafts, nuclear power plants, and chemical plants processing hazardous materials where the consequences of a minor fault in a system component can be catastrophic.

This chapter considers the FDD problem for the quadrotor helicopter in the presence of actuator faults. Such faults can be modeled as follows:

$$u_i^f = (1 - w_i) u_i \leq (1 - w_i) u_{\max} ; \quad (i = 1, \dots, 4) \quad (45.10)$$

where w_i represents the loss of effectiveness in the i th rotor, $w_i = 0$ denotes a healthy rotor, $w_i = 1$ denotes a complete loss of the i th rotor, and $0 < w_i < 1$ represents a partial loss of control effectiveness. During the mission and after the occurrence of a fault in one of the UAV rotors, two cases can be distinguished: (a) the damaged UAV cannot recover and the system is lost and (b) the damaged UAV recovers and maintains its stability. It can be shown from (45.6) and (45.9) that the required PWM inputs to keep a quadrotor UAV in hovering flight condition (i.e., for $x = 0$, $y = 0$, and $\psi = 0$) are $u_i^* = mg/4K$ for $i = 1, \dots, 4$. Thus, a damaged quadrotor can always maintain its altitude if

$$u_i^* = \frac{mg}{4K} \leq (1 - w_i) u_{\max} ; \quad i = 1, \dots, 4 \quad (45.11)$$

or

$$w_i \leq 1 - \frac{mg}{4K u_{\max}} ; \quad i = 1, \dots, 4 \quad (45.12)$$

45.3.1 Unscented Kalman Filter

This work employs a parameter estimation-based FDD where the unscented Kalman filter (UKF) is used to estimate the parameters w_i of (45.10). In the fault-free case, the estimates of w_i ($i = 1, \dots, 4$) are close to 0, and a deviation from 0 will be an indication for a fault occurrence. The UKF is a member of the linear regression Kalman filters (LRKF) and it was developed to overcome some of the shortcomings of the extended Kalman filter (EKF) in the estimation of nonlinear systems (VanDyke et al. 2004). The UKF is an extension of the traditional Kalman filter for the estimation of nonlinear systems by using the unscented

transformation (UT) where the UT is a method for calculating the statistics of a random variable which undergoes a nonlinear transformation (Julier and Uhlmann 1997). It uses a set of sample or *sigma points* that are determined from the a priori mean and covariance of the variable. The sigma points undergo the nonlinear transformation, and the mean and covariance of the variable are determined from the transformed sigma points. The main motivation for using UKF for FDD resides in the advantages and the superiority of this approach over the EKF and more specifically the better convergence characteristics and greater accuracy in the case of nonlinear systems (VanDyke et al. 2004).

In this chapter, based on the fact that all state variables are available from the sensors in the Qball-X4 system, UKF has been used for estimating only necessary parameters w_i ($i = 1, \dots, 4$). This strategy is different from the traditional scheme for using UKF for state or simultaneous state and parameter estimation (Vitale et al. 2009; Ma and Zhang 2010), and it has the advantage of simplifying the FDD scheme to be more suitable for real-time applications. The parameter estimation problem, also referred to as system identification, involves determining a nonlinear mapping $y_k = G(x_k, w)$ where x_k is the input, y_k is the output, and the nonlinear map G is parameterized by the parameter vector w . Typically, a training set is provided with sample pairs consisting of known inputs and desired outputs, $\{x_k, d_k\}$, where $k = 1, \dots, N$ and N is the total number of sample data. The error is defined as $e_k = d_k - G(x_k, w)$, and the goal of learning involves solving for the parameters w in order to minimize some given function of the error (der Merwe and Wan 2001). Parameters can be efficiently estimated online by writing a new state-space representation as follows:

$$w_k = w_{k-1} + r_k \quad (45.13)$$

$$d_k = G(x_k, w_k) + e_k \quad (45.14)$$

where the parameters w_k correspond to a stationary process with identity state transition matrix, driven by process noise r_k . The output d_k corresponds to a nonlinear observation on w_k . The UKF implementation for parameter estimation is then given hereafter.

Initialize the parameters vector and covariance with

$$\hat{w}_0 = E\{w\} \quad (45.15)$$

$$P_{w_0} = E\{(w - \hat{w}_0)(w - \hat{w}_0)^T\} \quad (45.16)$$

For $k \in \{1, \dots, \infty\}$, calculate the time update of the parameters vector and covariance:

$$\hat{w}_k^- = \hat{w}_{k-1} \quad (45.17)$$

$$P_{w_k}^- = P_{w_{k-1}} + Q_w \quad (45.18)$$

Calculate the sigma points from the a priori parameters mean and covariance:

$$\sigma_k = \begin{bmatrix} \hat{w}_k^- & \hat{w}_k^- + \nu \sqrt{P_{w_k}^-} & \hat{w}_k^- - \nu \sqrt{P_{w_k}^-} \end{bmatrix} \quad (45.19)$$

Calculate the expected measurement matrix using the nonlinear measurement model:

$$D_k = G(x_k, \sigma_k) \quad (45.20)$$

Calculate the mean measurement \hat{d}_k :

$$\hat{d}_k = \sum_{i=0}^{2L} w_i^m D_{i,k} \quad (45.21)$$

Calculate the measurement and the cross-correlation covariances:

$$P_{d_k} = \sum_{i=0}^{2L} w_i^c (D_{i,k} - \hat{d}_k) (D_{i,k} - \hat{d}_k)^T + R_w \quad (45.22)$$

$$P_{w_k d_k} = \sum_{i=0}^{2L} w_i^c (\sigma_{i,k} - \hat{w}_k^-) (D_{i,k} - \hat{d}_k)^T \quad (45.23)$$

Calculate the Kalman gain matrix from the cross-correlation and measurement covariances:

$$K_k = P_{w_k d_k} P_{d_k}^{-1} \quad (45.24)$$

Update measurements using equations:

$$\hat{w}_k = \hat{w}_k^- + K_k (d_k - \hat{d}_k) \quad (45.25)$$

$$P_{w_k} = P_{w_k}^- - K_k P_{d_k} K_k^T \quad (45.26)$$

Q_w and R_w are the process and measurement noise covariance matrices. $D_{i,k}$ is the i th column of the matrix D_k , and w_i^m and w_i^c are scalar weights defined as follows:

$$w_0^m = \frac{\lambda}{l + \lambda} \quad (45.27)$$

$$w_0^c = \frac{\lambda}{l + \lambda} + (1 - \alpha^2 + \beta) \quad (45.28)$$

$$w_i^m = w_i^c = \frac{1}{2(l + \lambda)} \quad ; \quad i = 1, \dots, 2l \quad (45.29)$$

where l is the dimension of the vector w , and $\lambda = \alpha^2(l + \kappa) - l$ and $v = \sqrt{(l + \lambda)}$ are two scaling parameters. α determines the spread of the sigma points around \hat{w} and is usually set to $1 \times 10^{-4} \leq \alpha \leq 1$. κ is a secondary scaling parameter set to $3 - l$ for parameter estimation. β is used to incorporate prior knowledge of the distribution of w (for Gaussian distributions, $\beta = 2$ is optimal).

The application of the above UKF algorithm to the Qball-X4 consists in plugging (45.9) into system dynamics given by (45.5) while taking into consideration the model of actuator faults in (45.10). By defining $(1 - w_i)$ as \bar{w}_i and discretizing the resulting equations using Euler's method, one obtains

$$\begin{aligned}
 x_{k+2} &= 2x_{k+1} - x_k + h^2 \frac{K}{m} (\bar{w}_1 u_{1k} + \bar{w}_2 u_{2k} + \bar{w}_3 u_{3k} + \bar{w}_4 u_{4k}) \quad (45.30) \\
 &\quad (\cos \phi_k \sin \theta_k \cos \psi_k + \sin \phi_k \sin \psi_k) \\
 y_{k+2} &= 2y_{k+1} - y_k + h^2 \frac{K}{m} (\bar{w}_1 u_{1k} + \bar{w}_2 u_{2k} + \bar{w}_3 u_{3k} + \bar{w}_4 u_{4k}) \\
 &\quad (\cos \phi_k \sin \theta_k \sin \psi_k - \sin \phi_k \cos \psi_k) \\
 z_{k+2} &= 2z_{k+1} - z_k + h^2 \frac{K}{m} (\bar{w}_1 u_{1k} + \bar{w}_2 u_{2k} + \bar{w}_3 u_{3k} + \bar{w}_4 u_{4k}) \\
 &\quad (\cos \phi_k \cos \theta_k) - h^2 g \\
 \theta_{k+2} &= 2\theta_{k+1} - \theta_k + h^2 \frac{KL}{J_1} (\bar{w}_1 u_{1k} - \bar{w}_2 u_{2k}) \\
 \phi_{k+2} &= 2\phi_{k+1} - \phi_k + h^2 \frac{KL}{J_2} (\bar{w}_3 u_{3k} - \bar{w}_4 u_{4k}) \\
 \psi_{k+2} &= 2\psi_{k+1} - \psi_k + h^2 \frac{KK_\psi}{J_3} (\bar{w}_1 u_{1k} + \bar{w}_2 u_{2k} - \bar{w}_3 u_{3k} - \bar{w}_4 u_{4k})
 \end{aligned}$$

where h is the sampling period. Finally, to perform fault detection and isolation, many rules can be used to evaluate the estimated parameters w_i such as the two-stage statistical hypothesis tests developed in Zhang and Jiang (2002).

45.3.2 Two-Stage Kalman Filter

The advantage of using two-stage Kalman filter (TSKF) is to simultaneously estimate both states and fault parameters, for the purpose of fault detection, isolation, and identification as well as providing full-state estimation for state feedback-based controllers when state vector is not available through measurements. To explain the basic idea of the TSKF, consider the following discrete linear state-space model:

$$\begin{aligned}
 x_{k+1} &= A_k x_k + B_k u_k + v_k^x \\
 y_{k+1} &= C_k x_{k+1} + v_{k+1}^y
 \end{aligned} \quad (45.31)$$

where $x_k \in R^n$, $u_k \in R^l$ and $y_{k+1} \in R^m$ are the state, control input, and output vectors, respectively. v_k^x and v_{k+1}^y are uncorrelated Gaussian random vectors with zero means and covariance matrices Q_k^x and R_k , respectively. In the application of Kalman filtering techniques, an accurate model of the process dynamics and measurements is required. However, in many practical cases, constant bias affects the system dynamics and observations and may lead to performance degradation of the filter if the bias is not incorporated in the model. By considering a bias vector $w_k \in R^p$ in the state-space equation, model (45.31) can be written as

$$\begin{aligned} x_{k+1} &= A_k x_k + B_k u_k + F w_k + v_k^x \\ w_{k+1} &= w_k + v_k^w \\ y_{k+1} &= C_k x_{k+1} + v_{k+1}^y \end{aligned} \quad (45.32)$$

where v_k^w is an uncorrelated Gaussian random vector with zero mean and covariance matrix Q_k^w . One possible solution to estimate the bias vector w_k is to augment it into the state vector to make an augmented state vector which is estimated by using the augmented state Kalman filter (ASKF). The augmented state vector is of dimension $n + p$ which makes the ASKF computationally expensive. Another drawback of this method is that numerical problems may arise during implementation. To reduce the complexity of this problem, Keller and Darouach (1997) presented two parallel reduced-order filters which optimally implement the augmented state filter. The proposed algorithm is called two-stage Kalman filter (TSKF). In the context of fault detection and diagnosis, Wu et al. (1998, 2000) modeled actuator faults (loss of control effectiveness) as a bias vector in state equations then used TSKF to estimate the augmented bias vector. In Wu et al. (1998), the authors proposed the use of forgetting factor for TSKF.

In the current study, the effectiveness of actuators is estimated as the augmented random bias vector in the TSKF structure. By referring to (45.10), the loss of control effectiveness modeled as a bias vector is

$$w_k = [w_{1k} \ w_{2k} \ \dots \ w_{lk}]^T ; \ 0 \leq w_{ik} \leq 1 ; \ i = 1, 2, \dots, l \quad (45.33)$$

where $w_{ik} = 0$ and $w_{ik} = 1$ means that the i th actuator is completely healthy or fully damaged, respectively. By incorporating actuator faults in (45.32), the bias-augmented discrete linear time-varying state-space model is written as

$$x_{k+1} = A_k x_k + B_k u_k - B_k U_k w_k + v_k^x \quad (45.34)$$

$$w_{k+1} = w_k + v_k^w \quad (45.35)$$

$$y_{k+1} = C_k x_{k+1} + v_{k+1}^y \quad (45.36)$$

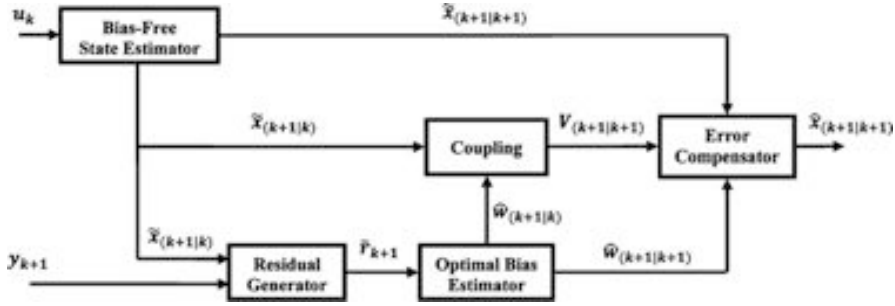

Fig. 45.12 The schematic diagram of the two-stage Kalman filter

where U_k is

$$U_k = \begin{bmatrix} u_{1k} & 0 & \dots & 0 \\ 0 & u_{2k} & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \dots & 0 & u_{lk} \end{bmatrix} \quad (45.37)$$

Since the additive noise v_k^w introduced into the bias evolution equation bears no relation to either the process noise v_k^x or the measurement noise v_{k+1}^y in the dynamic system model, the two-stage filtering algorithm by Keller and Darouach can be extended with some modification to obtain the bias estimates (Wu et al. 2000). It is worthy to note that the choice of Q_k^w plays an important role in the performance of the filter. In the most of real world situations, the loss of control effectiveness occurs abruptly, while in (45.34) it is modeled as a bias. To make the bias vector change fast enough (and also to track the true values), one may think of a large value for bias covariance. On the other hand, once the steady-state condition is reached, the bias covariance must be small to reduce the steady-state error in estimation. Then there is a trade-off between convergence speed and the accuracy of steady-state estimation of control effectiveness. The minimum variance solution to estimate the true values of biases is obtained by application of the TSKF.

Like other types of Kalman filters, the equations can be divided into two sets: the *time-update* equations and the *measurement-update* equations. The time-update equations, which can be distinguished by the $(k+1|k)$ subscription, are responsible to obtain a priori estimates by moving the state and error covariances one step ahead in the time domain. The measurement-update equations, shown by the $(k+1|k+1)$ subscription, are responsible to obtain a posteriori estimates through feedbacking measurements into the a priori estimates. In other words, time-update equations are used for prediction, while measurement-update equations are used for correction. Indeed the whole prediction-correction process is used to estimate the states as close as possible to their real values. Figure 45.12 shows a schematic flow diagram of the TSKF, and its implementation is given hereafter.

Estimate the bias-free state:

$$\tilde{x}_{k+1|k} = A_k \tilde{x}_{k|k} + B_k u_k + W_k \hat{w}_{k|k} - V_{k+1|k} \hat{w}_{k|k} \quad (45.38)$$

$$\tilde{P}_{k+1|k}^x = A_k \tilde{P}_{k|k}^x A_k^T + Q_k^x + W_k P_{k|k}^w W_k^T - V_{k+1|k} P_{k+1|k}^w V_{k+1|k}^T \quad (45.39)$$

$$\tilde{x}_{k+1|k+1} = \tilde{x}_{k+1|k} + \tilde{K}_{k+1}^x (y_{k+1} - C_{k+1} \tilde{x}_{k+1|k}) \quad (45.40)$$

$$\tilde{K}_{k+1}^x = \tilde{P}_{k+1|k}^x + C_{k+1}^T (C_{k+1} \tilde{P}_{k+1|k}^x C_{k+1}^T + R_{k+1})^{-1} \quad (45.41)$$

$$\tilde{P}_{k+1|k+1}^x = (I - \tilde{K}_{k+1}^x C_{k+1}) \tilde{P}_{k+1|k}^x \quad (45.42)$$

Determine the filter residual and its covariance:

$$\tilde{r}_{k+1} = y_{k+1} - C_{k+1} \tilde{x}_{k+1|k} \quad (45.43)$$

$$\tilde{S}_{k+1} = C_{k+1} \tilde{P}_{k+1|k}^x C_{k+1}^T + R_{k+1} \quad (45.44)$$

Estimate the optimal bias:

$$\hat{w}_{k+1|k} = \hat{w}_{k|k} \quad (45.45)$$

$$P_{k+1|k}^w = P_{k|k}^w + Q_k^w \quad (45.46)$$

$$\hat{w}_{k+1|k+1} = \hat{w}_{k+1|k} + K_{k+1}^w (\tilde{r}_{k+1} - H_{k+1|k} \hat{w}_{k|k}) \quad (45.47)$$

$$K_{k+1}^w = P_{k+1|k}^w H_{k+1|k}^T (H_{k+1|k} P_{k+1|k}^w H_{k+1|k}^T + \tilde{S}_{k+1})^{-1} \quad (45.48)$$

$$P_{k+1|k+1}^w = (I - K_{k+1}^w H_{k+1|k}) P_{k+1|k}^w \quad (45.49)$$

Calculate the coupling equations:

$$W_k = A_k V_{k|k} - B_k U_k \quad (45.50)$$

$$V_{k+1|k} = W_k P_{k|k}^w (P_{k+1|k}^w)^{-1} \quad (45.51)$$

$$H_{k+1|k} = C_{k+1} V_{k+1|k} \quad (45.52)$$

$$V_{k+1|k+1} = V_{k+1|k} - \tilde{K}_{k+1}^x H_{k+1|k} \quad (45.53)$$

Estimate the compensated error and its covariance:

$$\hat{x}_{k+1|k+1} = \tilde{x}_{k+1|k+1} + V_{k+1|k+1} \hat{w}_{k+1|k+1} \quad (45.54)$$

$$P_{k+1|k+1} = \tilde{P}_{k+1|k+1}^x + V_{k+1|k+1} P_{k+1|k+1}^w V_{k+1|k+1}^T \quad (45.55)$$

The application of the TSKF to the quadrotor UAV starts by deriving a linearized state-space model. Combining (45.6) and (45.9) yields to the linearized state-space model:

$$\begin{aligned}
\begin{bmatrix} \dot{x} \\ \ddot{x} \\ \dot{y} \\ \ddot{y} \\ \dot{z} \\ \ddot{z} \\ \dot{\theta} \\ \ddot{\theta} \\ \dot{\phi} \\ \ddot{\phi} \\ \dot{\psi} \\ \ddot{\psi} \end{bmatrix} &= \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & g & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -g & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} x \\ \dot{x} \\ y \\ \dot{y} \\ z \\ \dot{z} \\ \theta \\ \dot{\theta} \\ \phi \\ \dot{\phi} \\ \psi \\ \dot{\psi} \end{bmatrix} \\
&+ \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ K/m & K/m & K/m & K/m \\ 0 & 0 & 0 & 0 \\ KL/J_1 & -KL/J_1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & KL/J_2 & -KL/J_2 \\ 0 & 0 & 0 & 0 \\ KK_\psi/J_3 & KK_\psi/J_3 & -KK_\psi/J_3 & -KK_\psi/J_3 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ -1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} g \\
\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \end{bmatrix} &= \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x \\ \dot{x} \\ . \\ . \\ \psi \\ \dot{\psi} \end{bmatrix}
\end{aligned}$$

The covariance matrices for the implementation on Qball-X4 UAV are set to

$$\begin{aligned}
Q^x &= \begin{bmatrix} 10^{-6} \times I_{6 \times 6} & 0_{6 \times 6} \\ 0_{6 \times 6} & 10^{-12} \times I_{6 \times 6} \end{bmatrix}; \quad R = \begin{bmatrix} 10^{-6} \times I_{3 \times 3} & 0_{3 \times 3} \\ 0_{3 \times 3} & 10^{-12} \times I_{3 \times 3} \end{bmatrix}; \\
Q^w &= 10^{-1} \times I_{4 \times 4}
\end{aligned}$$

45.3.3 Adaptive Two-Stage Kalman Filter

The adaptive two-stage Kalman filter (ATSKF) is addressed for the purpose of adaptive estimation of control effectiveness factors. To make the ordinary TSKF more responsive to abrupt changes in control effectiveness factor (which has been modeled as a bias vector in (45.34)), some modification has been suggested in Wu et al. (2000) and Zhang and Jiang (2002). A common way to make recursive algorithm (like Kalman filter's family) less sensitive to previous data history is to use forgetting factor. In other words, the main goal of using forgetting factor is to make the Kalman filter more sensitive to abrupt changes in the control effectiveness parameters. When a forgetting factor is added to the optimal bias estimator part in (45.46), the new time-updated equation of bias covariance is written as

$$P_{k+1|k}^w = P_{k|k}^w / \lambda + Q_k^w, \quad 0 < \lambda \leq 1 \quad (45.56)$$

where λ is a forgetting factor which can have a predefined constant value. Using a constant value for forgetting factor may lead to instability of the TSKF. Indeed estimation error covariance matrix may increase rapidly due to the recursive nature of the algorithm. One way to prevent “blow up” in TSKF is to keep $P_{k+1|k}^w$ in a certain range. Parkum et al. (1992) used a nonuniform forgetting factor in recursive least-square-based parameter identification schemes. The idea is that, under the normal system operation condition, the error covariance matrix $P_{k|k}^w$ describes the bias estimation error. The bias estimation error should be kept in a range means that the error covariance matrix should not be so large or so small. Inspired by this fact, an adaptive technique is suggested in Parkum et al. (1992) and considered later in Zhang and Wu (1999) and Wu et al. (2000). This adaptive technique forces the error covariance matrix $P_{k+1|k}^w$ to stay within pre-described limits:

$$\sigma_{\min} I \leq P_{k+1|k}^w \leq \sigma_{\max} I \quad (45.57)$$

where σ_{\min} and σ_{\max} are positive constants and I is the identity matrix. A dyadic expansion of $P_{k|k}^w$ is given as

$$P_{k|k}^w = \sum_{i=1}^l \alpha_{k|k}^i e_k^i (e_k^i)^T, \quad \|e_k^1\| = \dots = \|e_k^l\| = 1 \quad (45.58)$$

where e_k^1, \dots, e_k^l and $\alpha_k^1, \dots, \alpha_k^l$ are the eigenvectors and eigenvalues of $P_{k|k}^w$, respectively. Substituting (45.58) into (45.56) gives

$$P_{k+1|k}^w = \sum_{i=1}^l \frac{\alpha_{k|k}^i}{\lambda_k^i} e_k^i (e_k^i)^T + Q_k^w, \quad 0 < \lambda_k^i \leq 1 \quad (45.59)$$

Replacing (45.46) by (45.59), the TSKF will turn to ATSKF. As suggested in Parkum et al. (1992), the forgetting factor λ_k^i can be chosen as a decreasing function of the amount of information received in the direction e_k^i . Since eigenvalue $\alpha_{k|k}^i$ of $P_{k|k}^w$ is a measure of the uncertainty in the direction of e_k^i , a choice of forgetting factor λ_k^i based on the above constraints can be

$$\lambda_k^i = \begin{cases} 1 & \text{if } \alpha_{k|k}^i > \alpha_{\max} \\ \alpha_{k|k}^i \left[\alpha_{\min} + \frac{\alpha_{\max} - \alpha_{\min}}{\alpha_{\max}} \alpha_{k|k}^i \right]^{-1} & \text{if } \alpha_{k|k}^i \leq \alpha_{\max} \end{cases} \quad (45.60)$$

where α_{\max} and α_{\min} are positive constants. The choice of α_{\max} and α_{\min} is made by the designer. If the ratio $\alpha_{\max}/\alpha_{\min}$ is close to one, then the adaptive forgetting factor approaches a constant value.

Fig. 45.13 The NAV Lab of Concordia University

45.4 Experimental Results

The UKF, TSKF, and ATSKF have been tested on the Qball-X4 test bed of the Networked Autonomous Vehicles (NAV) lab of Concordia University (Fig. 45.13). Several experiments are carried in the presence of actuator faults, flight data is collected, and then the filters are applied to the data off-board to diagnose faults. The experiments are taking place indoor in the absence of GPS signals, and thus the OptiTrack camera system from NaturalPoint is employed to provide the system position in the 3D space. In all experiments, the system is required to hover at an altitude of 1 m, and the faults are taking place at time instant $t = 15$ s.

45.4.1 Single Fault Scenario: Control Effectiveness Loss in the Third Motor

In the first scenario, a loss of control effectiveness of 45 % is simulated in the third motor (i.e., $w_3 = 0.45$). As can be seen in Fig. 45.14a, this fault does not affect the system along the x -direction, but it results in loss of altitude of 20 cm and a deviation of 80 cm from the desired position along the y -direction. Due to the presence of a controller, the system recovers and goes back to the desired hover

Fig. 45.14 System position along x , y , and z directions for single and simultaneous faults scenarios. (a) Single fault scenario, (b) Simultaneous faults scenario

position. Figure 45.15a shows the system’s behavior in the 3D space upon fault injection. The PWM inputs to the four motors are illustrated in Fig.45.16a. It is clear that before fault (up to 15 s), all the four PWM inputs are almost the same. After fault injection in the third motor, the baseline controller reacts by automatically increasing the third PWM input to compensate the occurred fault. The estimations

Fig. 45.15 System's 3D position for single and simultaneous faults scenarios, (a) Single fault scenario, (b) Simultaneous faults scenario

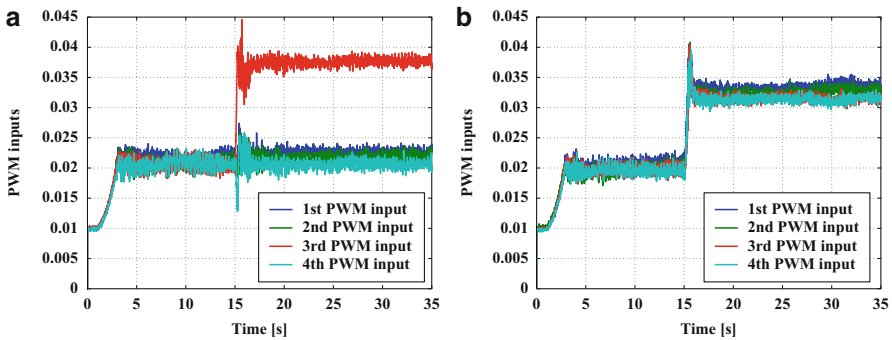

Fig. 45.16 The PWM inputs generated by the controller for single and simultaneous faults scenarios, (a) Single fault scenario, (b) Simultaneous faults scenario

of the actuator fault provided by the UKF, the TSKF, and the ATSKF are given in Figs. 45.17a, 45.18a, and 45.19a, respectively. The experimental application shows a fast and precise estimation of the fault amplitude despite model uncertainties. The estimates of w_1 , w_2 , and w_3 remain close to zero whereas that of w_3 converges to a value close to 0.45.

45.4.2 Simultaneous Faults Scenario: Control Effectiveness Loss in All Motors

In the second scenario, a loss of control effectiveness of 40 % is simulated in all motors (i.e., $w_i = 0.4$ for $i = 1, \dots, 4$). Unlike the previous case, this fault does not affect the system position in the x and y directions but results in a larger loss in altitude due to the feature of the faults, where the system drops to 0.4 m (see Fig. 45.14b). Figure 45.15b shows the system's behavior in the 3D space upon fault injection. The PWM inputs to the four motors are illustrated in Fig. 45.16b. Up to

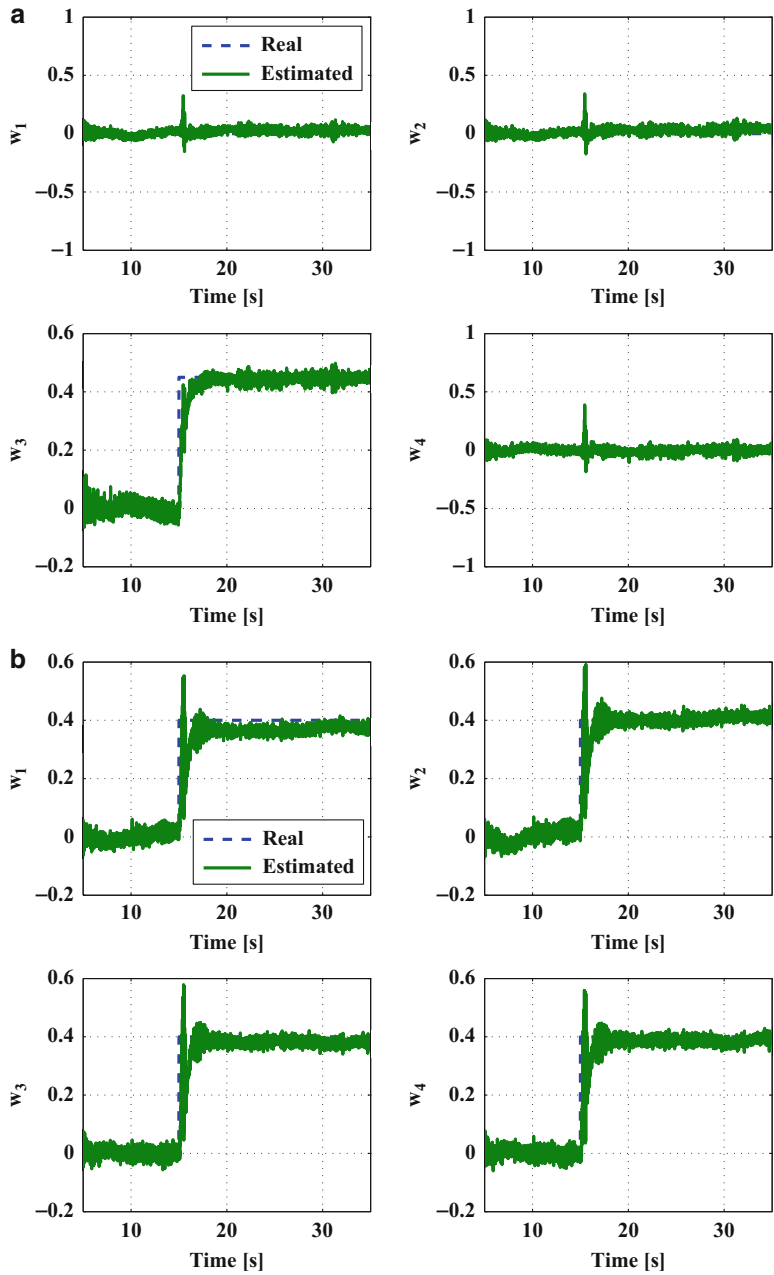

Fig. 45.19 ATSKF control effectiveness factors estimation for single and simultaneous faults scenarios. (a) Single fault scenario, (b) Simultaneous faults scenario

Table 45.1 Mean of execution times (in seconds) for 100 runs

| Fault case | UKF | TSKF | ATSKF |
|---------------------|-------------------------|-------------------------|-------------------------|
| Single fault | 2.8439×10^{-4} | 3.4478×10^{-4} | 7.2427×10^{-4} |
| Simultaneous faults | 2.8782×10^{-4} | 3.5102×10^{-4} | 7.3627×10^{-4} |

15 s and before fault injection, all the four PWM inputs are almost the same. After fault injection, the baseline controller automatically increases the PWM inputs to compensate the occurred faults. The estimation of the actuator faults is given in Figs. 45.17b, 45.18b, and 45.19b. Once again, the experimental application shows a fast and good estimation of all fault amplitudes despite model uncertainties.

45.4.3 Analysis of the Obtained Results

The application of UKF, TSKF, and ATSKF to the Qball-X4 has shown to be effective in estimating actuator faults. A comparison of the obtained results does not allow to draw an obvious superiority of one approach over the others. Moreover, fine-tuning the filter parameters can always improve the results, making them dependent on the gains selection. This is why a comparison which is based solely on Figs. 45.17–45.19 may not be sufficient. The ultimate objective of the present work is to implement the filters onboard the Qball-X4. Due to the limited calculation capabilities of the onboard microcomputer, the computational complexity of the filters is an important factor to investigate. In the current situation, the Gumstix embedded computer runs with a frequency of 200 Hz which is equivalent to a sample time of 0.005 s. In real-time systems, the timing behavior is an important property of each task. It has to be guaranteed that the execution of a task does not take longer than a specified amount of time. Thus, a knowledge about the maximum execution time of programs is of utmost importance (Puschner and Koza 1989). It turns out that each of the filters above is expected to execute in 0.005 s for every new set of data. For comparison purpose, the filters are implemented on a desktop computer running Intel Core i5 CPU with 2.67 GHz processing speed and 3 GB of RAM. Moreover, 100 different runs are carried out to reduce possible effects of programs running in the background. Table 45.1 gives a quantitative comparison of the mean time (in seconds) taken by each filter to execute. One can see that UKF is the fastest to execute with slight superiority over the TSKF mainly because UKF only considers the parameter estimation problem. On the other hand, the ATSKF is twice slower to execute than the TSKF. Figure 45.20 shows the execution times for each of the filters in the single fault case. The left-hand side of the figure illustrates the mean of the execution times for the 100 runs. The right-hand side shows one of the 100 runs and the execution time for each sample time.

45.5 Conclusion

This chapter considered the FDD and FTC problems for unmanned aerial vehicles. It presented a detailed review on the existing experimental works in these domains. The considered test beds can be categorized into two types: the fixed-wing as well

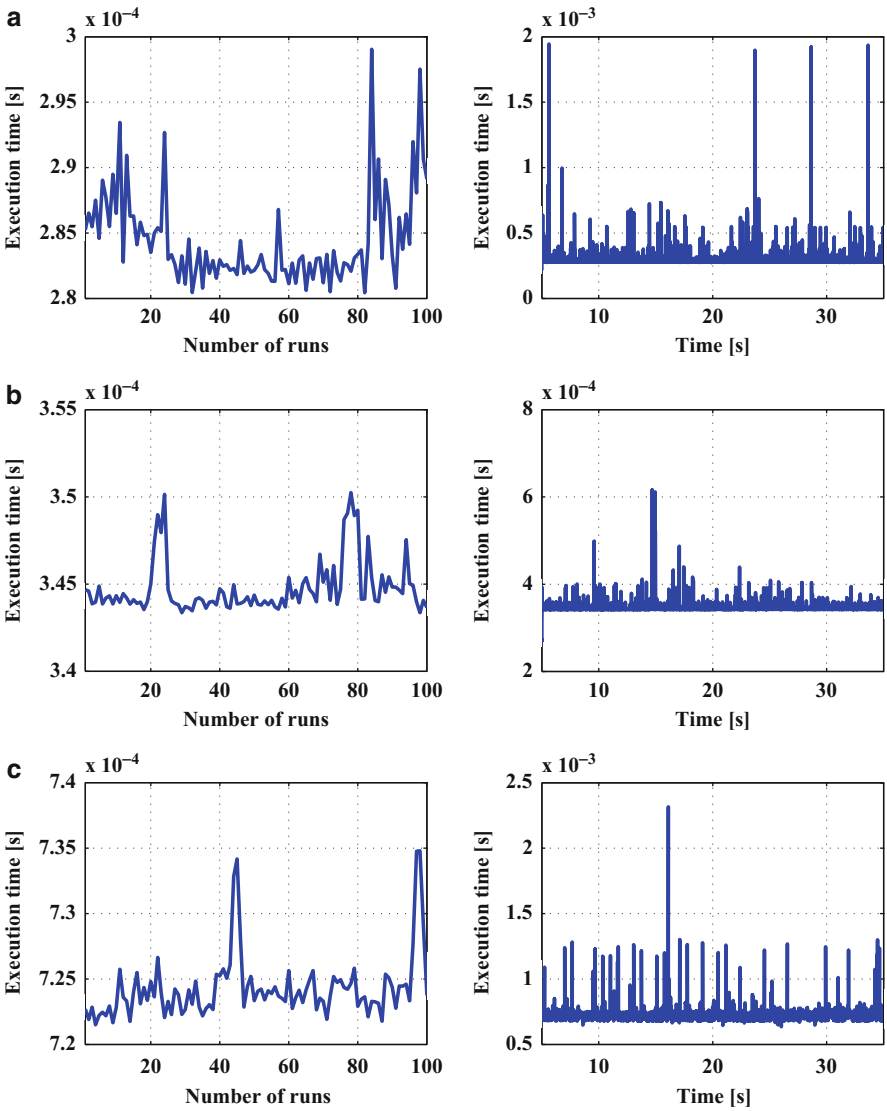

Fig. 45.20 Execution times of UKF, TSKF, and ATSKF in the single fault case, (a) The UKF execution time, (b) The TSKF execution time, (c) The ATSKF execution time

as the rotary-wing systems including the single-rotor and the multiple-rotor systems (also known as quadrotors). The chapter also presents some experimental results on the actuator FDD problem carried out at Concordia University and applied to a cutting-edge quadrotor test bed. The considered approaches are the UKF, the TSKF, and the ATSKF which have shown to be effective in estimating the actuator control effectiveness factors. A quantitative comparison is also given on the filter's execution times and their computational complexity to judge on their possible implementation onboard the quadrotor.

Acknowledgments This work is supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) Postdoctoral Fellowship (PDF) program to the first author and the NSERC Strategic Project Grant and Discovery Project Grant led by the third author. Support from Quanser Inc. and colleagues from Quanser Inc. for the development of the Qball-X4 UAV test bed is also highly appreciated.

Abstract

This chapter investigates a simultaneous state and parameter estimation-based fault detection and diagnosis (FDD) scheme for application to a realistic nonlinear six degree-of-freedom fixed-wing unmanned aerial vehicle (UAV) model: the NASA GTM (generic transport model). The NASA GTM UAV model was developed in the MATLAB/Simulink environment under the NASA Aviation

Safety Program (AvSP). By introducing partial loss faults in actuators into the NASA GTM, a dual unscented Kalman filter (DUKF) algorithm is applied for the purpose of online estimation of both flight states and fault parameters. A Bayesian rule is then used for detection and isolation decision-making. The developed FDD scheme has been implemented in both the nonlinear GTM and the linear parameter-varying (LPV) representation of the nonlinear GTM. Simulation results show satisfactory results for detecting and diagnosing the control effectors faults.

46.1 Introduction

Loss of control has become one of the main causes of airplane crashes and crash-related fatal accidents worldwide (see Belcastro 2011 and the references therein). Thus, it is necessary to enable airplanes to increase the fault tolerance capability when unexpected faults occur in the airplane during flight. When a fault occurs in an airplane, the first and main problem to be solved is to detect what and where the fault is, to determine the severity level (magnitude) of the fault, and then to provide a solution for handling or compensating for the fault-induced changes of the airplane to guarantee at least a safe landing. This has been the motivation and topics for fault detection and diagnosis (FDD) and fault-tolerant control (FTC) in aviation industry since the 1980s (Zhang and Jiang 2008; Sadeghzadeh and Zhang 2011). A good FDD scheme should be able to report detailed information for the post-fault system as quick and accurate as possible. As one of most recent efforts by NASA on the purpose of investigating flight dynamics, control, and behavior of aircraft under upset conditions, NASA has built a test bed, which is known as the AirSTAR Flight Test Facility, where an integral part of which is the GTM (generic transport model) unmanned aerial vehicle (UAV) (Jordan et al. 2006). The NASA GTM UAV is a 5.5 % dynamically scaled, turbine powered fixed-wing civil transport aircraft. Associated with the NASA Aviation Safety Program (AvSP), researches on adaptive control, fault-tolerant control, health monitoring and fault diagnosis, safe envelope assessment, and loss-of-control analysis have been carried out recently based on the GTM software simulation environment and real flight tests. A few examples of many relevant works are given in Pandita et al. (2009), Ruschmann et al. (2009), Ma and Zhang (2010a, b), Guo and Tao (2011, 2012), Kwatny et al. (2009), Gregory et al. (2010), Hovakimyan et al. (2011), Belcastro (2011), and Xu and Liu (2011). In this chapter, however, development and application of an FDD scheme is mainly presented based on the work carried out in Ma and Zhang (2010a, b) and Ma (2011), which is based on the nonlinear and linear parameter varying (LPV) model (Shin 2000; Marcos and Balas 2004; Pandita et al. 2009) of the GTM UAV in the event of actuator faults/failures. The FDD scheme used is a dual unscented Kalman filter (DUKF) (Julier and Uhlmann 1997; Wan and van der Merwe 2000) with real-time fault parameter estimation based on the measured outputs of the sensors and the control inputs to actuators.

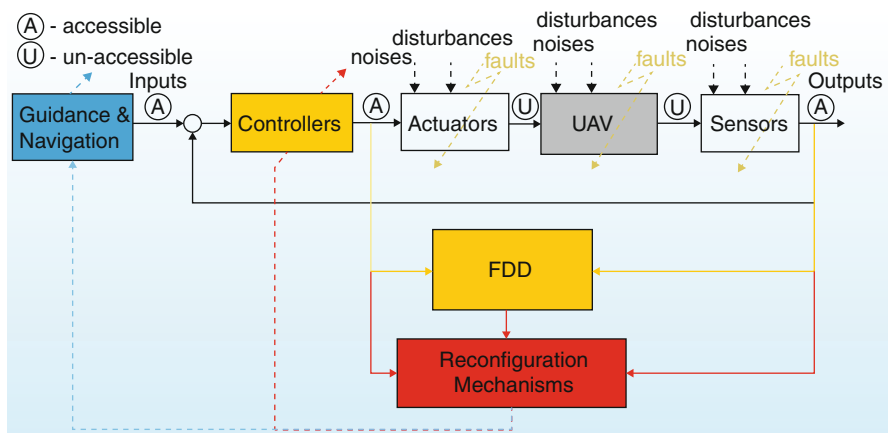

Fig. 46.1 A general structure of an active fault-tolerant control system

For a high performance FDD/FTC scheme, when a fault/failure/damage occurs in either an actuator, a sensor, or a component of the airplane/UAV, the FDD scheme should detect and diagnose the source and the magnitude of the fault timely and precisely. The reconfiguration scheme for FTC will design a reconfigurable/fault-tolerant controller based on the information provided by the FDD scheme to adapt post-fault airplane to an appropriate new operating condition under the fault/failure/damage. In the case of a new flight path for a safe landing to a nearest airport or landing area is needed, reconfiguration for guidance and navigation law (or reconfigurable guidance and navigation law (RGNL)) should also be needed. Therefore the entire airplane/UAV can still maintain its stability and achieve probably degraded but acceptable level of performance. Figure 46.1 depicts the general structure of such an active fault-tolerant control system (AFTCS) with the functional block diagrams of four main modules (instead of traditional three main modules as outlined in Zhang and Jiang (2008)—with insertion of a new RGNL block in the overall AFTCS). In this chapter, however, only the FDD functional block is considered with the overall content arrangement of this handbook. More specifically, an FDD scheme based on a dual unscented Kalman filter (DUKF) algorithm is described with application to the NASA GTM UAV.

The chapter is organized as follows. In Sect. 46.2, the nonlinear GTM and the LPV model of the nonlinear longitudinal GTM model will be briefly introduced. In Sect. 46.3, the UKF and DUKF are presented. In Sect. 46.4, an FDD scheme based on the DUKF is described. In Sect. 46.5, the simulation results for the nonlinear GTM and the LPV model of GTM are presented. Brief conclusion is given in Sect. 46.6.

46.2 Nonlinear GTM and LPV Model of Nonlinear Longitudinal Motion of the GTM

46.2.1 Brief Description of the Nonlinear Dynamic Model of GTM

In this section, brief introduction to the nonlinear NASA GTM UAV model and the LPV model representation of the nonlinear longitudinal motion of the GTM will be given.

The GTM is a dynamically scaled small fixed-wing unmanned aerial vehicle model developed by NASA to investigate modeling and control of large transport vehicles in upset conditions. The UAV is 5.5 % dynamically scaled to realistically simulate characteristics of a full-scale large civil transport jet aircraft.

The nonlinear dynamic equations of the GTM are

$$\dot{u} = [C_{X_{\alpha,\beta}} + C_{X\hat{q}} + C_{X_{\delta e}} + C_{X_{\delta T}} + (C_{X_{\delta r}} + C_{X_{\delta a}})] \frac{S\bar{q}}{m} - g \sin \theta + rv - qw \quad (46.1)$$

$$\dot{w} = [C_{Z_{\alpha,\beta}} + C_{Z\hat{q}} + C_{Z_{\delta e}} + C_{Z_{\delta T}} + (C_{Z_{\delta r}} + C_{Z_{\delta a}})] \frac{S\bar{q}}{m} + g \cos \theta \sin \phi - ru + pw \quad (46.2)$$

$$\begin{aligned} \dot{q} = & [C_{m_{\alpha,\beta}} + C_{m\hat{q}} + C_{m_{\delta e}} + C_{m_{\delta T}} + (C_{m_{\delta r}} + C_{m_{\delta a}})] \frac{S\bar{q}\bar{c}}{I_{yy}} + rp(I_{zz} - I_{yy}) \\ & + \frac{I_{xz}(p^2 - r^2)}{I_{yy}} \end{aligned} \quad (46.3)$$

$$\dot{v} = [C_{Y_{\alpha,\beta}} + C_{Y\hat{p}} + C_{Y_{\delta r}} + C_{Y_{\delta a}} + (C_{Y_{\delta e}} + C_{Y_{\delta \hat{r}}})] \frac{S\bar{q}}{m} + g \cos \theta \cos \phi + qu - pv \quad (46.4)$$

$$D = [C_{l_{\alpha,\beta}} + C_{l\hat{p}} + C_{l_{\delta r}} + C_{l_{\delta a}} + (C_{Y_{\delta e}} + C_{Y_{\delta \hat{r}}})] S\bar{q}b + rp(I_{zz} - I_{yy}) + I_{xz} \quad (46.5)$$

$$E = [C_{m_{\alpha,\beta}} + C_{m_{\hat{p}}} + C_{m_{\delta r}} + C_{m_{\delta a}} + (C_{m_{\delta e}} + C_{m_{\delta \hat{r}}})] S\bar{q}b + pq(I_{yy} - I_{xx}) + I_{xz} \quad (46.6)$$

$$\dot{p} = \frac{I_{yy}I_{zz}D + I_{xz}I_{yy}E}{I_{yy}I_{xx} + I_{xz}^2I_{yy}} \quad (46.7)$$

$$\dot{r} = \frac{I_{yy}I_{xz}D + I_{xx}I_{yy}E}{I_{yy}I_{xx} + I_{xz}^2I_{yy}} \quad (46.8)$$

$$\dot{\phi} = p + (q \sin \phi \sin \theta + r \cos \phi \sin \theta) / \cos \theta \quad (46.9)$$

$$\dot{\theta} = q \cos \phi - r \sin \phi \quad (46.10)$$

$$\dot{\psi} = (q \sin \phi + r \cos \phi) / \cos \theta \quad (46.11)$$

In order to simplify the dynamic equations, the following assumptions have been made:

1. $I_{xy} = 0$ and $I_{yz} = 0$.
 2. Mass is assumed to remain constant.
 3. The center of gravity is assumed to be constant and fixed at the nominal value.
- Lift, drag, and pitching moment coefficients are implemented by lookup tables in the MATLAB/Simulink environment.

The state variables of the six degree-of-freedom UAV are defined as

$$x = [u \ v \ w \ p \ q \ r \ \phi \ \theta \ \psi]^T$$

46.2.2 LPV Model of the GTM

As the emerging approach to control theory, linear parameter-varying (LPV) modeling and control of nonlinear systems have been widely studied in dynamic systems since the early 1990s (Shin 2000; Marcos and Balas 2004; Mohammadpour and Scherer 2012). Applications have been successful in certain cases. An LPV model simulates the actual nonlinear system by using time-varying real parameters like altitude and/or speed of an airplane to obtain smooth semi-linear models. However, there are a few investigations for FDD design with LPV model. Since FDD in this work is a model-based estimation, the LPV model is chosen for the FDD design to the nonlinear model of the GTM as well due to real-time implementation consideration.

For the sake of brevity, the basic definition of an LPV model for a nonlinear system is presented. LPV model is a class of finite-dimensional linear models of a nonlinear system whose state-space matrixes A , B , C , and D depend continuously on a time-varying parameter vector $\xi(t)$. Parameters $\xi(t)$ can be measured at the current time, and their values are constrained a priori to lie in some known, bounded set, and this set is continuous, but cannot be known in advance. The formal definition of an LPV model can be given as follows:

Given a compact subset $\mathcal{P} \subset \mathcal{R}^s$, the parameter variation set $\mathcal{F}_{\mathcal{P}}$ denotes the set of all piecewise continuous functions mapping \mathcal{R}^+ (time) into ξ with a finite number of discontinuities in any interval.

Given continuous functions, $A : \mathcal{R}^s \rightarrow \mathcal{R}^{n \times n}$, $B : \mathcal{R}^s \rightarrow \mathcal{R}^{n \times n_u}$, $C : \mathcal{R}^s \rightarrow \mathcal{R}^{n_y \times n}$, $A : \mathcal{R}^s \rightarrow \mathcal{R}^{n_y \times n_u}$, an n th-order LPV model of a given nonlinear system is defined as

$$\begin{bmatrix} \dot{x}(t) \\ y(t) \end{bmatrix} = \begin{bmatrix} A(\xi(t)) & B(\xi(t)) \\ C(\xi(t)) & D(\xi(t)) \end{bmatrix} \begin{bmatrix} x(t) \\ u(t) \end{bmatrix} \quad (46.12)$$

where $\xi(t) \in \mathcal{F}_{\mathcal{P}}$.

Now the key task is to select an adequate $\xi(t)$ such that the above LPV model is able to capture the nonlinearities of the system. So far, there are three techniques for

obtaining LPV models from a nonlinear system (Marcos and Balas 2004; Pandita et al. 2009; Kwatny et al. 2009).

- *Jacobian linearization approach.* It is implemented at a number of selected equilibrium points. The Jacobian linearization approach uses first-order Taylor series expansion of nonlinear model to create an LPV model which approximates the nonlinear system with respect to selected equilibrium points. The drawback of this approach is that it is easy to be divergent and hard to obtain the transient behavior of the nonlinear system.
- *State transformation approach.* This approach is proposed based on exact state transformations at a number of selected equilibrium points. It requires that $\xi(t)$ must be available in real time for measurement. The disadvantage of this approach is that the existence of trim map for the entire flight envelope of interest for a particular combination of the scheduling variables is not guaranteed.
- *The function substitution approach.* This approach is to obtain an LPV model at a unique trim point by decomposing the nonlinear function. The main drawback of this approach is the lack of theoretical validation.

For developing the LPV model based on the nonlinear GTM in longitudinal motion, the following nonlinear equations of motion of the GTM can be given as (Pandita et al. 2009)

$$V_{EAS} = \frac{1}{m} (F_x \cos \alpha + F_z \sin \alpha) \quad (46.13)$$

$$\dot{\alpha} = \frac{1}{m V_{EAS}} (-F_x \sin \alpha + F_z \cos \alpha) + q \quad (46.14)$$

$$\dot{\theta} = q \quad (46.15)$$

$$\dot{q} = \frac{M_y}{I_{yy}} \quad (46.16)$$

These equations contain transcendental functions and aerodynamic data which are obtained through wind tunnel testing and flight tests. The transcendental functions can be approximated by third-order Taylor series expansion as follows:

$$\sin x = x - \frac{1}{6}x^3 \quad (46.17)$$

$$\cos x = 1 - \frac{1}{2}x^2 \quad (46.18)$$

The aerodynamic data which are obtained by using lookup tables in the nonlinear model of the GTM can be approximated by polynomial equations (Ruschmann et al. 2009).

The LPV model of the longitudinal motion of the GTM has state variables $x = [\text{EAS } \alpha \ \theta \ q]^T$ with equivalent airspeed (EAS), angle of attack (α), pitch angle (θ), and pitch angular rate (q). The input vector u is given by $u = [\delta_e \ \delta_{th}]^T$, with δ_e

representing elevator deflection and δ_{th} representing throttle deflection. Therefore aerodynamic forces F_x and F_z and moment M_y are obtained through the following equations:

$$F_x = \bar{q} S_{\text{ref}} [C_x(\alpha) + C_x(\alpha, \delta_e) + C_x(\alpha, \hat{q})] + 2T_x(\delta_{th}) - mg \sin \theta \quad (46.19)$$

$$F_z = \bar{q} S_{\text{ref}} [C_z(\alpha) + C_z(\alpha, \delta_e) + C_z(\alpha, \hat{q})] + 2T_z(\delta_{th}) + mg \cos \theta \quad (46.20)$$

$$M_y = \bar{q} S_{\text{ref}} \bar{c} [C_m(\alpha) + C_m(\alpha, \delta_e) + C_m(\alpha, \hat{q})] + 2\Delta Z_{\text{ENG}} T_x(\delta_{th}) \quad (46.21)$$

where the aerodynamic coefficients of angle of attack α , pitch rate q , and elevator deflection δ_e are obtained through lookup tables.

For FDD purpose, partial loss of control effectiveness fault in elevator has been implemented in this work from the original LPV model of the GTM (Pandita et al. 2009; Ruschmann et al. 2009).

46.3 Unscented Kalman Filter (UKF) and Dual Unscented Kalman Filter (DUKF)

For nonlinear aircraft systems, the extended Kalman filter (EKF) has been widely applied (Zhang and Jiang 2008; VanDyke et al. 2004). The EKF is the nonlinear version of the Kalman filter (KF), and it linearizes nonlinear system about the current equilibrium point with the characteristics of random state variables described by mean and covariance. Hence, the EKF can only preserve the first-order system statistics and may quickly diverge if the system is not modeled correctly also due to the use of linearized model of the nonlinear system. The UKF is an improvement of the EKF to replace the EKF in nonlinear filtering problems. UKF was originally developed by Wan and van der Merwe (2000) and Julier and Uhlmann (1997), and it has been mainly used to nonlinear systems estimation, identification, and training of neural networks, etc.

The UKF picks a minimal set of sample points which are called *sigma points* around the mean by the unscented. These sigma points are then propagated through nonlinear functions and the covariance of the estimate is then recovered. In the UKF, the probability density is approximated by the nonlinear transformation of a random variable, which returns much more accurate results than the first-order Taylor expansion of the nonlinear functions used in the EKF. The approximation utilizes a set of sample points (*sigma points*), which captures the posterior mean and covariance accurately to the third-order Taylor series expansion for any nonlinearity (Wan and van der Merwe 2001). Therefore, the UKF captures both the first-order and second-order statistics of a nonlinear system. It has been demonstrated that the UKF has better filter performance compared with EKF and is equivalent to the performance of second-order EKF (Wan and van der Merwe 2000; Julier and

Fig. 46.2 Example of the UT for mean and covariance propagation (Wan and van der Merwe 2001)

Uhlmann 1997). Figure 46.2 shows an example of the unscented transformation (UT) for mean and covariance propagation.

From Fig. 46.2, one can see that the result of UKF is more accurate to capture the true mean and covariance than other Kalman filters can do.

The main motivation for using UKF to FDD application resides in the advantages and the superiority of this approach over the EKF and more specifically the better convergence characteristics and greater accuracy in the case of nonlinear systems (VanDyke et al. 2004). However, to provide good estimation to the unknown parameters in the system due to, for example, fault-induced parameter changes, a separate estimation to the unknown parameters is needed. In other words, an estimation scheme for simultaneous states and parameters based on UKF is needed. Inspired with EKF for such a simultaneous states and parameter estimation issue, a dual unscented Kalman filter (DUKF) scheme was proposed in Wan and van der Merwe (2001). This in fact motivated the research for using such a DUKF to the GTM fault detection and diagnosis application (Ma and Zhang 2010a; Ma 2011).

46.3.1 Unscented Transformation (UT)

The unscented transformation is a method for calculating the statistics of a random variable which undergoes a nonlinear transformation (Wan and van der Merwe 2001). It is built upon the principle that it is easier to approximate a probability distribution than an arbitrary nonlinear function. The approach is illustrated in Fig. 46.3.

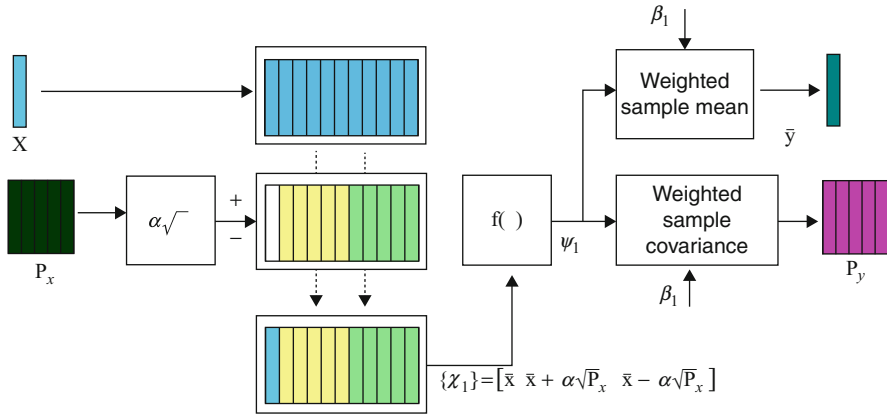

Fig. 46.3 The principle of the unscented transform (Wan and van der Merwe 2001)

Consider a nonlinear model $y = f(x)$, and the random variable x whose dimension is L , and assume x has mean \bar{x} and covariance P_x . The basic steps of UT are:

- Choose a set of points (sigma points) so that their sample mean and sample covariance are \bar{x} and P_x .
- Apply each sigma point in turn to the nonlinear function to yield a cloud of transformed points, and \bar{y} and P_y are the statistics of the transformed points.

The L -dimensional random variable x with mean \bar{x} and covariance P_x is approximated by $2L + 1$ sigma points. In order to calculate the statistics of y , χ , which is the matrix of $2L + 1$ sigma vectors χ_i , is formed:

$$\chi_0 = \bar{x} \quad (46.22)$$

$$\chi_i = \bar{x} + \left(\sqrt{(L + \lambda) P_x} \right)_i, \quad i = 1, \dots, L \quad (46.23)$$

$$\chi_i = \bar{x} - \left(\sqrt{(L + \lambda) P_x} \right)_i, \quad i = L + 1, \dots, 2L \quad (46.24)$$

The weights for the state and covariance are given by

$$\sigma_0^{(m)} = \frac{\lambda}{L + \lambda} \quad (46.25)$$

$$\sigma_0^{(c)} = \frac{\lambda}{L + \lambda} + (1 - \rho^2 + \sigma) \quad (46.26)$$

$$\sigma_i^{(m)} = \sigma_i^{(c)} = \frac{1}{2(L + \lambda)}, \quad i = 1, \dots, 2L \quad (46.27)$$

where $\lambda = \rho^2(L + \kappa) - L$ is a scaling parameter. ρ determines the spread of the sigma points around \bar{x} . The κ is a secondary scaling parameter, and σ is to incorporate prior knowledge of the distribution of x . $\left(\sqrt{(L + \lambda) P_x}\right)_i$ is the i th column of the matrix square root. In this book chapter, ρ , σ , and κ are equal to 1, 2, and $3 - L$, respectively. χ_i is propagated through the nonlinear function:

$$\mu_i = f(\chi_i), \quad i = 0, \dots, 2L \quad (46.28)$$

$$\bar{y} \approx \sum_{i=0}^{2L} \sigma_i^{(m)} \mu_i \quad (46.29)$$

$$P_y \approx \sum_{i=0}^{2L} \sigma_i^{(m)} (\mu_i - \bar{y}) (\mu_i - \bar{y})^T \quad (46.30)$$

where \bar{y} is the mean for y and P_y is the covariance of the posterior sigma points. Figure 46.3 presents the implementation of UT.

46.3.2 State Estimation

Consider a nonlinear transform of a random variable: $y = f(x)$

$$\text{Given: } \bar{x} = E[x], P_x = E[(x - \bar{x})(x - \bar{x})^T]$$

$$\text{Find: } \bar{y} = E[y], P_y = E[(y - \bar{y})(y - \bar{y})^T].$$

A set of $2L + 1$ sigma points is derived as following equations from the augmented state and covariance where L denotes the dimension of the augmented state.

$$\chi_{k-1|k-1}^0 = \chi_{k-1|k-1}^\rho \quad (46.31)$$

$$\chi_{k-1|k-1}^i = \chi_{k-1|k-1}^\rho + \left(\sqrt{(L + \lambda) P_{k-1|k-1}^\rho}\right)_i, \quad i = 1, \dots, L \quad (46.32)$$

$$\chi_{k-1|k-1}^i = \chi_{k-1|k-1}^\rho - \left(\sqrt{(L + \lambda) P_{k-1|k-1}^\rho}\right)_i, \quad i = L + 1, \dots, 2L \quad (46.33)$$

where $\left(\sqrt{(L + \lambda) P_{k-1|k-1}^\rho}\right)_i$ is the i th column of the matrix square root of $\sqrt{(L + \lambda) P_{k-1|k-1}^\rho}$. Using the definition, square root A of matrix B satisfies $B \equiv AA^T$. χ is the matrix of $2L + 1$ sigma vectors. The complete state estimation of the UKF is given in Table 46.1.

Table 46.1 The UKF state estimation algorithm

– Initialize the state vector and covariance with

$$\hat{x}_0 = E\{x_0\}$$

$$\hat{x}^\rho = E\{x^\rho\} = [\hat{x}_0^T \ 0 \ 0]^T$$

$$P_0 = E\{(x_0 - \hat{x}_0)(x_0 - \hat{x}_0)^T\}$$

$$P_0^\rho = E\{(x_0^\rho - \hat{x}_0^\rho)(x_0^\rho - \hat{x}_0^\rho)^T\} = \begin{bmatrix} P_0 & 0 & 0 \\ 0 & R^v & 0 \\ 0 & 0 & R^n \end{bmatrix}$$

– For $k \in \{1, \dots, N\}$, calculate the *sigma points* from the a priori state vector mean and covariance

$$\chi_{k-1}^\rho = [\hat{x}_{k-1}^\rho \quad \hat{x}_{k-1}^\rho + \eta\sqrt{P_{k-1}^\rho} \quad \hat{x}_{k-1}^\rho - \eta\sqrt{P_{k-1}^\rho}]$$

– For $k \in \{1, \dots, N\}$, calculate the *time update* of the state vector and covariance

$$\chi_{k|k-1}^x = F(\chi_{k-1}^x, u_{k-1}, \chi_{k-1}^n)$$

$$\mathcal{Y}_{k|k-1} = H(\chi_{i,k|k-1}^x, \chi_{k-1}^n)$$

$$\hat{x}_k^- = \sum_{i=0}^{2L} \sigma_i^{(m)} \chi_{i,k|k-1}^x$$

$$\hat{y}_k^- = \sum_{i=0}^{2L} \sigma_i^{(m)} \mathcal{Y}_{i,k|k-1}$$

$$P_k^- = \sum_{i=0}^{2L} \sigma_i^{(c)} (\chi_{i,k|k-1}^x - \hat{x}_k^-) (\chi_{i,k|k-1}^x - \hat{x}_k^-)^T$$

– For $k \in \{1, \dots, N\}$, calculate the *measurement update* of the state vector and covariance

$$P_{d_k \tilde{d}_k} = \sum_{i=0}^{2L} \sigma_i^{(c)} (\mathcal{D}_{i,k|k-1} - \hat{d}_k) (\mathcal{D}_{i,k|k-1} - \hat{d}_k)^T + R_k^e$$

$$P_{x_k d_k} = \sum_{i=0}^{2L} \sigma_i^{(c)} (\chi_{i,k|k-1}^x - \hat{x}_k^-) (\mathcal{D}_{i,k|k-1} - \hat{d}_k)^T$$

$$\mathcal{K}_k = P_{x_k d_k} P_{d_k \tilde{d}_k}^{-1}$$

$$\hat{x}_k = \hat{x}_k^- + \mathcal{K}_k (d_k - \hat{d}_k)$$

$$P_k = P_k^- - \mathcal{K}_k P_{d_k \tilde{d}_k} \mathcal{K}_k^T$$

where $\eta = \sqrt{L + \lambda}$, $x^\rho = [x \ v \ n]^T$, $\chi^\rho = [(\chi^x)^T \ (\chi^v)^T \ (\chi^n)^T]^T$, λ is the composite scaling parameter, L is the dimension of augmented states, N is the total number of sample data, R^v is process noise covariance matrix, R^n is measurement noise covariance matrix, and σ_i is the weights as calculated in Eq. (46.27)

46.3.3 Parameter Estimation

The parameter estimation problem involves determining a nonlinear mapping $y_k = G(x_k, \gamma)$ where x_k is the input, y_k is the output, and the nonlinear map G is parameterized by the parameter vector γ . Typically, a training set is provided with sample pairs consisting of known inputs and desired outputs, $\{x_k, d_k\}$, where $k = 1, \dots, N$ and N is the total number of sample data. The error is defined as $e_k = d_k - G(x_k, \gamma)$, and the goal of estimation involves solving for the parameters γ in order to minimize some given function of the error (der Merwe and Wan 2001). Parameters can be efficiently estimated online by writing a new state-space representation as follows:

$$\gamma_k = \gamma_{k-1} + r_{k-1}^\gamma \quad (46.34)$$

$$d_k = G(x_k, \gamma_k) + e_k \quad (46.35)$$

where $\eta = \sqrt{L + \lambda}$, λ is the composite scaling parameter, L is the dimension of parameters to be estimated, N is the total number of sample data, R^r is process noise covariance matrix, and R^e is measurement noise covariance matrix

where γ_k corresponds to a stationary process, driven by process noise r_{k-1}^γ , and the output d_k corresponds to a nonlinear observation on γ_k . The complete parameter estimation of the UKF is given in Table 46.2.

46.3.4 The DUKF Estimation

The dual estimation problem, referred to as dual unscented Kalman filter (DUKF), consists of simultaneously estimating the states x and the unknown parameters γ in a coupled sequential way from the measured noisy data sequence y_k . The DUKF estimation solves this problem through performing the state and parameter estimation simultaneously, however, in a slightly different way as in the two-stage Kalman filter (TSKF) (Wu et al. 2000; Zhang and Jiang 2002). In reviewing the currently available simultaneous estimation of state and parameter techniques that can be applied to any Kalman filter, three methods are classified in this book chapter. These techniques include the following: joint, separated, and dual

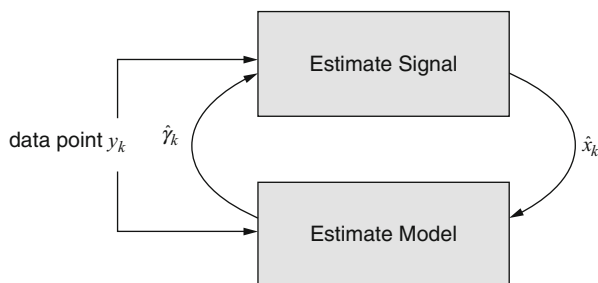

Fig. 46.4 Sequential approach of DUKF designed to pass over the data one point at a time for simultaneous state and parameter estimation (Wan and van der Merwe 2001)

estimation. They all use an analogous filter to estimate the parameters concurrently with the states. However, the joint method (e.g., the EKF) is the simplest of the three to conceptualize: the parameter vector of interest is simply appended onto the original state vector. The time update for the parameter vector portion of the augmented state vector allows no change beyond the effects of process noise, but the entire augmented covariance matrix is propagated as one (Cui and Chen 2009). Different from the joint method, the separated method (e.g., the TSKF) separates estimation of states and parameters with a reduced order of the two coupled sequential estimation processes for the states and parameters separately, therefore, reducing significantly the computational requirement comparing with the joint method. Certain speeding-up techniques, such as forgetting factors commonly used in system identification applications, can also be used for achieving fast convergence of parameter estimation, as the adaptive two-stage Kalman filter (ATSKF) proposed in Wu et al. (2000) and Zhang and Jiang (2002) for linear systems and the adaptive two-stage extended Kalman filter (ATSEKF) proposed in Zhang and Wu (1999) for nonlinear systems. The dual estimation method intertwines a pair of distinct sequential filters, one estimating the original/true states and the other estimating the parameters (Wan and van der Merwe 2001; VanDyke et al. 2004). The dual estimation technique is investigated in this work. The primary benefit of dual estimation is the ability to temporarily decouple the parameter filter from the state filter as needed. Decoupling can prevent erratic behavior due to poor measurements or initial estimate of the parameter estimation from causing the state filter to diverge (VanDyke et al. 2004).

At every time instant with new measurement, the UKF state filter estimates the states using the current parameter estimates $\hat{\gamma}_k$ obtained from Table 46.2, while the UKF parameter filter estimates the parameters based on the current state estimates \hat{x}_k obtained from Table 46.1. Such a sequential estimation scheme is shown in Fig. 46.4.

46.4 Fault Detection and Diagnosis Based on Dual Unscented Kalman Filter

46.4.1 Brief Introduction to FDD

The problem of fault detection and diagnosis (FDD) in dynamic systems has drawn a lot of attention since the 1960s. Many different techniques have been developed and successfully applied to various practical systems, as can be seen in several published comprehensive survey papers and books listed in Zhang and Jiang (2008) and more recent applications to UAVs in Amoozgar et al. (2013) and Zhang et al. (2013). Among the existing techniques, model-based approaches play an important role. Most model-based FDD methods rely on the concept of analytical redundancy. The essence of this concept is the comparison of the actual outputs of the monitored system with the outputs obtained from a mathematical model of the monitored system. The discrepancies, called as *residuals*, are used as an indication of faults. The diagnostic procedure usually consists of two steps: (1) residuals generation/generator and (2) residuals evaluation/evaluator (decision-making), as shown in Fig. 46.5. Typically, the FDD scheme has three tasks: (1) *fault detection* indicates that something has gone wrong in the monitored system, i.e., fault detection determines the occurrence of a fault and the time of the fault occurrence; (2) *fault isolation* determines the location and type of the fault (which component is faulty); and (3) *fault identification* determines the magnitude (size) of the fault. Fault isolation and identification are usually referred to as *fault diagnosis* in the literature (Isermann and Balle 1997; Zhang and Jiang 2008).

In engineering systems, including UAVs, faults can occur in actuators, sensors, and other system components. Faults can appear in the form of slowly developing (incipient) changes or abrupt changes. Further, depending on the physical properties of the fault, a fault can be added on the system in an additive or multiplicative way. Therefore, an effective FDD scheme should be able to fulfil the following basic tasks: (1) detect, isolate, and identify faults in actuators, sensors, and components; (2) detect, isolate, and identify abrupt faults as well as incipient faults and (3) detect, isolate, and identify additive and multiplicative faults.

46.4.2 Residual Generation

Based on the fundamental principle used in each technique, the existing residual generation algorithms can be classified into four categories: (1) state estimation based, (2) parameter estimation based, (3) parity space based, (4) as well as the combination of these three, as shown in Fig. 46.6. Different FDD schemes, based on different model representations of the systems, fulfil different tasks and possess different performance in FDD. For example, some of schemes can only fulfil the first two tasks: fault detection and isolation (FDI). Therefore, FDI, instead of FDD, is often used in the literature.

Fig. 46.5 Two-stage procedure of FDD schemes: residual generation and residual evaluation

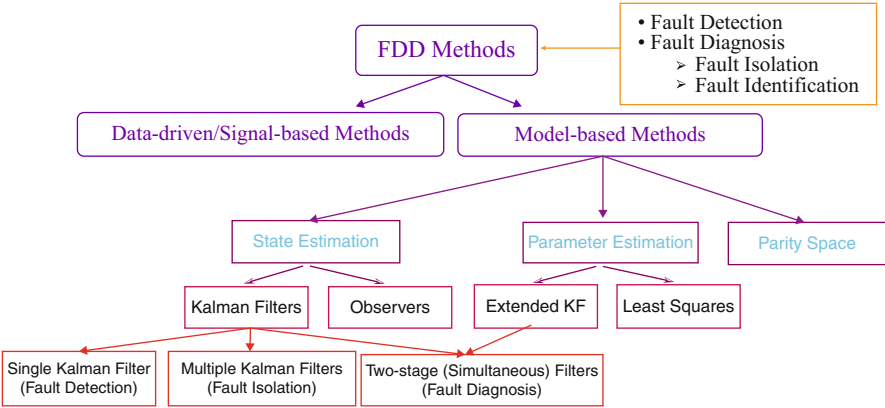

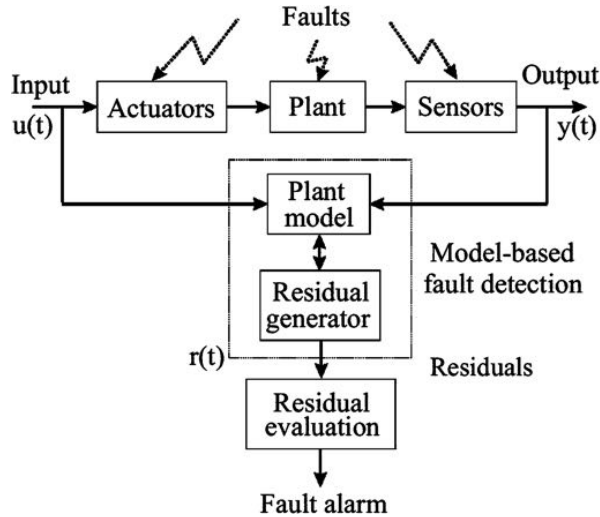

Fig. 46.6 Classification of FDD methods for residual generation

In state estimation-based approaches, the model of the system and the input-output data are utilized to synthesize an estimator (an observer in deterministic case and a Kalman filter in stochastic case). If the system operates normally, the residual of the estimator should be very small (or a white noise process in Kalman filter case). Otherwise, it will be large (or nonwhite). Therefore, such a residual signal can be used for the purpose of fault detection.

In parameter estimation-based approaches, the parameters of the system are estimated online in real time based on input-output data. The estimated parameters are then compared with the nominal ones for the purpose of FDD. In the absence of a system fault, the difference between these two parameter sets should be very small.

However, if a fault has occurred in the system, the difference will be relatively large. Therefore, FDD can be carried out simply by checking the parameter discrepancies.

Parity equations are a relatively simple and straightforward approach to build residuals that indicate faults. More sophisticated schemes with the ability to detect different faults can be gained from multi-input and multi-output processes. Parity equations require the knowledge of a fixed parameterized model that serves as a reference for the measured behavior. They are closely related to observer methods but their design is easier. A direct design from state-space equations or directly from the Laplace-transformed differential equations of the process is possible. Parity equations are especially suitable for additive faults. However, they are sensitive to noise. Parity equations do not need permanent excitation and require less computational effort than parameter estimation, but do not give the same deep insight into the process as parameter estimation. To combine the advantages of parameter estimation and parity equations, it is proposed to supervise the process online with parity equations and to perform parameter estimation after a fault is detected.

A common feature among these methods is to generate a residual signal which should be sensitive to the occurrence of the fault and robust to disturbances and model uncertainties. Because different residual generating mechanisms have been used in different methods, their performance will be different even under the same fault scenario. Subsequently, a very important question arises: which method is most appropriate for a given application? With consideration of using FDD for providing necessary information on the status of post-failure system for control (even guidance and navigation) reconfiguration, the states and system parameter information are necessary for maintaining system/UAV stability and acceptable performance after fault occurrence. Therefore, the three functions in FDD for detection, isolation/localization, and identification are all needed (Zhang and Jiang 2006, 2008). These considerations and requirements are in fact the motivation of this book chapter and the works carried out at (Ma and Zhang 2010a, b).

In particular, the proposed FDD scheme is on the basis of the abovementioned DUKF for residual generation using the simultaneous state and fault parameter estimation.

46.4.3 Residual Evaluation/Decision-Making

Finally, to perform fault detection and isolation, many rules can be used to evaluate the estimated parameters γ^i such as the two-stage statistical hypothesis tests developed in Zhang and Jiang (2002).

In the first stage, the statistical quantities of the system under the normal operation, such as mean values and variances, are determined, and then the same quantities during the continuous system operation are calculated. By defining an appropriate statistical detection variable to accentuate the deviation in the statistical quantities from their normal values, the detection and isolation of the reduction/loss of control effectiveness can be achieved recursively.

Stage I. Under the normal condition, one has

$$\hat{\mathbf{y}}_k \sim \mathcal{N}(\bar{\boldsymbol{\mu}}_{\hat{\mathbf{y}}_0}, \boldsymbol{\sigma}_{\hat{\mathbf{y}}_0}^2) \quad (46.36)$$

where $\hat{\mathbf{y}}_k \in \mathfrak{R}^l$ is the estimate of the reduction of control effectiveness and it can also be used as the residual vector for fault detection. $\bar{\boldsymbol{\mu}}_{\hat{\mathbf{y}}_0} = [\bar{\mu}_{\hat{y}_0^1} \ \bar{\mu}_{\hat{y}_0^2} \ \dots \ \bar{\mu}_{\hat{y}_0^l}]^T$ and $\boldsymbol{\sigma}_{\hat{\mathbf{y}}_0}^2 = \text{diag}[\sigma_{\hat{y}_0^1}^2 \ \sigma_{\hat{y}_0^2}^2 \ \dots \ \sigma_{\hat{y}_0^l}^2]$ are the mean and variance, respectively. These values are obtained, for $i = 1, \dots, l$, by

$$\bar{\mu}_{\hat{y}_0^i} = \frac{1}{N_1} \sum_{j=1}^{N_1} \hat{y}_j^i \quad (46.37)$$

$$\sigma_{\hat{y}_0^i}^2 = \frac{1}{N_1 - 1} \sum_{j=1}^{N_1} [\hat{y}_j^i - \bar{\mu}_{\hat{y}_0^i}]^2 \quad (46.38)$$

The sample size N_1 is chosen to ensure the sufficiency in statistics.

Stage II. Define the following moving window-based statistical quantities:

$$\begin{aligned} \bar{\mu}_{\hat{y}_k^i} &= \frac{1}{N_2} \sum_{j=k-N_2+1}^k \hat{y}_j^i \\ &= \bar{\mu}_{\hat{y}_{k-1}^i} - \frac{1}{N_2} [\hat{y}_{k-N_2}^i - \hat{y}_k^i] \end{aligned} \quad (46.39)$$

$$\begin{aligned} \sigma_{\hat{y}_k^i I}^2 &= \frac{1}{N_2 - 1} \sum_{j=k-N_2+1}^k [\hat{y}_j^i - \bar{\mu}_{\hat{y}_0^i}]^2 \\ &= \sigma_{\hat{y}_{k-1}^i I}^2 - \frac{1}{N_2 - 1} \left[(\hat{y}_{k-N_2}^i)^2 - (\hat{y}_k^i)^2 - 2\bar{\mu}_{\hat{y}_0^i} \varepsilon_k^i \right] \end{aligned} \quad (46.40)$$

$$\begin{aligned} \sigma_{\hat{y}_k^i II}^2 &= \frac{1}{N_2 - 1} \sum_{j=k-N_2+1}^k [\hat{y}_j^i - \bar{\mu}_{\hat{y}_k^i}]^2 \\ &= \sigma_{\hat{y}_{k-1}^i II}^2 + \frac{1}{N_2 - 1} \left[2\varepsilon_k^i \bar{\mu}_{\hat{y}_{k-1}^i} - (\hat{y}_{k-N_2}^i)^2 + (\hat{y}_k^i)^2 - \frac{1}{N_2 - 1} (\varepsilon_k^i)^2 \right] \end{aligned} \quad (46.41)$$

where $\varepsilon_k^i = \hat{y}_{k-N_2}^i - \hat{y}_k^i$ and N_2 is the length of the moving window.

Consequently, a fault in the i th actuator is declared at time k if the following detection index

$$d_k^i = \frac{\sigma_{\hat{y}_k^i I}^2}{\sigma_{\hat{y}_0^i}^2} - \ln \frac{\sigma_{\hat{y}_k^i II}^2}{\sigma_{\hat{y}_0^i}^2} - 1, \quad i = 1, \dots, l \quad (46.42)$$

exceeds a preset threshold η^i .

$$d_k^i \underset{H_0}{\overset{H_i}{\geq}} \eta^i \quad (46.43)$$

where $H_0 = \{\text{No significant reduction in the effectiveness of the } i\text{th actuator}\}$ and $H_i = \{\text{There is significant reduction in the effectiveness of the } i\text{th actuator}\}$. Here, “significant reduction” is a design parameter and should be reflected in the selection of the threshold η^i . The selection of the window length, N_2 , and the threshold, η^i , represents some trade-off between the probability of false alarm and the probability of missed detection.

46.5 Simulation Results

Simulation results and analysis of the nonlinear GTM and the LPV model of GTM using the above DUKF-based FDD scheme are presented in this section. For simulations, it is assumed that the collective elevator actuator encounters a partial loss fault while others remain healthy although the DUKF-based FDD does not have any limitation for handling multiple, simultaneous, and consecutive faults. Consideration of only elevator fault in this work is mainly due to the fact that the longitudinal motion of the GTM UAV has been considered in the simulation validation of the FDD scheme where the only available redundant actuator in UAV longitudinal motion is the engine throttle. The throttle of the GTM UAV is assumed to be kept constant at its trim setting throughout the maneuver. The response to the UAV is captured through equivalent airspeed, angle of attack, pitch angle, and pitch angular rate.

For nonlinear model of GTM, two scenarios are simulated: (1) a 50 % loss of control effectiveness fault in elevator at 5 s and (2) a 20 % loss of control effectiveness fault in elevator at 6 s. To reduce the execution time, the measurement interval of $T = 0.02$ s is used.

The UKF parameters are listed as follows:

$$\rho = 1, \sigma = 2, \kappa = 3 - L, L = 15.$$

where L is the dimension of the augmented states.

46.5.1 FDD Results Based on Nonlinear Model

Assume that at time instant 5 s, elevator encounters a 50 % (50 % of the original normal value) partial loss fault in control effectiveness. The estimation results for states and fault parameters are shown in Figs. 46.7 and 46.8, respectively.

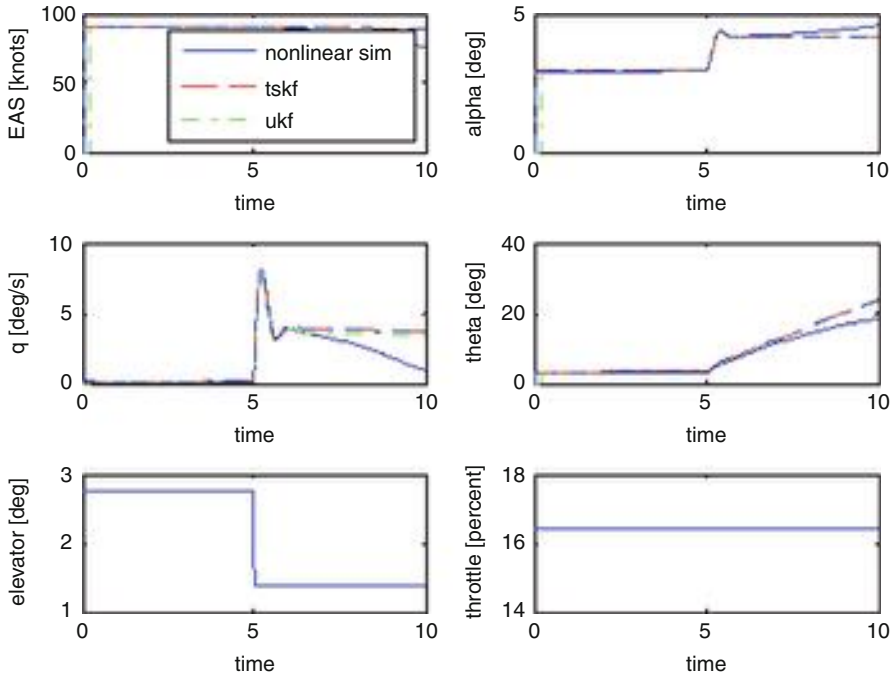

Fig. 46.7 Results of estimated states under 50 % loss of control effectiveness

As shown in the figures, the two-stage Kalman filter (TSKF) and adaptive two-stage extended Kalman filter (ATSEKF) developed in Zhang and Wu (1999), Wu et al. (2000), and Zhang and Jiang (2002) have also been implemented in GTM for comparison.

From Figs. 46.7 and 46.8, one can see that DUKF can correctly estimate all the states and fault magnitudes within the given time limits in the nonlinear model. It is easy to implement DUKF in the nonlinear model since it does not need to linearize the model. Compared with the TSKF, almost the same estimate for fault parameter has been achieved. However, the DUKF is computationally more expensive.

Figures 46.9 and 46.10 show the simulation results for a 20 % loss of control effectiveness fault (i.e., 80 % of the normal value) in elevator occurred at 6 s. It can be seen that good and almost same performance have also been achieved by both DUKF and TSKF.

In the above simulation cases, the actuator faults have been detected at 5.3 s and 6.3 s, respectively, with 0.3 s time delay. It can be viewed that similar parameter estimation accuracy has been achieved by both DUKF and TSKF.

Fig. 46.8 Results of estimated parameters under 50 % loss of elevator effectiveness

Fig. 46.9 Results of estimated states under 20 % loss of elevator effectiveness

Fig. 46.10 Results of estimated parameters under 20 % loss of elevator effectiveness

46.5.2 FDD Results Based on LPV Model

In this case, DUKF and ATSEKF use the measured outputs and outputs of the LPV model, a 20 % loss of control effectiveness fault in elevator at 6 s is considered. The measurement interval is $T = 0.01$ s.

In Fig. 46.11, the estimation outputs of DUKF and ATSEKF are close to the LPV output at the beginning; however, with the time growing, the DUKF and ATSEKF cannot follow the output of LPV model. For fault parameter estimation, as shown in Fig. 46.12, the estimation results demonstrate that DUKF can also detect and identify the fault precisely based the LPV model when a 20 % partial loss fault occurs at 6 s in elevator, with similar performance as that of ATSEKF.

Figures 46.11–46.12 show that the states estimation of the DUKF and ATSEKF in the GTM LPV environment matched well with the measured outputs and also it filtered the measurement noises and two Kalman algorithms detect and identify the fault precisely when the elevator encounters a partial loss.

46.5.3 Comparison of DUKF with TSKE/ATSEKF

The simulation results based on the GTM six degree-of-freedom nonlinear simulation environment show that DUKF provides similar estimation performance

Fig. 46.11 Results of estimated states under 20 % loss of elevator effectiveness

compared with TSKF. DUKF is computationally more expensive, especially for nonlinear models whose coefficients are implemented by lookup tables in the MATLAB/Simulink. The reason is that DUKF algorithm requires the $2L + 1$ sigma points, where L is the dimension of the augmented state vector. These $2L + 1$ sigma points join the measurement update and time update, so it makes the computation $2L + 1$ times larger than that of TSKF/ATSEKF. Since ATSEKF linearizes the system at each sample point, it could lead to a poor performance by introducing unknown errors due to linearization. Such a linearization operation at each time step makes also the implementation more demanding comparing with DUKF in which nonlinear model of the system can be directly used for estimation with no need to linearize the system.

Experimental validation of FDD schemes based on a parameter estimation alone UKF, two-stage Kalman filter, and an adaptive two-stage Kalman filter with applications to a quadrotor helicopter UAV test bed available at the author's Networked Autonomous Vehicles Lab (NAVL) in Concordia University are presented in another chapter in this handbook. Interested readers are referred to Chamseddine et al. (2013) for details.

46.6 Conclusion

An online FDD scheme has been presented in this chapter. The proposed FDD scheme is based on the DUKF for simultaneous state and fault parameter estimation. Simulation results indicate that DUKF can correctly estimate all the states and fault parameters within the given time limit in the NASA nonlinear GTM UAV model and the LPV model of the nonlinear UAV model. Convergence of parameter estimation is also very fast. However, the DUKF is also computationally more expensive, especially for nonlinear model whose coefficients are implemented by lookup tables in MATLAB/Simulink.

For the nonlinear model and LPV model of the NASA GTM UAV, simulation results show that DUKF and TSKF/ATSEKF provide similar parameter estimation accuracy and FDD performance. In this work, only actuator faults have been considered. In practice, faults can also occur in sensors and system components such as wing damages. Furthermore, only partial loss type faults have been considered. Future works include consideration of actuator stuck failures and wing damages, improvement of robustness and performance of DUKF-based FDD algorithm, and integration with fault-tolerant control to form a complete active fault-tolerant control system for the GTM UAV.

In conclusion, DUKF has the advantage that it separates state estimation and parameter estimation. Such a feature benefits fault parameter estimation needed in an FDD task. Furthermore DUKF can use the nonlinear model of system directly with no need to linearize the system.

Acknowledgments This work was partially supported by Natural Sciences and Engineering Research Council of Canada (NSERC) through a strategic project and a discovery project and also by the NASA Aviation Safety Program (AvSP) through a project on “Fault Diagnosis and Prognosis and Reliable Flight Envelope Assessment.”

Abstract

A fault detection and isolation scheme is presented to handle three successive faults in the skew-configured inertial sensors of an unmanned aerial vehicle. The skew-configured inertial sensors are composed of the primary inertial measurement unit and the redundant secondary inertial measurement unit. Since small unmanned aerial vehicles are restricted by cost and payload space, the secondary small and low-cost inertial measurement unit is installed with a skewed angle in addition to the primary inertial measurement unit. In the hybrid fault detection and isolation scheme, a parity space method and an in-lane monitoring method are combined to increase system tolerance to the occurrence of multiple successive faults during flight. The first and second faults are detected and isolated by the parity space method. The third fault is detected by the parity space method and isolated by the in-lane monitoring method based on the discrete wavelet transform. Hardware-in-the-loop tests and flight experiments with a fixed-wing unmanned aerial vehicle are performed to verify the performance of the proposed fault diagnosis scheme.

47.1 Introduction

Modern flight control systems are designed to tolerate various faults in sensors and actuators during flight; these faults must be detected and isolated as soon as possible to allow the overall system to continue its mission. A fault means an unpermitted deviation of characteristic properties or parameters of the system from the normal condition, and a failure means a permanent interruption of partial systems (Patton et al. 1989; Isermann and Balle 1997). If any successive faults in a subsystem are not resolved, a serious failure might be caused not only in the subsystem but also in the whole system. A widely used precaution for these types of malfunctions is the fault detection and isolation (FDI) technique, which is based on a redundancy management system. Here, fault detection refers to the decision of whether or not a fault occurs, and fault isolation is defined as the process of finding and excluding the faulty component. Generally, the FDI technique is categorized into hardware redundancy and analytic redundancy managements. Hardware redundancy management (Gilmore and McKern 1970; Potter and Deckert 1972; Ray and Desai 1984) involves multiple redundant sensors or actuators and makes the system heavy and complicated. On the other hand, since the analytic redundancy management uses a mathematical model of the system redundancy, the typically used model-based FDI methods (e.g., observers (Patton et al. 2000), parity space (Gertler 1998) and parameter estimation (Isermann and Balle 1997; Isermann 2006)) are prone to modeling errors. In addition, a related robustness problem should be addressed as defined in Chen and Patton (1999). Recently, an in-lane monitoring method based on signal processing has been widely used for diagnosing the sensors or actuators of various systems as embedded computing technology develops (Patton 1997; Zhang and Yan 2001).

The triple or quadruple hardware redundancies generally used for large conventional aircraft or high-performance military aircraft are not suitable for small aircraft or unmanned aerial vehicle (UAV) systems because small and inexpensive systems are limited by cost and payload space. Therefore, this study considers a limited redundancy system consisting of a primary inertial measurement unit (IMU) and an additional small and low-cost IMU. A parity space approach and an in-lane monitoring technique are used in concert to increase tolerance to multiple successive faults in the IMU during flight. If an additional sensor is mounted in the same direction as the primary sensor, the first fault on each axis can be detected, but cannot be isolated because there are only two sensors for each axis; therefore, it is impossible to decide which sensor is functioning properly. To overcome this limitation, a skew-configured IMU is considered in this study. The skewed configuration refers to the configuration of the sensors that are mounted in orientations other than the orthogonal axes, provided that the measurements in three degrees of freedom can be expressed as independent linear combinations of the orthogonal components (Kim et al. 2004, 2007). This sensor configuration has been used to facilitate proper fault diagnosis for the IMUs of space shuttles and rockets (Sudano et al. 1988; Potter and Suman 1977; Jankovitz and Perdsock 1988; DeAngelis 1990; Krogmann 1990; McClary and Walborn 1994; Titterton and Weston 1997). However, designing a skew-configured IMU with peripheral devices such as low-level individual inertial sensors, accelerometers, and gyroscopes is costly and time-consuming because it involves optimal alignment and calibration problems. To cope with this difficulty, this study proposes that a low-cost off-the-shelf IMU can be mounted to a plane relatively inclined to the plane of the primary IMU, which is aligned with aircraft body coordinates. Because this idea is easy and practical, it can be applied to various unmanned systems regardless of whether the mission takes place over ground, sea, or air.

The previous works (Kim et al. 2004, 2007) proposed a model-free fault detection and an isolation technique for a sensor system with limited redundancy using the parity equation and wavelet transform. The basic idea of that technique is also applicable to the successive triple faults of the skew-configured dual IMU system. The first and second faults can be detected and isolated by the parity space approach (Gilmore and McKern 1970), and the third fault can be detected and isolated by the in-lane monitoring method based on the discrete wavelet transform (Kim et al. 2004, 2007; Bogges and Narcowich 2001; Daubechies 1992; Mallat 1999; Li 1999; Santoso et al. 1996; Mallat 1989; Dohono and Johnstone 1994). Finally, hardware-in-the-loop simulation (HILS) experiments and flight tests were performed to verify the performance and practicability of the proposed FDI scheme.

The rest is organized as follows: Sect. 47.2 summarizes the model-free hybrid FDI method composed of the parity space method and the discrete wavelet transform. Section 47.3 describes peripheral device configuration and alignment/calibration process of the proposed skew-configured IMU. Section 47.4 presents the results and analysis of the HILS and flight test. Conclusion is given in Sect. 47.5.

47.2 Algorithms for Model-Free Hybrid FDI

The analytic redundancy management is categorized into a model-based FDI and a signal-based FDI. The model-based FDI requires a mathematical model of a system, whereas the signal-based FDI does not. Therefore, the accuracy of the mathematical model affects the FDI performance of the model-based FDI. The hybrid FDI technique proposed in this study consists of two methods: the parity space method and the in-lane monitoring method based on the discrete wavelet transform. The parity space method is a model-based FDI, and the in-lane monitoring method is a signal-based FDI. In the parity space method, the fault in inertial sensors is detected and isolated using the geometrical relationship between skew-configured sensors. If the geometrical model is perfectly known, the parity space method is independent of the aircraft motion, which is model-free. However, the parity space method cannot isolate a certain level of successive faults due to the limited independent relationship between healthy sensors. For instance, in the case of a cone configuration of six sensors, the third fault can be detected but cannot be isolated by the parity space method alone. To deal with this problem, the parity space method is combined with the in-lane monitoring method based on the discrete wavelet transform; therefore, successive faults in the inertial sensors can be isolated by the in-lane monitoring method.

Figure 47.1 describes a schematic of the proposed FDI technique. When the first fault occurs in Sensor 1, FDI is accomplished by a three-dimensional parity vector as shown in line A of Fig. 47.1. The second fault in Sensor 2 is also detected and isolated using a two-dimensional parity vector as shown in line B of Fig. 47.1. Lastly, the successive third fault that could occur in Sensors 3–6 is detected by a one-dimensional parity vector and isolated by the discrete wavelet transform as shown in line C of Fig. 47.1. The parity space method is explained in Sect. 47.2.1, and the in-lane monitoring method is presented in Sect. 47.2.2. The detailed procedure of the FDI is described in Sect. 47.2.3.

47.2.1 Parity Space Method

The parity space method is extended from a static parity relationship that is widely applied to various FDI problems, as described in several papers (Chow and Willsky 1984; Patton and Chen 1994; Gertler 1997; Ding et al. 1999; Hwang et al. 2010). To address the parity relation in a sensor fault problem, the discrete state-space aircraft model is considered:

$$x(k+1) = Ax(k) + Bu(k) + v(k) \quad (47.1)$$

$$y(k) = Cx(k) + Du(k) + w(k) + f(k) \quad (47.2)$$

where $x(k) \in R^n$ is a state vector, $u(k) \in R^q$ is an input vector, $y(k) \in R^m$ is an output vector, $v(k) \in R^n$ and $w(k) \in R^m$ are noise or disturbance vectors,

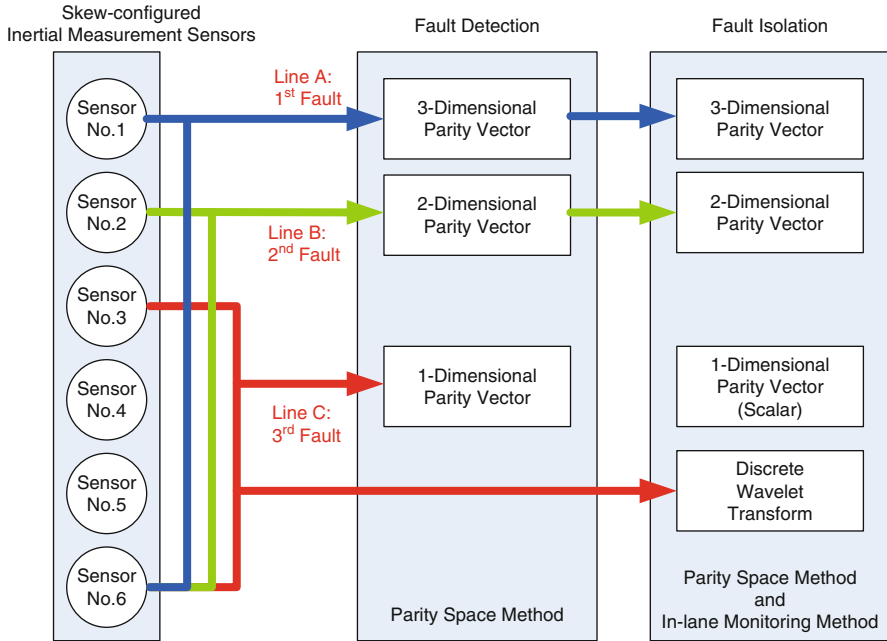

Fig. 47.1 Hybrid fault detection and isolation of three successive faults in inertial sensors

$f(k) \in R^m$ is a fault vector of the sensor, $A \in R^{n \times n}$ is a system matrix, $B \in R^{n \times q}$ is an input matrix, $C \in R^{m \times n}$ is a measurement matrix, and $D \in R^{m \times q}$ is an input-to-output matrix. The $v(k)$ and $w(k)$ are zero-mean white noise vectors with the Gaussian distribution. Each element of the fault vector $f_i(k)$ ($i = 1, 2, \dots, m$) corresponds to a fault signal of each sensor. The state-space model can be transformed to the input-output equation as

$$y(z) = G_u(z)u(z) + C(zI - A)^{-1}v(z) + w(z) + f(z) \quad (47.3)$$

where

$$G_u(z) = C(zI - A)^{-1}B + D \quad (47.4)$$

Patton and Chen (1994) showed that, in the static parity relation approach, a residual vector is generally defined as

$$r(z) = H_u(z)u(z) + H_y(z)y(z) \quad (47.5)$$

where H_u and H_y are parity matrices with respect to the input vector and the output vector, respectively. The residual vector is defined to be insensitive to the input vector as follows:

$$H_u(z) = -H_y(z)G_u(z) \quad (47.6)$$

$$r(z) = H_y(z) \left[C(zI - A)^{-1} v(z) + w(z) + f(z) \right] \quad (47.7)$$

Note that the residual vector in Eq. (47.7) is independent from the input vector $u(z)$ and the state vector $x(z)$. When a sensor fault does not occur, the residual vector is a zero-mean vector as shown in Eq. (47.8). When a sensor fault occurs, the residual vector is a nonzero vector as shown in Eq. (47.9). Consequently, the residual vector in the static parity relation is sensitive to the sensor fault and insensitive to the input and the state.

$$E[r(z)|_{f(z)=0}] = E\left[C(zI - A)^{-1} v(z) + w(z)\right] \approx 0 \quad (47.8)$$

$$E[r(z)|_{f(z) \neq 0}] = E\left[C(zI - A)^{-1} v(z) + w(z) + f(z)\right] \approx E[f(z)] \quad (47.9)$$

The parity vector $p(k)$ is introduced similar to the residual vector in Eq. (47.5) as

$$p(k) = H_u(k) u(k) + H_y(k) y(k) \quad (47.10)$$

$$H_u(k) = -H_y(k) D \quad (47.11)$$

Then, the primary residual vector $v(k) \in R^m$ is represented as (Hwang et al. 2010)

$$v(k) = y(k) - Du(k) = C(k)x(k) + w(k) + f(k) \quad (47.12)$$

Finally, the parity vector is defined as

$$p(k) = H_y(k) v(k) \quad (47.13)$$

In this study, $x(k) \in R^3$ is an angular rate vector in the aircraft body coordinate: roll rate, pitch rate, and yaw rate. Initial $y(k) \in R^6$ is measured with skew-configured inertial sensors which are composed of two IMUs. The initial measurement matrix is $C(k) \in R^{6 \times 3}$ which transforms the angular rates in the body coordinate to the angular rates in the sensor coordinate. Therefore, initial $p(k)$ is a three-dimensional vector, and initial $H_y(k)$ is a 3-by-6 matrix with the following orthonormal properties (Potter and Deckert 1972; Ray and Desai 1984):

$$H_y(k) C(k) = O_{3 \times 3} \quad (47.14)$$

$$H_y(k) H_y^T(k) = I_{3 \times 3} \quad (47.15)$$

where $O_{3 \times 3}$ is a zero matrix, $I_{3 \times 3}$ is a identity matrix, and the parity matrix $H_y(k)$ is the null space matrix of $C(k)$. In detail, $H_y(k)$ is a transpose matrix of the null space of $C^T(k)$. The null space is calculated using the singular value decomposition (Junkins and Kim 1993). Because the rank of $C^T(k) \in R^{3 \times 6}$ is always three due to the orthogonal configuration of the conventional IMU, $C^T(k)$ is factored as

$$C^T(k) = U \Sigma V^T = [U_1 \ U_2] \begin{bmatrix} \Sigma_1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} V_1^T \\ V_2^T \end{bmatrix} \quad (47.16)$$

where $U \in R^{3 \times 3}$ and $V \in R^{6 \times 6}$ are normalized unitary matrices, $\Sigma \in R^{3 \times 6}$, and Σ_1 is a diagonal matrix of three singular values of $C^T(k)$. The first three columns of V are orthonormal vectors spanning the column space of $C^T(k)$, and the last three columns of V are orthogonal vectors spanning the null space of $C^T(k)$. Note that all the orthogonal vectors v_i lying in the null space of $C^T(k)$ satisfy $C^T(k) v_i = 0$; therefore, $H_y(k)$ is the transpose of an orthogonal set of the null space of $C^T(k)$ as follows:

$$C^T(k) [v_1 \ v_2 \ v_3] = C^T(k) V_2 = 0 \quad (47.17)$$

$$H_y(k) = V_2^T \quad (47.18)$$

Using Eqs. (47.12)–(47.14), the parity vector can be represented as

$$p(k) = H_y(k) [C(k)x(k) + w(k) + f(k)] = H_y(k)w(k) + H_y(k)f(k) \quad (47.19)$$

This relationship indicates that the parity vector is a function of the noise signal $w(k)$ and the fault signal $f(k)$, not the system states $x(k)$ and the control input $u(k)$. In this study, a fault detection function is defined as the norm of the parity vector as

$$F_D(k) = \|p(k)\| = \sqrt{p(k)^T p(k)} \quad (47.20)$$

When all sensors are normal, $F_D(k)$ is close to zero as long as all sensor signals are unbiased with zero-mean noise. Once a fault occurs in a certain sensor, the term $H_y(k)f(k)$ in Eq. (47.19) becomes nonzero. As a result, $F_D(k)$ becomes larger than a predetermined threshold for a given confirmation time t_c , then it is declared that the fault occurred. Here, the threshold values are chosen as $3 - \sigma$ values for each fault case as follows:

$$T_1 = k_1 (3 \times \sqrt{3} \times \sigma_{\max}), \quad T_2 = k_2 (3 \times \sqrt{2} \times \sigma_{\max}), \quad T_3 = k_3 (3 \times \sigma_{\max}) \quad (47.21)$$

where T_i is a threshold value for the i -th fault occurrence, k_i is a safety factor, and σ_{\max} is a maximum standard deviation among all inertial sensors. The safety factor makes the threshold value larger than $E[H_y(k)w(k)]$ and smaller than $E[H_y(k)w(k) + H_y(k)f(k)]$; this can be further tuned by trial and error. Note that $\sqrt{3}$ and $\sqrt{2}$ are related to the dimensions of the matrix $H_y(k)$.

A fault isolation function of the j -th sensor is defined as an inner product of the j -th normalized column vector in $H_y(k)$ and the parity vector $p(k)$ as follows:

$$F_{I,j}(k) = h_j^T p(k) / \|h_j\| \quad (47.22)$$

where h_j is the j -th column vector of $H_y(k)$. The parity vector indicates the direction of the fault vector $f(k)$ in the space of $H_y(k)$ because $p(k)$ is a linear transformation of $f_i(k)$ by $H_y(k)$ in Eq. (47.19). If all sensors are normal, then all fault isolation values are zero. If a fault occurs in the j -th inertial sensor, then the fault isolation function value of the j -th inertial sensor becomes equal to $h_j^T h_j f(k) / \|h_j\|$. In a geometrical sense, the parity vector including the fault signal indicates the direction of the column vector h_j of the faulty sensor. Therefore, the j -th inertial sensor having the largest fault isolation value should be isolated, and then a new parity vector is reconstructed using the remaining healthy sensors.

In this study, six inertial sensors are initially considered. The first and second faults in any inertial sensors will be detected by Eq. (47.20) and isolated by Eq. (47.22). However, the third fault can be detected but cannot be isolated because (i) the parity vector is not a vector with a specific direction but rather a scalar and (ii) the fault signal that is transformed into the column space of $H_y(k)$ is not always dominant in that column space.

47.2.2 In-Lane Monitoring Method Based on the Discrete Wavelet Transform

In the parity space method described in Sect. 47.2.1, the third fault in any of the four remaining inertial sensors cannot be isolated due to the lack of the parity vector. In other words, the parity space method isolates the fault only if sufficient numbers of inertial sensors are provided. On the other hand, the in-lane monitoring method is based on the discrete wavelet transform of each sensor signal. Not only the first and second faults but also the third fault in inertial sensors can be detected and isolated by the in-lane monitoring method. However, the in-lane monitoring method might give a false alarm when an aircraft is maneuvering rapidly because any sudden change in the signal could be detected by the discrete wavelet transform. Because of this, the in-lane monitoring method should be combined with the parity space approach (Gilmore and McKern 1970). Note that the parity space method is not affected by a sudden change in the signal as long as the parity vector is not changed. Consequently, this study proposes the first and second faults of inertial sensors be detected and isolated with the parity space method, and the third fault in one of the four remaining inertial sensors be detected and isolated using a combination of the parity space method and the in-lane monitoring method.

Fourier transform has been widely used for analyzing stationary signals; however, it is less useful for analyzing nonstationary signals because of its time-varying frequency contents (Bogges and Narcowich 2001). On the other hand, the wavelet transform provides time-frequency localization (Daubechies 1992) in the sense that it can zoom in on the high-frequency signal for a short duration or zoom out on slow oscillations (Mallat 1999; Li 1999). Furthermore, in terms of the computational load, the wavelet transform is better than the windowed Fourier transform because the discrete wavelet transform requires $\log_2 N$ computational steps, whereas the fast Fourier transform requires $N \log_2 N$ steps for a discrete signal of given length N .

Recently, multi-resolution signal decomposition based on the orthonormal properties of the discrete wavelet transform has been widely used to divide the sensor signal into two parts, an approximated signal and a detailed signal (Mallat 1989). These signals are obtained by convolving the sensor signal with a type of low-pass filter for “the approximations” and a type of high-pass filter for “the details.” This also helps to reduce the computational load of the next step’s decomposition by decreasing the number of samples. Note that the detailed signal contains noise or fault signals such as sharp edges, transitions, jumps at the bias, drifts, and spikes.

Consider a discrete-time sensor signal $c_j(n)$ at the discrete-time step n . This is divided into an approximated part $c_{j+1}(n)$ and a detailed part $d_{j+1}(n)$ using the following relationship:

$$c_{j+1}(n) = \sum_{k=-\infty}^{\infty} h(k-2n) c_j(n) \quad (47.23)$$

$$d_{j+1}(n) = \sum_{k=-\infty}^{\infty} g(k-2n) c_j(n) \quad (47.24)$$

where $h(n)$ and $g(n)$ are the low-pass and high-pass filter coefficients, respectively, which can be determined from the following two-scale relationship between the scaling function $\phi(t)$ and the wavelet function $\psi(t)$.

$$\phi(t) = \sqrt{2} \sum_{n=-\infty}^{\infty} h(n) \phi(2t-n) \quad (47.25)$$

$$\psi(t) = \sqrt{2} \sum_{n=-\infty}^{\infty} g(n) \phi(2t-n) \quad (47.26)$$

where

$$g(n) = (-1)^{1-n} h(1-n) \quad (47.27)$$

If the scaling function $\phi(t)$ is defined as the signal basis, the low-pass filter coefficients $h(n)$ can be obtained by Eq. (47.25). Note that because the design of the scaling function and the wavelet basis is beyond the scope, Daubechies wavelets are selected for the application in this study. A detailed description of the wavelet selection will be discussed further at the end of this section. The low-pass filter coefficients $g(n)$ and the wavelet function $\psi(t)$ can be successively designed in Eq. (47.26). Figure 47.2 describes the process of signal decomposition into the approximated signal and the detailed signal.

The following example is provided to illustrate the mechanism of the discrete wavelet transform. If the low-pass filter is $h(0) = 1/\sqrt{2}$, $h(1) = 1/\sqrt{2}$, then the high-pass filter can be computed using Eq. (47.27) as

$$g(0) = -1/\sqrt{2}, \quad g(1) = 1/\sqrt{2} \quad (47.28)$$

Fig. 47.2 Multi-resolution signal decomposition

Consider the following discrete-time sensor signal:

$$c_0 = (0.9, 1.1, 1.5, 1.3) \quad (47.29)$$

This is divided into the approximated part and the detailed part using Eqs. (47.23) and (47.24).

$$c_1 = (1.0, 1.4), \quad d_1 = (-0.1, 0.1) \quad (47.30)$$

The multi-resolution signal decomposition technique can localize and discriminate a high-frequency signal from the original signal, and therefore it can be applied to detect a sensor fault included in the high-frequency signal. For this reason, the choice of a wavelet basis is important for fault diagnosis. The first consideration for selecting a wavelet basis is a vanishing moment. If a wavelet function satisfies the following condition, it has n vanishing moments:

$$\int t^k \psi(t) dt = 0 \text{ for } k = 0, 1, \dots, n-1 \quad (47.31)$$

This means that the larger its vanishing moment is, the larger the order polynomials it can suppress will be. In other words, it can make the wavelet transform more localized by removing smooth functions. Another consideration is the support size. The shorter the support size, the better time localization it has. Daubechies wavelets have good time localization and orthogonal properties because they have the shortest compact support for a given number of vanishing moments. Therefore, Daubechies wavelets are considered as the wavelet basis in this study. It is well-known that short and fast transient singularities can be easily detected using a Daubechies 2 or 4 wavelet, whereas slow-moving anomalies, such as drift, can be detected using Daubechies 8 or 10. In this study, a Daubechies 2 wavelet was adopted to detect the fault signal because sensor faults usually have fast transient characteristics caused by instantaneous physical shock or electromagnetic interference. The high-pass filter coefficients $h(n)$ of the Daubechies 2 wavelet are shown in the following equations (Mallat 1999):

$$\begin{aligned}
h[0] &= 0.482962913145 \\
h[1] &= 0.836516303738 \\
h[2] &= 0.224143868042 \\
h[3] &= -0.129409522551
\end{aligned} \tag{47.32}$$

The threshold for FDI can be set by modifying the threshold of the wavelet shrinkage technique generally used for de-noising as follows (Kim et al. 2007; Dohono and Johnstone 1994):

$$T_4 = k_w \sigma_w \sqrt{2 \ln N_w} \tag{47.33}$$

where N_w is the length of the signal, σ_w is the standard deviation of the measurement noise, and k_w is the safety factor, which can be determined considering the system characteristics and the operational environment.

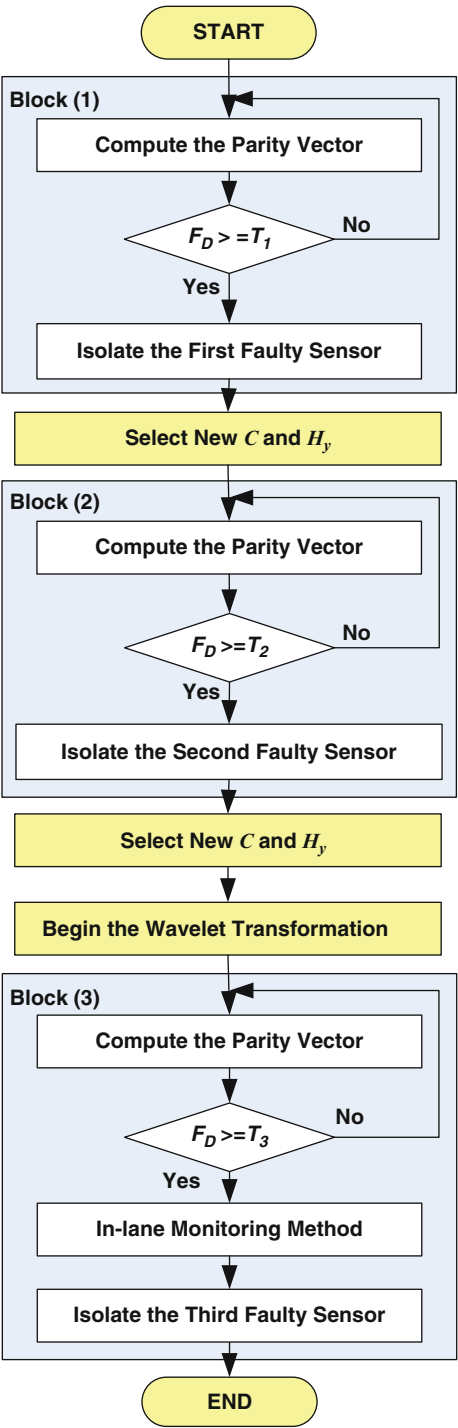

In this study, the discrete wavelet transform is conducted using 32 samples of the sensor data $c_0 = [y(k-31), y(k-30), \dots, y(k-1), y(k)]$, and fault detection is based on the maximum value of the detailed signal $[d_1(k-16), d_1(k-15), \dots, d_1(k-1), d_1(k)]$ to grab the high-frequency faulty signals.

47.2.3 Model-Free Hybrid Fault Detection and Isolation

The model-free hybrid FDI combines the parity space method with the in-lane monitoring method based on the discrete wavelet transform. Successive faults in the skew-configured IMU are detected by the parity space method and then isolated by the in-lane monitoring method as well as the parity space method. This diagnosis is known as a model-free scheme because it does not require any dynamic model of the aircraft. A flowchart of the model-free hybrid FDI technique is shown in Fig. 47.3. Triple faults successively occurring in the inertial sensors are detected and isolated by the following procedures:

1. When the first fault occurs in the i -th inertial sensor, the fault detection function F_D in Eq. (47.20) exceeds the threshold T_1 , and the occurrence of the fault is detected. The fault isolation functions $F_{I,i}$ in Eq. (47.22) for each sensor are calculated, and the sensor with the largest value is isolated from the measurement as shown in Block (1) of Fig. 47.3. The output matrix C and the parity matrix H_y are selected according to the remaining five sensors.
2. When the second fault occurs in the j -th inertial sensor, it can be detected and isolated similar to the above process as shown in Block (2) of Fig. 47.3. Then, the discrete wavelet transform of the remaining four sensor signals begins immediately after the second fault isolation.
3. When the third fault occurs in the k -th sensor, F_D exceeds the threshold T_3 , and the fault occurrence is detected. Then, a sudden change in the k -th sensor is detected by the in-lane monitoring method based on the discrete wavelet transform, and the corresponding sensor is isolated from the inertial measurement system as shown in Block (3) of Fig. 47.3.

Fig. 47.3 Flowchart of hybrid fault detection and isolation

In this way, triple successive faults can be treated during the flight, and the UAV can perform its mission continuously. A measurement matrix C , which is originally 6-by-3, is reduced to a 5-by-3 matrix after the first fault isolation and is downsized to a 4-by-3 matrix after the second fault isolation. A parity matrix H_y , which is originally 3-by-6, is reduced to a 2-by-5 matrix after the first fault isolation and is reset to a 1-by-4 matrix after the second fault isolation.

47.3 Hardware Configuration for the Flight Test

The skew-configured IMU and the fault signal generation board were constructed to verify the performance of the proposed hybrid FDI scheme. The fault signal generation board produces virtual fault signals instead of real fault signals. The hybrid FDI algorithm is processed in the flight control computer. The performance of the proposed FDI is verified through ground and flight experiments. Figure 47.4 describes the system configuration and the test procedure. The details of the design/calibration procedures and functions of the skew-configured IMU, the fault signal generation board, and the fixed-wing UAV are described below.

47.3.1 Skew-Configured Inertial Measurement Unit

The primary IMU of the experimental UAV system is the *Crossbow AHRS400*. The secondary IMU is the *XSENS MTi-68*, which is a small and low-cost IMU compared to the primary IMU. The secondary IMU is mounted on the inclined plane with respect to the aircraft body coordinate, whereas the primary IMU is aligned with the aircraft body coordinate. The inclination angle of the secondary IMU is determined by optimizing the navigation index and the fault detection performance index. A detailed optimization procedure can be found in the references (Park 2004). Figure 47.5 illustrates the designed structure of the mounting surface for the secondary IMU.

As shown in Fig. 47.5, the primary IMU is aligned with the aircraft body coordinate (X_1, Y_1, Z_1) , whereas the secondary IMU is aligned with the slope plane (X_2, Y_2, Z_2) . As a result, six inertial sensors are configured in a cone shape. With this configuration, the measurement matrix $C(k)$ and the parity matrix $H_y(k)$ in Eqs. (47.12) and (47.13) are analytically calculated as follows:

$$C(k) = \begin{bmatrix} -1 & 0 & 0 & 0.6667 & 0.6667 & -0.3333 \\ 0 & 1 & 0 & -0.3333 & 0.6667 & 0.6667 \\ 0 & 0 & -1 & 0.6667 & -0.3333 & 0.6667 \end{bmatrix}^T \quad (47.34)$$

Fig. 47.4 System configuration and test procedure

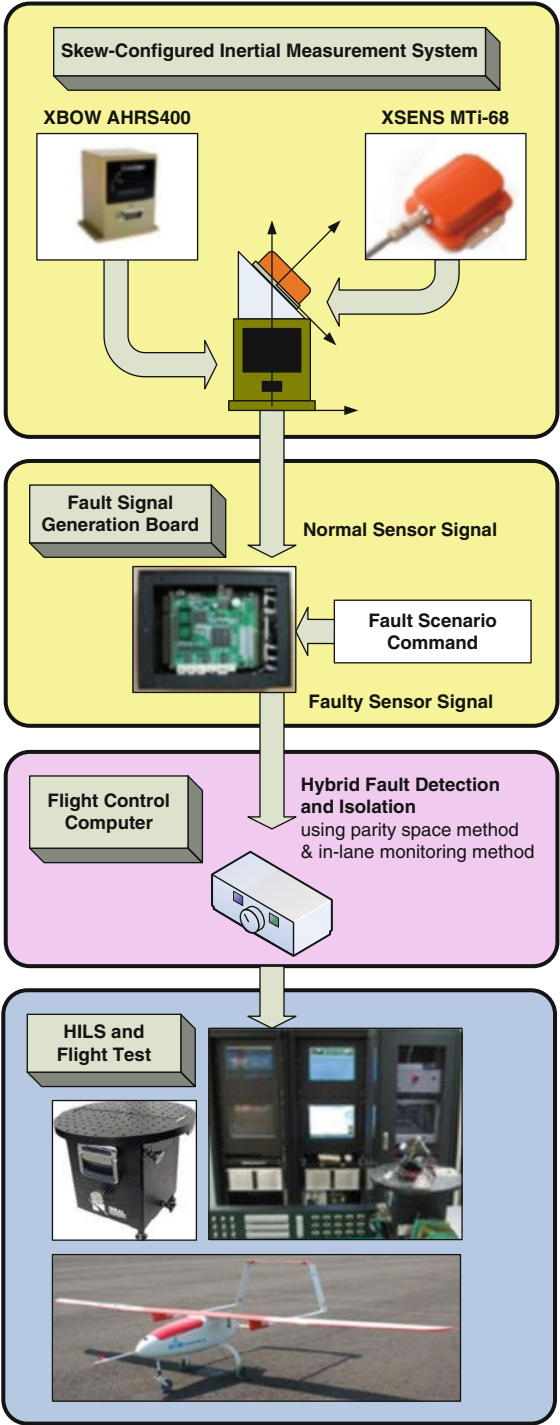

Fig. 47.5 Configuration of two inertial measurement units

$$H_y(k) = \begin{bmatrix} 0.4714 & 0.2357 & 0.4714 & 0.7071 & 0.0000 & 0.0000 \\ 0.4714 & -0.4714 & -0.2357 & 0.0000 & 0.7071 & 0.0000 \\ -0.2357 & -0.4714 & 0.4714 & 0.0000 & 0.0000 & 0.7072 \end{bmatrix} \quad (47.35)$$

In practice, the skew-configured IMU contains small alignment errors in $C(k)$ and $H_y(k)$. Therefore, the assembled IMUs should be calibrated with an initialization experiment, which compensated for the bias of the skew-configured IMU with a 5-min history of each signal in the stationary condition. The sensor system was placed on a single-axis rate table, *Ideal Aerosmith 1291BR*, and was rotated about three different axes (X_1, Y_1, Z_1) with six constant angular velocities: 100, 50, 20, -20, -50, and -100 deg/s. Using the signals from these experiments, the measurement matrix $C(k)$ in Eq. (47.12) with $w(k) = 0$ and $f(k) = 0$ was computed as

$$C(k) = z(k) x_r^\dagger(k) \quad (47.36)$$

where $z(k)$ is a 6-by-18 output matrix of the skew-configured IMU and $x_r^\dagger(k)$ is a pseudo inversion of an 18-by-3 reference input matrix. The columns of $z(k)$ comprise 18 rotating conditions; these are the rotating axis X_1 with 100 deg/s, the rotating axis Y_1 with 100 deg/s, the rotating axis Z_1 with 100 deg/s, and so on. As a result of this initialization experiment, the calibrated $C(k)$ and $H_y(k)$ were obtained as follows:

$$C(k) = \begin{bmatrix} -1.0018 & 0.0031 & -0.0063 & 0.6885 & 0.65889 & -0.3041 \\ -0.0030 & 1.0018 & -0.0121 & -0.3163 & 0.6554 & 0.6865 \\ -0.0021 & -0.0028 & -0.9999 & 0.6555 & -0.3660 & 0.6635 \end{bmatrix}^T \quad (47.37)$$

$$H_y(k) = \begin{bmatrix} 0.4845 & 0.2295 & 0.4613 & 0.7070 & 0.0012 & -0.0001 \\ 0.4656 & -0.4644 & -0.2595 & -0.0002 & 0.7073 & -0.0012 \\ -0.2185 & -0.4809 & 0.4700 & -0.0007 & 0.0017 & 0.7072 \end{bmatrix} \quad (47.38)$$

47.3.2 Fault Signal Generation Board

In practice, it is difficult to make the inertial measurement sensors partially fail during flight. A fault signal generation board is considered to produce virtual fault signals instead of real fault signals. The fault signal generation board receives normal sensor signals from the skew-configured IMU and adds virtual fault signals to normal sensor signals according to the failure scenario. The modified sensor signals are transmitted to a flight control computer that will perform FDI. In this way, inertial measurement sensors can be virtually broken by the fault generation board.

The fault signal generation board was designed with digital signal processing units: *Texas Instrument's TMS320LF2407A* and *TL16C754BPN*. It has 5 serial communication ports and 20 digital input/output ports. The fault signal generation board has a communication port and six light-emitting diodes on the outside. Through its 15-pin communication port, 2 IMUs are connected to the fault signal generation board. In addition, commands from the ground station and the corresponding virtual sensor signals are communicated through this port.

47.3.3 Experimental Unmanned Aerial Vehicle System

The performance of the proposed FDI approach was verified with an experimental UAV, *Durumi 2*, developed and operated by the *Korea Aerospace Research Institute*. This UAV has performed various flight experiments for real-time system identification and fault-tolerant control systems (Park et al. 2006). Its wing span is 4.8 m, and its body length is 2.7 m as shown in Fig. 47.6. Its total weight is 37 kg, including a maximum payload weight of 12 kg. The maximum speed is 120 km/h, and its stall speed is 55 km/h. In addition, all of the control surfaces are fractioned into two pieces able to move independently for a fault-tolerant mission.

The skew-configured IMU was loaded on the payload of this experimental UAV as shown in Fig. 47.7. A hexahedron in the lower right corner is the primary IMU, the *Crossbow AHRS400*. An upper flat unit on the slope is the redundant secondary IMU, *XSENS MTi-68*, which is smaller than the primary unit. Note that the secondary unit is cheaper and has a poorer resolution. These two IMUs are directly connected to the fault signal generation board. The modified sensor output in the fault signal generation board is transmitted to the flight control computer.

Fig. 47.6 Experimental UAV, Durumi 2

Fig. 47.7 Skew-configured inertial measurement system in the payload

47.4 HILS Test and Flight Experiments

HILS test and flight experiments were performed to evaluate the performance of the proposed hybrid FDI system. Note that the operational inspection of the FDI algorithm was done in advance by a ground test using the single-axis rate table. The fault diagnosis performance of the HILS and the flight test are discussed below.

47.4.1 HILS Test Results

The objective of the ground experiment was to verify the hybrid FDI algorithm and determine the parameters of the algorithm. The bias and misalignment errors of the skew-configured IMU were calibrated with the initialization experiment. The ground test also inspected the function of the fault signal generation board.

Table 47.1 Parameters for the hybrid fault detection and isolation

| Parameter | Variable | Value |
|--|-------------------|-----------------|
| Maximum standard deviation of the inertial sensor signals in Eq. (47.21) | σ_{\max} | 0.81 |
| Safety factors of the fault detection in Eq. (47.21) | (k_1, k_2, k_3) | (1.5, 1.5, 1.3) |
| Confirmation time of the fault detection function | t_c | 0.25 (s) |
| Safety factor of the threshold in Eq. (47.33) | k_w | 1.5 |
| Sampling number for the wavelet transform in Eq. (47.33) | N_w | 32 |

As a result of various ground experiments including constant rotations, oscillations, and random vibrations, the FDI parameters for the parity equation and the maximum absolute value of the wavelet transform at each sampling time (this will be called “the discrete wavelet transform” hereafter for simplicity) were determined as summarized in Table 47.1.

Figure 47.8 shows one of the ground experimental results: the sensor signals, the parity norm, the discrete wavelet transform, and the isolated sensor number, respectively. In this test, 10 deg/s bias faults successively occurred in Sensors 1, 2, and 5. The first fault occurred in Sensor 1 at 6.2 s. As shown in the second plot, the fault detection function $F_D(k)$, the norm of the parity vector, increased when the fault occurred. That is, the first fault was detected when the residual exceeded the prescribed threshold T_1 . Simultaneously, the fault isolation function $F_{I,1}(k)$ declared Sensor 1 to be faulty, as shown in the bottom plot, and therefore, Sensor 1 is isolated from the measurement.

In the same way, the second fault occurring in Sensor 2 at 8.4 s was detected when the residual exceeded the threshold T_2 as shown in the second plot of Fig. 47.8. Among the remaining five sensors, the fault isolation function $F_{D,2}(k)$ declared Sensor 2 to be the faulty sensor as shown in the bottom plot. Then, Sensor 2 was isolated from the measurement. At that time, the wavelet transform of the remaining four sensor signals began as shown in the third plot.

Whereas the first and the second faults are detected and isolated by the parity space method, the third faults are detected by the parity space method and isolated by the in-lane monitoring method. The second plot of Fig. 47.8 shows that the residual exceeded the threshold T_3 when the third fault occurred in Sensor 5 at 11.2 s. Simultaneously, the faulty Sensor 5 was detected and isolated by monitoring the wavelet transform as shown in the third and fourth plots. In brief, the results of the ground HILS test showed the viability of the proposed approach and encouraged the necessity for real flight experiments.

47.4.2 Flight Experimental Result

The fault diagnosis performance of the hybrid FDI system was also verified through the flight test. The command for the type and magnitude of the fault signal is transmitted from the ground station according to the sensor failure scenario.

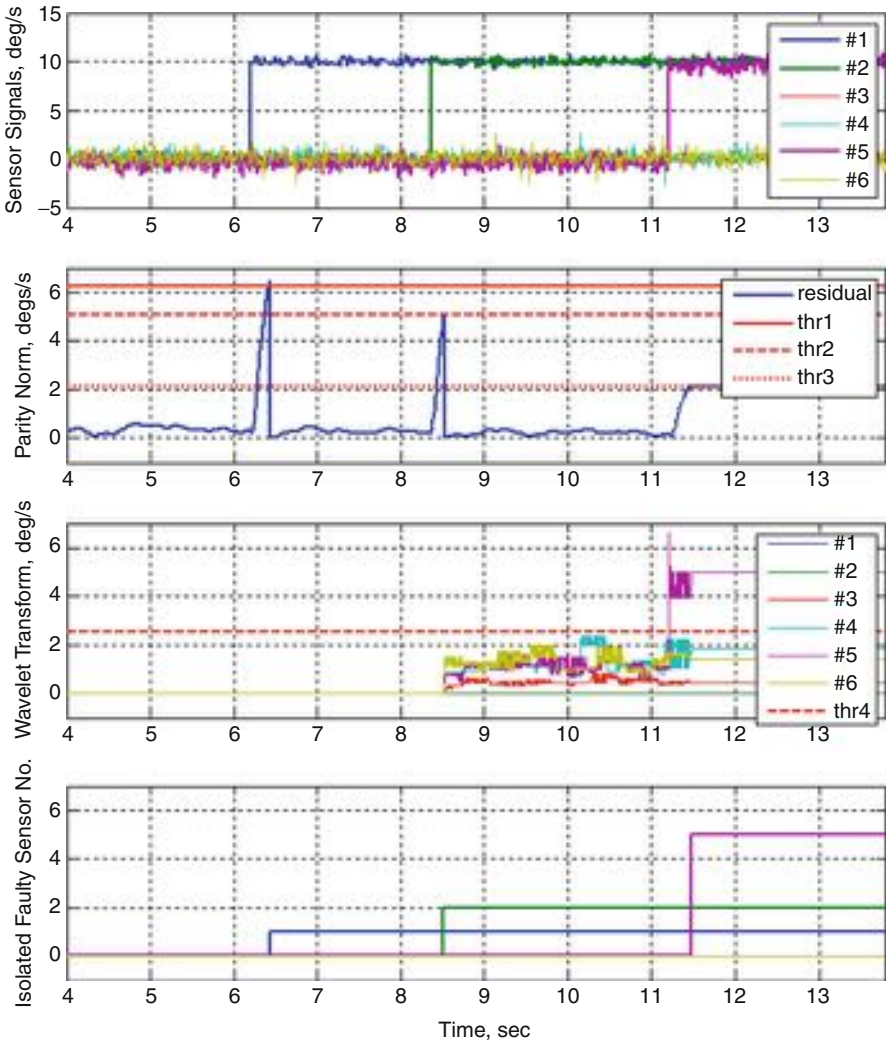

Fig. 47.8 Ground test result of the hybrid fault detection isolation system

In the flight test, two types of sensor fault were considered, a bias fault and a stuck fault. The bias and stuck faults are basic errors that can be generated in sensors due to both hardware and software problems. If the sensor is badly calibrated before or during the flight, the measurement can be easily biased in the decoding process. After hardware failure, the sensor output might be stuck to any last value that was normal or biased in the computing algorithm. The detectable magnitude of the sensor fault is numerically computed according to the noise level and the configuration of the skew-configured IMU. Once the parity matrix $H_y(k)$

in Eq. (47.13) and the threshold T_i in Eq. (47.21) are determined, the fault magnitude, which can be always detected, is computed as

$$\|f(k)\| = T_i / \|h_j\|_{\min} \tag{47.39}$$

where h_j is the j -th column vector of $H_y(k) = [h_1 \ h_2 \ \dots \ h_m]$. When all six inertial sensors are normal, the constantly detectable magnitude is 5.9 deg/s. When five inertial sensors are normal, the constantly detectable magnitude is 6.6 deg/s. When four inertial sensors are normal, the constantly detectable magnitude is 10.9 deg/s. If the corresponding column vector h_j is larger than the denominator of Eq. (47.39) in a certain case, the sensor fault smaller than the constantly detectable magnitude can be detected usually but not always. Note that the detectable fault magnitude increases from 5.9 to 10.9 as the number of normal sensors decreases.

Thirty-six experiments were performed during the flight test according to the failure scenario, including seven sets of successive triple faults. Table 47.2 summarizes the fault types and magnitudes of each sensor failure scenario. Although the parameters of the hybrid FDI system had been shown to be tolerant to 10 deg/s bias errors in the ground test, the fault diagnosis performance in the flight test was superior than the expected performance from the ground test. Therefore, three additional failure scenarios (5 through 7) were tested.

Table 47.3 summarizes the flight experimental results for each sensor failure scenario. In the flight test, the aircraft maneuvered to perform level flights, bank turns, climbs, and descents. The result of the fault isolation is simply displayed as follows: success, partial success, and fail. In failure scenarios 1 through 5, the proposed FDI technique successfully detected and isolated the successive sensor faults under various real flight situations. In failure scenarios 6 and 7, all of the first/second faults were successively detected and isolated by the proposed FDI system, but the third fault was partially isolated in some cases even though all of the third faults were detected by the parity space method without any problems. Those cases that missed the fault isolation will be discussed in detail in the next subsection.

Next, one of the flight experimental results is discussed in detail. The UAV was in a coordinate turn for 23 s. The mean velocity and the mean altitude over the ground were 35 m/s and 170 m, respectively. The successive stuck and bias faults

Table 47.2 Sensor failure scenarios commanded from the ground station

| Scenario number | First fault | | | Second fault | | | Third fault | | |
|-----------------|-------------|-------|--------|--------------|-------|--------|-------------|-------|--------|
| | deg/s | Type | Sensor | deg/s | Type | Sensor | deg/s | Type | Sensor |
| 1 | 15 | Bias | 1 | 15 | Bias | 3 | 15 | Bias | 5 |
| 2 | 15 | Bias | 2 | 15 | Bias | 4 | 30 | Stuck | 6 |
| 3 | 10 | Bias | 1 | 10 | Bias | 3 | 10 | Bias | 5 |
| 4 | 10 | Bias | 2 | 10 | Bias | 4 | 30 | Stuck | 6 |
| 5 | 8 | Bias | 1 | 10 | Stuck | 3 | 8 | Bias | 5 |
| 6 | 8 | Bias | 2 | 10 | Stuck | 4 | 8 | Bias | 6 |
| 7 | 10 | Stuck | 5 | 8 | Bias | 1 | 10 | Stuck | 3 |

Table 47.3 Flight experimental results of the fault detection and isolation

| Scenario number | Flight status | FDI parameters | Fault isolation (success/total) |
|-----------------|------------------|---|---------------------------------|
| 1 | Level flight | $k_1 = 1.8, k_2 = 1.8, k_3 = 1.5, t_c = 0.12$ | Success (2/2) |
| | Bank turn | | Success (2/2) |
| | Climb/descent | | Success (2/2) |
| 2 | Level flight | $k_1 = 1.5, k_2 = 1.5, k_3 = 1.2, t_c = 0.12$ | Success (2/2) |
| | Bank turn | | Success (2/2) |
| | Climb/descent | | Success (2/2) |
| 3 | Level flight | $k_1 = 1.3, k_2 = 1.3, k_3 = 1.1, t_c = 0.12$ | Success (2/2) |
| | Bank turn | | Success (2/2) |
| | Climb/descent | | Success (2/2) |
| 4 | Bank turn | | Success (2/2) |
| 5 | Level flight | $k_1 = 1.3, k_2 = 1.3, k_3 = 1.1, t_c = 0.12$ | Success (2/2) |
| | Bank turn | | Success (3/3) |
| | Climb/descent | | Success (2/2) |
| 6 | Level flight | | Partial success (2/4) |
| | Bank turn | | Success (2/2) |
| | Climb/descent | | Partial success (2/4) |
| 7 | Roll oscillation | | Partial success (1/3) |

were generated in Sensors 5, 1, and 3 according to the failure scenario 7. Figure 47.9 shows the sensor signals, the parity norm, the discrete wavelet transform, and the isolated sensor number, respectively. The first fault took place in Sensor 5 at 1,274.5 s. Its signal was stuck at 10 deg/s as shown in the first plot. The fault detection function $F_D(k)$ increased immediately when the fault occurred, as shown in the second plot. The first fault was detected when this residual exceeded the prescribed threshold T_1 . Then, the fault isolation function $F_{I,5}(k)$ declared that Sensor 5 was the faulty sensor, as shown in the fourth plot. Consequently, Sensor 5 was isolated from the skew-configured inertial measurement system, and the fault diagnosis parameters were updated for a five-sensor configuration.

The second fault, an 8 deg/s bias error in Sensor 1 at 1,283.5 s, was detected in the same way. The wavelet transform of the remaining four inertial sensor signals began after the isolation of the second faulty inertial sensor. When the third fault occurred in Sensor 3, which stuck at 10 deg/s after 1,287.8 s, the residual exceeded the threshold T_3 , as shown in the second plot of Fig. 47.9. The parity space method could no longer identify the faulty sensor because of an insufficient number of remaining healthy sensors. However, the wavelet transform of each sensor signal could identify the timing of the abrupt signal change caused by the fault. As shown in the third plot, the wavelet-transformed signal of Sensor 3 exceeded the predefined threshold T_4 and that sensor was thus successfully isolated. Other flight experiments in Scenarios 1 through 5 showed similarly satisfactory performance; the UAV was able to continue performing its mission with the skew-configured IMU composed of the remaining three sensors.

Fig. 47.9 Flight test results of the hybrid fault detection and isolation system

47.4.3 Analysis

47.4.3.1 Comparison of the State Vector with or Without FDI

The performance of the proposed FDI technique against three successive faults can be analyzed by comparing the body-coordinate sensor signals collected during the faulty situation to those collected during a healthy, fault-free situation. The healthy body-coordinate angular rates are calculated from normal sensor signals, and the faulty body-coordinate angular rates are calculated from all six sensor signals.

Figures 47.10 and 47.11 illustrate the difference between the healthy and the faulty angular rates of failure scenario 7 without and with application of the FDI scheme, respectively. As shown in Fig. 47.10, without the application of the

Fig. 47.10 Comparison between healthy and faulty signals without FDI

hybrid FDI, the body-coordinate sensor output (blue line) could not provide accurate signals (red line) when successive faults occurred according to failure scenario 7 (Sensor 5 stuck at 10 deg/s, Sensor 1 bias of 8 deg/s, and Sensor 3 stuck at 10 deg/s, successively). Abrupt changes in the roll, pitch, and yaw rate signals due to the stuck faults in Sensors 5 and 3 can be seen at 1,274.5 and 1,288.1 s, respectively. Notably, the error between the healthy and faulty signals increased suddenly when the first stuck fault occurred. The error became even larger and more remarkable after the second and third faults.

Fig. 47.11 Comparison between healthy and faulty signals with FDI

Figure 47.11 shows that the proposed FDI scheme enhances the accuracy of the body-coordinate sensor output. The computed body-coordinate sensor outputs (blue line) are consistent with the healthy signals (red line) except the short interval when the faults occurred because the FDI algorithm requires almost a half second to detect and isolate the faulty sensor. Table 47.4 presents a quantitative error analysis based on the error norm between the healthy and faulty signals. The errors obtained without FDI decreased by up to 29 % when the proposed FDI is applied. Therefore,

Table 47.4 Error norm analysis between healthy and faulty signals

| Axis | w/o FDI | w/ FDI | Ratio |
|------------|---------|--------|--------|
| Roll rate | 139.02 | 82.68 | 1:0.59 |
| Pitch rate | 121.57 | 32.58 | 1:0.29 |
| Yaw rate | 98.42 | 35.95 | 1:0.37 |

the flight experiments demonstrated that the proposed hybrid FDI technique with the skew-configured IMU can continuously provide healthy sensor outputs despite successive stuck and bias faults in the individual sensors.

47.4.3.2 False Alarm Due to the Smooth Transition

As summarized in Table 47.3, several partially successive tests of failure scenarios 6 and 7 failed to isolate the third fault in the skew-configured IMU. Figure 47.12 shows one of the partially successive FDI results of failure scenario 7. In this scenario, three successive faults occurred: Sensor 5 stuck at 10 deg/s, Sensor 1 experienced an 8 deg/s bias error, and Sensor 3 stuck at 10 deg/s. As depicted in the fourth plot, the first and second faulty sensors were correctly isolated but the third faulty sensor was not isolated because the wavelet-transformed signals did not exceed the threshold.

As can be seen in the first plot of Fig. 47.12, the third fault in Sensor 3, which stuck at 10 deg/s after 1,395.5 s, did not generate a sufficiently remarkable signal change compared to the general sensor noise to be identified by the wavelet transform based on the Daubechies 2 wavelet function. Because the wavelet transform is a signal processing technique based on each sensor output, the fault may not be identified if the magnitude of the fault signal is smaller than the magnitude of the noise signal or if noise characteristics vary over time.

Since the wavelet transform is primarily designed to avoid emergencies when a third fault occurs, the UAV should return to base by homing guidance if the parity space method detects a third fault but the in-lane monitoring system is unable to identify the failed sensor. If the UAV cannot return to base, it may be useful to generate a virtual sensor signal based on model-based propagation after the third fault. Nevertheless, this approach would yield errors if the discrepancy caused by the modeling uncertainties exceeds the fault signal. Alternatively, the wavelet transform could be run in parallel based on the higher scale’s wavelet basis function (e.g., Daubechies 9 or 10) to identify a slow or weak signal change. The capability of the flight control computer should be considered since this method requires a higher computation load.

47.4.3.3 False Alarm Due to the Computational Delay

The computational delay in the wavelet transformation is another cause of the partially successful results. Confirmation of the presence of a faulty signal involves six steps of the fault detection algorithm and requires 0.12 s. A faulty signal that lasts less than 0.12 s is considered temporary noise and may be ignored. Moreover,

Fig. 47.12 Partially successful result: insensitivity of the wavelet transform to the stuck fault

the discrete wavelet transform monitors signal changes based on 32 previous signal samples. If the change in the faulty signal is small, the parity norm increases slowly. Therefore, the 32 samples of the wavelet transform might not contain the faulty signal because the fault signal is detected by the parity norm. Figure 47.13 shows one of the partially successful FDI results from failure scenario 6. In this scenario, Sensor 2 experienced an 8 deg/s bias error, Sensor 4 stuck at 10 deg/s, and Sensor 6 experienced an 8 deg/s bias error. As shown in the third plot, the wavelet transformation of the signal from Sensor 6 exceeded the threshold due to the third bias fault at 945.9 s. The third fault could not therefore be detected because the fault detection function in the second plot increased slowly and did not guarantee the existence of the faulty sensor. This problem can be easily overcome by considering the previous history of the wavelet-transformed signal.

Fig. 47.13 Partially successful result: computational delay in the fault detection function

47.4.3.4 False Alarm Due to the Aircraft Motion

The proposed fault diagnosis method is theoretically independent of aircraft motion or trajectory. Four maneuvers were performed to verify that the aircraft motion does not affect fault diagnosis performance: level flight, bank turn, climb/descent, and oscillating roll motion. As summarized in Table 47.3, the fault diagnosis result was successful regardless of aircraft maneuver when FDI parameter k_i was large. However, false alarms occurred as the FDI parameter decreased because the fault diagnosis became more sensitive to sensor noise or signal change. Even though aircraft states and actuator inputs do not affect the parity vector, a sudden maneuver does affect the time delay between the present aircraft state and the measured states in some inertial sensors. One of the fast maneuvers, an oscillating roll, was performed in flight scenario 7. If the response times of the inertial sensors are not

synchronized, different responses to a fast maneuver might break the orthonormal properties of parity relation and cause a false alarm. Therefore, the redundant secondary IMU should be chosen to have similar response characteristics to those of the primary IMU.

47.5 Conclusion

A model-free hybrid FDI scheme was proposed to provide system tolerance to the occurrence of multiple successive faults in the inertial sensors during flight. The hybrid FDI scheme combines the parity space method with the in-lane monitoring method based on the discrete wavelet transform. This scheme was successfully verified through the hardware-in-the-loop simulation and flight experiments. The skew-configured inertial sensor system was developed with the primary IMU and the redundant secondary IMU. In addition, three successive fault signals were generated virtually with the fault signal generation board during the real flight experiments. The first and the second faults in arbitrary inertial sensors were detected and isolated by the parity space method, and the third sensor fault was detected by the parity space method and isolated by the in-lane monitoring method based on the discrete wavelet transform. The proposed fault diagnosis scheme is applicable to the robust navigation and control of robots, unmanned air/ground vehicles, and satellites.

UAV Modeling, Simulation, Estimation and Identification

Lora Weiss

Kimon P. Valavanis and George J. Vachtsevanos

Modeling and simulation techniques are essential and crucial in the design, operation, and performance assessment of UAVs. Together with estimation and identification, they are integral components of the overall UAV design process. They afford the opportunity to develop, test, and evaluate sensing, control, and cooperative control algorithms, among others. Software-in-the-loop and hardware-in-the-loop simulations are typical prerequisites to flight testing. UAV Modeling, Simulation, Estimation and Identification presents a treatment of these topics from first principles to mechanisms that lead to UAV qualification and certification.

► **Flight Dynamics Modeling of Coaxial Rotorcraft UAVs** by Wang, Cui, Chen, and Lee aims at presenting a thorough approach related to systematic modeling of UAV flight dynamics by talking about the UAV model formulation, parameter identification, and model verification. The presented methodology of UAV model formulation and parameter identification is based on modeling two kinds of coaxial helicopters. This is a challenging problem as modeling of coaxial helicopters, despite the common governing kinematic and dynamic principles, deserves special attention due to their distinctive mechanical structure and aerodynamics behavior. The modeling procedures and parameter identification technique presented in this chapter may also serve as a guideline for modeling other types of aerial vehicles.

► **Modeling of a Micro UAV with Slung Payload** by Feng, Rabbath, and Su derives a mathematical and simulation model of a micro UAV carrying a payload.

When the load is slung underneath a UAV by cable, the flight dynamics of the UAV are altered, which makes the stability of the UAV disturbed. The unstable oscillation degrades UAV performance, and the accurate placement of the load will be affected. Unlike external disturbances, the negative effects are related to the characteristics of the UAV and the payload. In order for the UAV to be able to adopt the change of the system dynamics and reduce the effects caused by the swing of the load, one modeling method of a micro UAV with single slung payload is addressed. The slung payload is treated as a pendulum-like mass point, and the coupling factors between the UAV and the payload are considered. The derived model may be used to estimate the negative effects acting on the UAV, and it may also be used to estimate the trajectory of the load, which allows for improving the accuracy of placement of the loads.

► **Command and Control of Autonomous Unmanned Vehicles** by Scheidt describes a series of experiments, including 2011 experiments in which 16 fully autonomous unmanned vehicles, including 9 unmanned air vehicles, were used to simultaneously support mounted, dismounted, and maritime users. During these experiments users provided abstract mission-level ISR needs to the “vehicle cloud.” These needs were interpreted by the vehicles, which self-organized and efficiently achieved the user’s objectives. The starting point is using information theory to examine UAV command and control (C2). The information theoretic analysis provides a justification and use cases for *autonomous* UAVs. An autonomous unmanned vehicle system “Organic Persistent Intelligence Surveillance and Reconnaissance” (OPISR) is introduced. OPISR is an autonomous unmanned vehicle system that combines the immediate response to tactical ISR needs provided by organic assets with the time-on-station, minimal logistics provided by persistent unmanned systems. OPISR autonomous vehicles collectively interpret real-time tactical intelligence surveillance and reconnaissance (ISR) objectives submitted by any number of disadvantaged users, gather the required ISR data, and return the needed intelligence directly to the affected user. OPISR is an ad hoc, decentralized system that requires no central base or authority and is capable of functioning in communications-denied environment.

Abstract

In many unmanned aerial vehicle (UAVs)-related engineering projects, flight dynamics modeling of the controlled platform usually forms the foundation of the whole project development. An accurate mathematical model of the controlled UAV not only makes high-performance model-based control law design possible but also provides insights into the mechanical design of the aerial platform so that radical improvements can be made at the beginning of the development. However, the topic of flight dynamics modeling is somehow not paid enough

attention to across the general engineering audience. This chapter aims to disseminate the knowledge of systematic modeling of UAV flight dynamics by talking about UAV model formulation, parameter identification, and model verification. The methodology of UAV model formulation and parameter identification based on the case study of two kinds of coaxial helicopters will be explained. Modeling of coaxial helicopters, despite the common governing kinematic and dynamic principles, deserves special attention due to their distinctive mechanical structure and aerodynamics behavior. The modeling procedures and parameter identification process presented in this chapter also serve as a guideline for modeling other types of aerial vehicles.

49.1 Introduction

In recent years, unmanned aerial vehicles (UAVs) have been more actively involved in military and civil operations. Possible UAV applications include reconnaissance and intelligence gathering, forest patrol, coastline monitoring, and search and rescue (Tsach et al. 2010). In all kinds of UAV development, the flight dynamics modeling of the controlled platform always forms the cornerstone of the whole project. UAV modeling not only provides an accurate mathematical model so that advanced model-based control law design techniques can be used but also provides insights into the mechanical design of the aerial platform itself. Moreover, in contrast to those conventional manned aerial vehicles, UAV platforms are normally custom-made or largely modified from off-the-shelf products to cope with the payload requirement and the mounting geometry of the onboard avionics. UAV platforms may possess different working principles, ranging from fixed-wing, rotorcraft, flapping-wing to mono-copters like the Samurai (Rosen and Seter 1991). To model some of the special types of aerial platforms, the well-established work for the conventional aerial platforms in literature cannot be applied directly. Hence, it is especially useful to let UAV developers understand how the models are derived and how to identify unknown parameters embedded within the models.

Many works related to flight dynamics modeling and model-based parameter identification of aerial vehicles are conducted in literature. Some of them are done for the ultimate purpose of UAV development. In Heffley and Mnich (1988), a mathematical model for the conventional single-rotor helicopter with adequate complexity was derived, and the report highlighted the formulation of the main rotor thrust generation. In Johnson (1994), a fairly comprehensive and detailed coverage of helicopter working theory and design considerations were provided in aspects including helicopter vertical flight, forward flight, mathematics of rotating systems, rotary wing dynamics and aerodynamics, aeroelasticity, and stability and control. Based on the above works, Cai et al. (2012) obtained a comprehensive nonlinear model of a miniature single-rotor helicopter. This work has also later been extended in a book (Cai et al. 2011) with other UAV-related topics like UAV construction, software development, and controller design.

In more recent years, the development of UAV platforms has entered the era of miniature, microscale, and even nanoscale. The used-to-be efficient conventional fixed-wing or single-rotor helicopter structure may not be an optimum design anymore. The reduced form factor has also resulted in more innovative and unconventional aerodynamic designs, and for these new types of platforms, quite a few new modeling works have been published. In Nonami et al. (2010), the mathematical model of a miniature coaxial helicopter is derived in the transfer function form. The identified linear model is used for optimal controller design. In Bermes (2010), the design and dynamic modeling and the simulation of an autonomous coaxial micro helicopter platform (muFly) are investigated. A modular dynamic model is developed, which incorporates the active and passive flapping characteristics of a hingeless rotor system, the stabilizer bar dynamics, roll-pitch steering by swashplate or displacing center of mass, etc.

Coaxial helicopter is an attractive UAV platform due to its small dimension, high thrust-to-weight ratio, and aerodynamic symmetry. If a coaxial helicopter and a single-rotor helicopter are of the same weight, the size of the coaxial helicopter can be 35–40 % smaller. In addition, the aerodynamic symmetry of coaxial helicopters successfully gets rid of the yaw moment and side forces commonly seen in single-rotor helicopters. Thus, the coaxial helicopter is much more effective in fast forward flights. These advantages make the coaxial helicopter ideal for UAV operation in confined environments such as indoor and cluttered outdoor. There are two types of coaxial helicopters. One has rotor blades with a fixed collective pitch, while the other is with variable collective pitch. In the following content of this chapter, they will be called the fixed-pitch coaxial and the variable-pitch coaxial in short. The dynamic modeling of these two kinds of coaxial helicopters will form the main discussion in this chapter.

A major difference of modeling between the coaxial helicopter and the conventional single-rotor helicopter is the pair of concentric rotors, in which each of them rotates with the induced velocity affected by the other. Such relationship is described in Colin (1997). Detailed studies of the wake dynamics of the two rotors were also documented in Kim and Brown (2006), Rand and Khromov (2010), and Lim et al. (2009). Another specialty of coaxial helicopter is the stabilizer bar attached to the top rotor hub, which passively stabilizes the helicopter. It, however, causes strong influences to the rotor dynamics especially to the fixed-pitch coaxial configuration as the upper rotor is not linked to any servo. As a result, the cyclic pitch control of the upper rotor is solely induced by the stabilizer bar. The stabilizer bar dynamics is commonly modeled as a first-order lag system (Mukherjee and Waslander 2011). In the works shown in Mukherjee and Waslander (2011) and Schafrroth et al. (2010), the tip-path-plane (TPP) dynamics is separated into the upper and lower portion, where only the lower TPP is controlled by the servo inputs.

In a few recent works on the modeling of miniature coaxial helicopter, although fairly complete nonlinear or linear models are obtained, the works lack intuitive explanation of the model formulation. Moreover, their methods of parameter identification are not comprehensive enough. For example, in Neamtu et al. (2010),

the helicopter dynamics were treated as a black box, while the whole system is vaguely identified using the CIPHER (Comprehensive Identification from Frequency Responses) toolkit. To complement the existing work, this book chapter presents the detailed derivation of the nonlinear model for both the fixed-pitch and the variable-pitch coaxial helicopters.

The content of this chapter is organized as follows: Sect. 49.2 briefly gives the working principles of both the fixed-pitch and the variable-pitch coaxial helicopters. Next, Sect. 49.3 will comprehensively formulate the coaxial flight dynamics system, starting from kinematics, rigid-body dynamics, and then force/torque composition and generation. Some parts of the model formulation can be shared by both types of coaxial helicopters, while the differences in rotor thrust generation and rotor flapping dynamics will be separately explained. Model-based parameter identification will be introduced in Sect. 49.4 with the fixed-pitch coaxial as an example. Last but not least, Sect. 49.5 will verify the derived model of the fixed-pitch coaxial case and proves the fidelity of the overall modeling methodology.

49.2 Working Principle of Coaxial Helicopters

Before any rigorous derivation of the flight dynamic models of the aforementioned two types of coaxial helicopters, the general working principles of the two will first be introduced so that it will be easier for readers to understand the later detailed model formulation. First of all, both platforms have a pair of contrarotating rotors (upper and lower) to provide the fundamental lift force for the overall platform. This is indeed where the term “coaxial” comes from.

For the fixed-pitch coaxial helicopter, as shown in Fig. 49.1, the collective pitch of the rotor blades cannot be changed. Hence, the heave and yaw motion of the platform can only be controlled by varying the rotational speed of the rotors, which are linked to two separate motors with step-down gears. In general, the summation of the motor speeds determines the helicopter vertical motion, while the difference of the two determines the yaw motion. Rolling and pitching are accomplished by introducing a cyclic pitch to the lower rotor via a dual-servo-controlled swashplate. In this way, a tilted flapping of the rotor blades can be induced, and the generated rotor thrust becomes non-vertical. In the case of the platform shown in Fig. 49.1, which is called the Esky Big Lama, the cyclic pitch of the upper rotor is not actively controlled. Instead, the rotor hub tethers together with a stabilizer bar. As the stabilizer bar is purposely constructed with relatively high moment of inertia, when the helicopter fuselage suddenly tilts, the stabilizer bar tends to remain rotating at the original level plane. This introduces a cyclic pitch to the upper rotor, and it is purposely designed in a way that the thrust tilting resulted from this cyclic pitch counters the instantaneous motion of the helicopter. Therefore, this kind of fixed-pitch coaxial helicopters is inherently stable with regard to their attitude angles.

Fig. 49.1 Description of the fixed-pitch coaxial helicopter

On the other hand, the variable-pitch coaxial helicopter, as shown in Fig. 49.2, is a mini coaxial helicopter customized according to the design of full-scale coaxial helicopter from the Kamov design bureau. Its rotor head is equipped with integrated hinges and shock-resistant dampers. This helicopter also consists of two contrarotating rotors. However, unlike the fixed-pitch coaxial, the rotational speeds of the variable-pitch coaxial helicopter's rotors are maintained at the same constant speed in normal flight conditions. The dynamic motion of the helicopter is achieved by actively changing the pitch angles of both upper and lower rotors via the upper swashplate and the lower swashplate, respectively. The pitch angles of both rotors are constituted by collective pitch and cyclic pitch, which are mixed controlled by three servos linked to the lower swashplate. The two swashplates are always parallel to each other since they are circumferentially connected by three rigid linkages. The upper rotor is attached with a Bell-Hiller stabilizer bar which introduces damping to the rotor's cyclic pitch. Collective and cyclic inputs from servos are transferred to the lower swashplate and also induced to the top swashplate, resulting in the dynamic movement of the helicopter in heave direction or pitch-roll direction. The yaw direction control is realized by changing the collective pitch angle of the lower rotor. For this particular platform, the upper rotor and lower rotor are driven by the same brushless direct current (DC) electric motor with the same gear ratio. Hence, the rotational speeds of the upper rotor and the lower rotor are always the same.

Fig. 49.2 Description of the variable-pitch coaxial helicopter

49.3 Model Formulation

49.3.1 Model Overview

The mathematical model of any continuous physical dynamic system can be expressed in the following compact form:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, \mathbf{w}), \quad (49.1)$$

where \mathbf{x} is the state vector, \mathbf{u} is the input vector, and \mathbf{w} represents external disturbances. For the case of the fixed-pitch coaxial helicopter system, the system state and input vectors can be defined as

$$\mathbf{x} = (x \ y \ z \ u \ v \ w \ \phi \ \theta \ \psi \ p \ q \ r \ a_{\text{up}} \ b_{\text{up}} \ a_{\text{dw}} \ b_{\text{dw}} \ \Omega_{\text{up}} \ \Omega_{\text{dw}} \ r_{\text{fb}})^T, \quad (49.2)$$

Table 49.1 Physical meaning of state variables

| Symbol | Physical meaning | Unit |
|----------------------|--|--------------------------------|
| x | | |
| y | \mathbf{p} , position in the ground frame | m |
| z | | |
| u | | |
| v | \mathbf{v}_b , linear velocity in the body frame | m/s |
| w | | |
| ϕ | Roll | rad |
| θ | Pitch | |
| ψ | Yaw | |
| } attitude angle | | |
| p | | |
| q | $\boldsymbol{\omega}$, angular velocity in body frame | rad/s |
| r | | |
| a_{up} | Longitudinal | flapping angle of upper blades |
| b_{up} | Lateral | |
| a_{dw} | Longitudinal | flapping angle of lower blades |
| b_{dw} | Lateral | |
| Ω_{up} | Rotational speed of the upper rotor | |
| Ω_{dw} | Rotational speed of the lower rotor | |
| r_{fb} | Controller state of yaw stability augmentation | NA |

$$\mathbf{u} = (\delta_{\text{ail}} \delta_{\text{ele}} \delta_{\text{thr}} \delta_{\text{rud}})^T, \quad (49.3)$$

$$\mathbf{w} = (\omega_u \omega_v \omega_w)^T. \quad (49.4)$$

For the case of the variable-pitch coaxial helicopter system, the system state and input vectors can be defined as

$$\mathbf{x} = (x \ y \ z \ u \ v \ w \ \phi \ \theta \ \psi \ p \ q \ r \ a_{\text{up}} \ b_{\text{up}} \ a_{\text{dw}} \ b_{\text{dw}} \ r_{\text{fb}})^T, \quad (49.5)$$

$$\mathbf{u} = (\delta_{\text{ail}} \delta_{\text{ele}} \delta_{\text{thr}} \delta_{\text{rud}})^T, \quad (49.6)$$

$$\mathbf{w} = (\omega_u \omega_v \omega_w)^T. \quad (49.7)$$

The physical meanings of the state, input, and disturbance variables are listed in Tables 49.1–49.3. It should be noted that the fixed-pitch coaxial helicopter has two additional state variables, Ω_{up} and Ω_{dw} , because its rotor rotational speeds keep changing during normal flights and its motor dynamics is not fast enough to be neglected. On the other hand, the rotors of the variable-pitch coaxial platform always rotate at the same speed. Thus, no dynamics need to be considered.

With regard to the input definition, the conventional radio-controlled (RC) joystick signals, aileron (δ_{ail}), elevator (δ_{ele}), throttle (δ_{thr}), and rudder (δ_{rud}), normalized to $[-1, 1]$ with respect to their corresponding minimum and maximum values, are chosen as the primary system inputs. This kind of input definition makes sure that the modeling methodology is also applicable to other types of

Table 49.2 Physical meaning of input variables

| Variables | Physical meaning | Range |
|----------------------|--|-----------|
| δ_{ail} | Control deflection for lateral cyclic pitch | $[-1, 1]$ |
| δ_{ele} | Control deflection for longitudinal cyclic pitch | $[-1, 1]$ |
| δ_{thr} | Control deflection for collective pitch | $[-1, 1]$ |
| δ_{rud} | Control deflection for collective pitch of tail rotor | $[-1, 1]$ |
| $\bar{\delta}_{rud}$ | Control deflection for yaw-stability-augmentation controller | $[-1, 1]$ |

Table 49.3 Physical meaning of wind disturbance variables

| Variables | Physical meaning |
|------------|---|
| ω_u | Wind velocity in the helicopter x -axis |
| ω_v | Wind velocity in the helicopter y -axis |
| ω_w | Wind velocity in the helicopter z -axis |

aerial platforms. Usually, the helicopter attitude angles (ϕ, θ), heading (ψ), and 3D position (x, y, z) are chosen to be the ultimate controlled outputs as they can comprehensively define the state of the helicopter in the full 6 degree-of-freedom (6DoF) space.

Furthermore, to derive a mathematical model of a complex system, it is preferable to modularize the overall system into subsystems so that the divide-and-conquer strategy can be used. Here, an overview of the two model structures is shown in Figs. 49.3 and 49.4. From the inputs to the state variables, there are numerous blocks representing all the subsystems involved. The two models share quite a few similarities but preserve their own distinctive features as well. On the one hand, the input and output definitions are unified for both, and the same kinematics and dynamics blocks can be used to relate the body-frame forces and moments to the helicopter 6DoF motion. On the other hand, the two models are different in the mechanism in generating the individual forces and moments. This results in two different sets of intermediate model blocks. In the following sections, mechanisms in all these blocks will be explained in detail. The similar blocks between these two types of platforms will be discussed together, while the different blocks will be discussed separately.

49.3.2 Kinematics and Rigid-Body Dynamics

As a common practice of aeronautic analysis, model formulation of a flying vehicle normally assumes that the target platform is a rigid body. Thus, it follows the universal 6DoF kinematics equations and the Newton-Euler dynamics equations. Two main coordinate frames are generally involved to link the equations. One is the north-east-down (NED) frame, and the other is the helicopter body frame. While the NED frame is stationary with respect to a static observer on the ground, the body

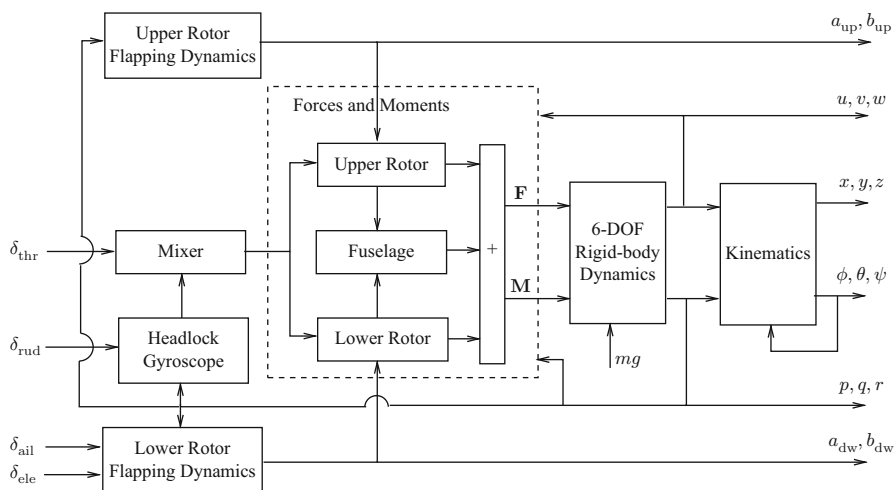

Fig. 49.3 Model structure of fixed-pitch coaxial helicopter

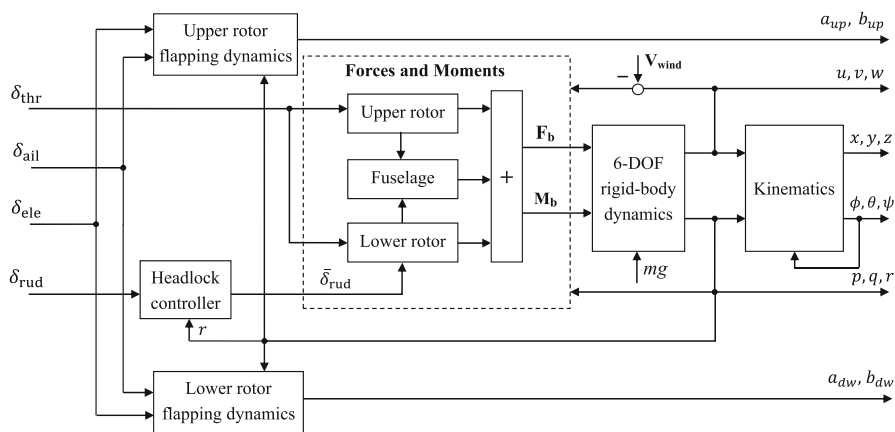

Fig. 49.4 Model structure of variable-pitch coaxial helicopter

frame is placed at the center of gravity (CG) of the coaxial helicopter, where its origin and orientation move together with the helicopter fuselage (see Fig. 49.5). It is worth noting that the listed formulas to describe the kinematics and dynamics of the coaxial helicopter are indeed universal to all other rigid-body vehicles.

The relationship between the helicopter NED-frame position and its body-frame velocity is determined by the following navigation equation:

$$\begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{z} \end{pmatrix} = \begin{bmatrix} c_\psi c_\theta & c_\psi s_\theta s_\phi - s_\psi c_\phi & c_\psi s_\theta c_\phi + s_\psi s_\phi \\ s_\psi c_\theta & s_\psi s_\theta s_\phi + c_\psi c_\phi & s_\psi s_\theta c_\phi - c_\psi s_\phi \\ -s_\theta & c_\theta s_\phi & c_\theta c_\phi \end{bmatrix} \begin{pmatrix} u \\ v \\ w \end{pmatrix}, \quad (49.8)$$

Fig. 49.5 Coordinate frames and various forces and torques

where x, y, z are the NED-frame position components of the helicopter and u, v, w are the body-frame velocity components. ϕ, θ, ψ are the conventional roll, pitch, yaw angles of the helicopter fuselage and s_*, c_* denote $\sin(*), \cos(*),$ respectively. It is also critical to point out that the Euler angle derivatives, $\dot{\phi}, \dot{\theta}, \dot{\psi},$ are not orthogonal to each other. They are related to the body-frame angular rates, $p, q, r,$ by the following equation:

$$\begin{pmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{pmatrix} = \begin{bmatrix} 1 & s_\phi s_\theta / c_\theta & c_\phi s_\theta / c_\theta \\ 0 & c_\phi & -s_\phi \\ 0 & s_\phi / c_\theta & c_\phi / c_\theta \end{bmatrix} \begin{pmatrix} p \\ q \\ r \end{pmatrix}. \quad (49.9)$$

Note that the above equation has singularity at $\theta = 90^\circ$. If full-envelope flight is required, a quaternion representation is recommended. However, normal maneuvering of a coaxial helicopter will not hit such an extreme condition. Thus, it is still adequate to use this relatively simple equation.

Next, by treating the whole coaxial platform as a rigid mass, the 6DoF dynamics can be described by the following Newton-Euler equations:

$$\begin{pmatrix} \dot{u} \\ \dot{v} \\ \dot{w} \end{pmatrix} = \frac{1}{m} \begin{pmatrix} F_x \\ F_y \\ F_z \end{pmatrix} - \begin{pmatrix} p \\ q \\ r \end{pmatrix} \times \begin{pmatrix} u \\ v \\ w \end{pmatrix}, \quad (49.10)$$

$$\begin{pmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{pmatrix} = \mathbf{J}^{-1} \left\{ \begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} - \begin{pmatrix} p \\ q \\ r \end{pmatrix} \times \mathbf{J} \begin{pmatrix} p \\ q \\ r \end{pmatrix} \right\}, \quad (49.11)$$

where F_x, F_y, F_z are projections of the net force, $\mathbf{F},$ onto the helicopter body-frame $x-, y-, z$ -axis and M_x, M_y, M_z are projections of the net torque, $\mathbf{M},$ onto the body-frame $x-, y-, z$ -axis. The compositions of \mathbf{F} and \mathbf{M} come from

various parts of the coaxial helicopter. For the fixed-pitch and variable-pitch coaxial helicopters, although their force and torque compositions are more or less the same (explained in Sect. 49.3.3), the individual force and torque generation will have different formulations because of their different working principles (explained in Sects. 49.3.4 and 49.3.5, respectively). Till now, the unknown parameters that need to be identified are m , the total mass of the platform, and \mathbf{J} , the moment of inertia of the platform, which is in the form of

$$\mathbf{J} = \begin{bmatrix} J_{xx} & -J_{xy} & -J_{xz} \\ -J_{xy} & J_{yy} & -J_{yz} \\ -J_{xz} & -J_{yz} & J_{zz} \end{bmatrix}.$$

Since the coaxial helicopters are normally designed to be symmetric in both longitudinal and lateral directions, J_{xy} , J_{xz} , J_{yz} are extremely small and can be assumed to be zero. The identification method of J_{xx} , J_{yy} , J_{zz} will be explained in Sect. 49.4, which talks about various approaches in the problem of model-based parameter identification.

49.3.3 Force and Torque Composition

As mentioned in Sect. 49.3.2, forces and torques acting on the coaxial helicopter come from various mechanical parts. First of all, the helicopter weight exerts a force of mg in the NED-frame z -axis. After converting it to the body frame, the vector is shown as the second term on the right-hand side of Eq. 49.12.

Next, when the rotor blades spin, they generate thrusts, \mathbf{T}_i ($i = \text{up, dw}$), in the direction perpendicular to their respective tip path plane (TPP). When the upper and lower TPPs deviate from their default orientation, the thrust vectors no longer pass through the CG of the helicopter, thus creating rotational torque. The torque vectors caused by the rotor thrusts can be calculated by $\mathbf{l}_{\text{up}} \times \mathbf{T}_{\text{up}}$ and $\mathbf{l}_{\text{dw}} \times \mathbf{T}_{\text{dw}}$, where \mathbf{l}_{up} and \mathbf{l}_{dw} are the displacement vectors from helicopter CG to the upper rotor hub, and the lower rotor hub respectively. The deviation of the TPP can be described by the longitudinal flapping angle a_i and the lateral flapping angle b_i . The thrust decomposition to the body-frame axes can be approximated by Eq. 49.14. Nonzero a_i and b_i also directly result in flapping torque on the rotor hub. This torque can be simplified as the second term on the right-hand side of Eq. 49.13, where K_β is called the effective spring constant, and it has the same value for both the upper and lower rotors provided they are rotating at approximately the same speed.

Furthermore, the rotation of the rotors creates the drag torque, \mathbf{Q}_{up} and \mathbf{Q}_{dw} , around the body-frame z -axis. When the coaxial helicopter hovers without yaw motion, the two torques have the same magnitude, thus canceling each other. Else, if the net drag torque is nonzero, yaw acceleration is generated. In addition, the change of rotational speeds of the rotors also generates the so-called reaction torques on the helicopter body (denoted by $\mathbf{Q}_{\text{r,up}}$ and $\mathbf{Q}_{\text{r,dw}}$). They are described in (Eq. 49.16),

where J_{up} and J_{dw} are the moment of inertia of the upper rotor (with stabilizer bar) and the lower rotor with respect to the rotor shaft. They can be calculated by measuring the mass and dimension of the rotor blades and stabilizer bar and assuming a regular geometric shape.

Lastly, when the helicopter moves in air, its fuselage experiences drag forces, X_{fus} , Y_{fus} , Z_{fus} , due to air resistance. This drag force is usually related to the linear speed and up-front surface area of the aerial vehicle.

Equations (49.12) and (49.13) have summarized all the forces and torques mentioned above, with (49.14)–(49.16) explaining how to evaluate the individual terms:

$$\begin{pmatrix} F_x \\ F_y \\ F_z \end{pmatrix} = \sum \mathbf{T}_i + mg \begin{pmatrix} -s\theta \\ s_\phi c\theta \\ c_\phi c\theta \end{pmatrix} + \begin{pmatrix} X_{\text{fus}} \\ Y_{\text{fus}} \\ Z_{\text{fus}} \end{pmatrix}, \quad (49.12)$$

$$\begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} = \sum \mathbf{l}_i \times \mathbf{T}_i + \sum K_\beta \begin{pmatrix} b_i \\ a_i \\ 0 \end{pmatrix} + \sum \mathbf{Q}_{\text{d},i} + \sum \mathbf{Q}_{\text{r},i}, \quad (49.13)$$

$$\mathbf{l}_i = |\mathbf{l}_i| \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix}, \quad \mathbf{T}_i = |\mathbf{T}_i| \begin{pmatrix} -\sin a_i \\ \sin b_i \\ -\cos a_i \cos b_i \end{pmatrix}, \quad (49.14)$$

$$\mathbf{Q}_{\text{d},\text{up}} = |\mathbf{Q}_{\text{d},\text{up}}| \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad \mathbf{Q}_{\text{d},\text{dw}} = |\mathbf{Q}_{\text{d},\text{dw}}| \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix}, \quad (49.15)$$

$$\mathbf{Q}_{\text{r},\text{up}} = J_{\text{up}} \dot{\Omega}_{\text{up}} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad \mathbf{Q}_{\text{r},\text{dw}} = J_{\text{dw}} \dot{\Omega}_{\text{dw}} \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix}. \quad (49.16)$$

49.3.4 Force and Torque Formulation of Fixed-Pitch Coaxial Helicopter

The generation of individual forces and torques on the fixed-pitch coaxial and the variable-pitch coaxial has quite different formulations. In this section, a full formulation of the fixed-pitch coaxial force and torque generation will be provided. That means, by tracing all the formulas listed in this section, the forces and torques exerted on the fixed-pitch coaxial helicopter can be exhaustively related to the four fundamental inputs in a rigorous way.

49.3.4.1 Thrust and Torque from Rotors

Here, the magnitude of the rotor thrust and drag torque, $|\mathbf{T}_i|$ and $|\mathbf{Q}_{d,i}|$, will first be investigated. According to the aerodynamic actuator disk theory (Bramwell et al. 2001), the magnitude of thrust generated by the rotors can be formulated as follows:

$$|\mathbf{T}_i| = \rho C_{T,i} A (\Omega_i R)^2, \quad (49.17)$$

where ρ is the density of air, $C_{T,i}$ is the lift coefficient, A is the rotor disk area, Ω_i is the rotational speed of the rotor, and R is the rotor blade length. Since this is a fixed-pitch coaxial helicopter, $C_{T,i}$, like the other parameters in (49.17), is constant. The only variable is Ω_i . Hence, the equation can be simplified to

$$|\mathbf{T}_i| = k_{T,i} \Omega_i^2, \quad (49.18)$$

where $k_{T,i}$ is a lumped thrust coefficient that needs to be identified. Similar assumptions and formulation can be applied to the relationship between the drag torque and the rotational speed of the rotors:

$$|\mathbf{Q}_{d,i}| = k_{Q,i} \Omega_i^2. \quad (49.19)$$

49.3.4.2 Rotor Flapping Dynamics

For this specific type of coaxial helicopter, the rotor collective pitch is fixed, while the cyclic pitch can be changed. For the lower rotor, the rotor hub is connected to the aileron and the elevator servos via a swashplate. When the swashplate tilts, it teeters the rotor hub and creates a cyclic pitch on the rotor. For every cycle of rotation, the rotor blade will reach the maximum angle of attack at a particular phase angle at which the lift on the blade is largest. This results in the flapping of the rotor disk. The whole mechanism is a combination of gyroscopic precession and aerodynamic precession. For the case of Esky Big Lama, if one observes the rotor blade in a slow motion, the maximum rotor flapping occurs roughly at 45° lag with respect to the occurrence of maximum angle of attack. This explains why the aileron and elevator servos of the off-the-shelf coaxial platform are connected to the swashplate 45° off the body-frame x -, y -axis. In this way, the aileron servo mainly controls the lateral flapping of the lower rotor, and the elevator servo mainly controls the longitudinal flapping. However, the flapping phase lag is not exactly equal to 45° (slightly larger than 45° from test bench observations) due to mechanical modifications to the original RC platform (original rotor blades have been replaced by stiffer ones for larger payload). This results in non-negligible coupling between the servo inputs and the lower rotor longitudinal and lateral flapping angles. As the lower rotor does not have any additional damping mechanism attached, its flapping process is almost instantaneous. By assuming a first-order dynamics, the time constant can be observed via a high-speed camera. The result turns out to be 0.0375 s (see Fig. 49.6), which is very small as compared to dynamics of other parts of the coaxial helicopter

Fig. 49.6 Step response of servo motion attached to the lower rotor (*top*: $t = 0$; *center*, $t \approx 0.0375$ s; *bottom*, $t = \infty$). This figure looks dim because it was taken by a high-speed camera

and thus can be ignored. Hence, the relationship between servo inputs and lower rotor flapping angles can be formulated in a static way:

$$a_{dw} = A_{a,dw} \delta_{ele} + A_{b,dw} \delta_{ail} - A_q q, \quad (49.20)$$

$$b_{dw} = B_{b,dw} \delta_{ail} + B_{a,dw} \delta_{ele} - B_p p, \quad (49.21)$$

where aileron (δ_{ail}) and elevator (δ_{ele}) are the servo inputs, $A_{a,dw}$ and $B_{b,dw}$ are the on-axis steady-state ratio from servo inputs to flapping angles, and $A_{b,dw}$ and $B_{a,dw}$ are the off-axis (coupling) values. The last term which depends on angular rates, p and q , comes from an effect called rotor damping, which was considered in literature either in linear or quadratic form. Here, a linear form is chosen because of its simplicity.

For the upper rotor system, a stabilizer bar is attached to the rotor hub, so that they teeter together. As the stabilizer bar has large moment of inertia, it tends to remain at its original rotating plane. Hence, at the moment when the helicopter body tilts, the stabilizer bar TPP will remain at the level plane, thus creating a cyclic pitch on the upper rotor which leads to blade flapping. The torque generated by this flapping redresses the rotational motion of the helicopter and significantly stabilizes the whole platform attitude. Similar to the lower rotor system, the stabilizer bar is installed at 45° phase lead to the rotor blade. In this way, the maximum flapping happens at the direction that precisely counters the rotational motion of the helicopter. Again, there is coupling between the longitudinal and lateral channels because the flapping phase lag is not exactly 45° . The following equations describe the above mentioned dynamics:

$$\dot{\phi}_{sb} = \frac{1}{\tau_{sb}} (\phi - \phi_{sb}), \quad (49.22)$$

$$\dot{\theta}_{sb} = \frac{1}{\tau_{sb}} (\theta - \theta_{sb}), \quad (49.23)$$

$$a_{up} = A_{a,up} (\theta_{sb} - \theta) + A_{b,up} (\phi_{sb} - \phi) - A_q q, \quad (49.24)$$

$$b_{up} = B_{b,up} (\phi_{sb} - \phi) + B_{a,up} (\theta_{sb} - \theta) - B_p p, \quad (49.25)$$

where ϕ_{sb} and θ_{sb} are the roll and pitch angles of the stabilizer bar TPP, $A_{a,up}$ and $B_{b,up}$ are the on-axis steady-state ratio from the stabilizer bar teetering angles to the upper rotor flapping angles, and $A_{b,up}$ and $B_{a,up}$ are the off-axis (coupling) values. τ_{sb} is the time constant of approximated first-order flapping dynamics. Again, the same rotor damping effects (terms depending on p and q) are considered for the upper rotor flapping dynamics.

49.3.4.3 Fuselage Drag

When the helicopter fuselage moves in air, it experiences drag force acting on the opposite direction of the motion. For the body-frame horizontal directions, the rotor

downwash is deflected by u and v . In the situation when u (or v) is less than v_i (the induced velocity of air at the lower rotor), the downwash effect needs to be taken into account. Otherwise, the downwash effect is relatively weak and can be ignored. The fuselage in all three directions is considered as a flat plate perpendicular to the helicopter motion; thus, the drag coefficient is approximately unity. As such, the horizontal fuselage drag forces are formulated in a quadratic form:

$$X_{\text{fus}} = -\frac{\rho}{2} S_x u \cdot \max(v_i, |u|), \quad (49.26)$$

$$Y_{\text{fus}} = -\frac{\rho}{2} S_y v \cdot \max(v_i, |v|), \quad (49.27)$$

$$v_i = \sqrt{\frac{|T_{\text{dw}}|}{2\rho\pi R^2}}, \quad (49.28)$$

where S_x and S_y are the effective drag area along the body-frame x - and y -axis, respectively.

For the vertical direction, since the fuselage is constantly exposed to the lower rotor downwash, it is commonly formulated in the following form:

$$Z_{\text{fus}} = -\frac{\rho}{2} S_z (w - v_i) |w - v_i|. \quad (49.29)$$

However, as the lift coefficient test for identifying $k_{T,i}$ in Eq. 49.18 was done with the presence of the fuselage (so the term $\frac{\rho}{2} S_z v_i^2$ has already been taken into account), the above equation needs to be compensated as

$$Z_{\text{fus}} = -\frac{\rho}{2} S_z w \cdot \max(v_i, |w|), \quad (49.30)$$

where S_z is the effective drag area along the body-frame z -axis.

49.3.4.4 Motor Speed Dynamics

Two brushless DC motors are used on the Esky Big Lama coaxial platform. Their rotational speed dynamics follows the well-known differential equation of electro motors:

$$J_{\text{mot}} \dot{\omega} = \frac{k_m U - k_m k_e \omega}{R_{\text{mot}}} - d\omega - M_L, \quad (49.31)$$

where J_{mot} is the motor moment of inertia, k_m and k_e are the mechanical and electrical motor constants, U is the input voltage, R_{mot} is the resistance of the circuit, d is the friction coefficient, and M_L is the external torque acting on the motor shaft. Here, M_L is equal to the rotor drag torque $Q_{d,i}$ appeared in Eq. 49.19. If the helicopter operates at a near-hover condition, everything can be approximated as linear. M_L can be assumed to be a combination of a constant trimming value, M_L^* ,

and another term proportional to extra rotational speed as compared to the trimming speed, Ω^* :

$$M_L = M_L^* + k_L(\Omega - \Omega^*). \quad (49.32)$$

By further considering that the rotational speed of rotor, Ω , and the rotational speed of the motor, ω , are perfectly proportional by the gear ratio, the rotor speed dynamics can be simplified to the following first-order equations:

$$\dot{\Omega}_{\text{up}} = \frac{1}{\tau_{\text{mt}}}(m_{\text{up}}\delta_{\text{up}} + \Omega_{\text{up}}^* - \Omega_{\text{up}}), \quad (49.33)$$

$$\dot{\Omega}_{\text{dw}} = \frac{1}{\tau_{\text{mt}}}(m_{\text{dw}}\delta_{\text{dw}} + \Omega_{\text{dw}}^* - \Omega_{\text{dw}}), \quad (49.34)$$

where Ω_{up}^* and Ω_{dw}^* are the trimming values of the rotor rotational speed at hovering, τ_{mt} is the time constant of the motor speed dynamics, and m_{up} , m_{dw} are the steady-state ratio between the change of rotor speeds and the change of motor inputs.

49.3.4.5 Mixer and Headlock Gyro Dynamics

In order to largely decouple the throttle-heave and the rudder-yaw dynamics, the throttle and rudder signals are passed into a hardware mixer and transformed to dual motor control signals:

$$\delta_{\text{up}} = \delta_{\text{thr}} + \bar{\delta}_{\text{rud}}, \quad (49.35)$$

$$\delta_{\text{dw}} = \delta_{\text{thr}} - \bar{\delta}_{\text{rud}}. \quad (49.36)$$

It can be seen that when the throttle signal δ_{thr} increases, inputs to both motors increase; when the rudder signal $\bar{\delta}_{\text{rud}}$ increases, the input to the motor connected to the upper rotor increases while the input to the motor connected to the lower rotor decreases.

Note that the rudder signal in the above mixer equation is not the original signal δ_{rud} . From δ_{rud} to $\bar{\delta}_{\text{rud}}$, there is a hardware headlock gyro which helps refine the rudder signal and acts as the most inner-loop yaw motion stabilizer. Usually, there is a PI controller embedded inside the headlock gyro, and it can be formulated as follows:

$$\dot{r}_{\text{fb}} = K_a\delta_{\text{rud}} - r, \quad (49.37)$$

$$\bar{\delta}_{\text{rud}} = K_P(K_a\delta_{\text{rud}} - r) + K_I r_{\text{fb}}, \quad (49.38)$$

where r_{fb} is the augmented state variable needed by the integral control. At this point, the full dynamics of a coaxial helicopter have been mathematically formulated, but the model parameters are yet to be identified. In Sect. 49.4, the identification methods will be comprehensively given.

49.3.5 Force and Torque Formulation of Variable-Pitch Coaxial Helicopter

For the case of the variable-pitch coaxial helicopter, the formulation of force and torque generation will not be thoroughly listed as some of the formulas are very much like its fixed-pitch counterpart. For example, the formulas about fuselage drag and the headlock gyro PI controller are more or less the same. As such, only formulations that have significant differences when compared to the fixed-pitch coaxial case will be listed and explained here.

It should also be noted that the main differences compared occur in two areas, namely, the rotor thrust generation and the rotor flapping dynamics. In this section, the formulations about thrust generation and rotor flapping dynamics of the variable-pitch coaxial helicopter will be derived from a more fundamental perspective, thus capturing more aerodynamic details. This also reflects the fact that model formulation of aerial vehicles can be done at different levels of complexity. If the model is to be used for accurate structural analysis and optimization or controller design for aggressive maneuvering, then a more precise and complicated modeling approach should be adopted. However, if the planned flight missions are relatively stable and peaceful, a simplified model formulation is usually more than enough, such as that of the fixed-pitch coaxial case.

Thorough aerodynamics study of coaxial rotor system is itself a big research topic. NASA researcher (Colin 1997) has provided a good survey covering the aerodynamics research worldwide, including America, Russia, Japan, and Germany. Of all the surveyed techniques, blade element momentum theory (BEMT) (Leishman 2006) is a standard method for preliminary rotor analysis before complex high-level analysis, such as free vortex models (FVM) and Lagrangian particle vortex methods (LPVM). In this chapter, the detailed derivation and reasoning of BEMT will not be repeated. Only the main computation procedures are listed for easier reference and understanding.

49.3.5.1 Thrust and Torque from Rotors

The formal analysis of helicopter rotor motion usually starts from its thrust, torque, and power generation. The rotor thrust, torque, and power can be expressed as

$$T = \rho C_T A \Omega^2 R^2, \quad (49.39)$$

$$Q = \rho C_Q A \Omega^2 R^3, \quad (49.40)$$

$$P = \rho C_P A \Omega^3 R^3. \quad (49.41)$$

Here, ρ is the air density, A is the rotor disk area, Ω is the rotor rotational speed, and R is the rotor radius. C_T , C_P , C_Q are the rotor thrust coefficient, power coefficient, and torque coefficient, respectively. It should be noted that the power is related to torque by $P = \Omega Q$. Hence, $C_P = C_Q$ numerically. All the parameters in Eqs. 49.39–49.41 are constant except for the three coefficients C_T , C_P , C_Q .

First of all, the incremental thrust coefficient is defined as

$$dC_T = \frac{1}{2} \sigma C_{l_\alpha} r^2 dr = \frac{\sigma C_{l_\alpha}}{2} (\theta_u r^2 - \lambda r) dr, \quad (49.42)$$

where C_{l_α} is the lift-curve slope of the airfoil section, which can be obtained by checking the official wind tunnel test results if the blade airfoil is standard. σ is the rotor solidity defined as the ratio of the blade area against the rotor disk area. θ_u is the blade pitch distribution on the upper rotor. r is the nondimensional radial distance along the blade. λ is the nondimensional induced velocity which can be expressed in terms of r and λ_∞ as

$$\lambda(r, \lambda_\infty) = \sqrt{\left(\frac{\sigma C_{l_\alpha}}{16F} - \frac{\lambda_\infty}{2}\right)^2 + \frac{\sigma C_{l_\alpha}}{8F} \theta_u r} - \left(\frac{\sigma C_{l_\alpha}}{16F} - \frac{\lambda_\infty}{2}\right), \quad (49.43)$$

where F is the factor to account for the Prandtl tip loss defined as

$$F = \left(\frac{2}{\pi}\right) \cos^{-1}(e^{-f}), \quad (49.44)$$

where f is given in terms of the number of blades N_b and the radial position of the blade element r :

$$f = \frac{N_b}{2} \left(\frac{1-r}{r\phi} \right), \quad (49.45)$$

and ϕ is the induced inflow angle, which equals to $\lambda(r)/r$.

For both the upper and lower rotors, the same principles can be applied. However, as the inner part of the lower rotor operates in the *vena contracta* of the upper rotor, the analysis can be more complicated. From the flow visualization results of Taylor (1950), the author stated that the wake of the upper rotor contracts fully within $0.25R$ below the upper rotor. The ideal wake contraction ratio, r_c , is 0.707, but in practice it is found closer to 0.8. The contracted wake is defined as $A_c = \pi r_c^2 R^2$. The inner area of the lower rotor encounters incoming stream-tubes with velocity $V_\infty + (A/A_c)v_u$ ($V_\infty + 2v_u$ in the ideal case). For beam sections lying inside the upper rotor contraction area, the inflow distribution is given as

$$\lambda(r, \lambda_\infty) = \sqrt{\left(\frac{\sigma C_{l_\alpha}}{16F} - \frac{\lambda_\infty + (A/A_c)\lambda_u}{2}\right)^2 + \frac{\sigma C_{l_\alpha}}{8F} \theta_l r} - \left(\frac{\sigma C_{l_\alpha}}{16F} - \frac{\lambda_\infty + (A/A_c)\lambda_u}{2}\right), \quad (49.46)$$

where θ_l is the blade pitch distribution on the lower rotor. For points outside the contraction area, the inflow distribution is given as

$$\lambda(r, \lambda_\infty) = \sqrt{\left(\frac{\sigma C_{l_\alpha}}{16F} - \frac{\lambda_\infty}{2}\right)^2 + \frac{\sigma C_{l_\alpha}}{8F} \theta_l r} - \left(\frac{\sigma C_{l_\alpha}}{16F} - \frac{\lambda_\infty}{2}\right). \quad (49.47)$$

When the inflow velocity distribution is obtained, the total thrust lift coefficient could be found by integrating Eq. 49.42 as

$$C_T = \int_{r=0}^{r=1} dC_T. \quad (49.48)$$

For the rotor torque coefficient and power coefficient, their incremental calculation is also provided by BEMT:

$$dC_Q = dC_P = \frac{\sigma}{2}(\phi C_l + C_d)r^3 dr, \quad (49.49)$$

where C_d is the rotor drag coefficient. By knowing the fact that $\lambda = \phi r$, the incremental power is defined as

$$\begin{aligned} dC_P &= \frac{\sigma}{2}\phi C_l r^3 dr + \frac{\sigma}{2}C_d r^3 dr \\ &= \frac{\sigma}{2}C_l \lambda r^2 dr + \frac{\sigma}{2}C_d r^3 dr \\ &= dC_{P_u} + dC_{P_o}. \end{aligned} \quad (49.50)$$

The induced power coefficient can be obtained by integrating dC_{P_u} as follows:

$$C_{P_u} = \int_{r=0}^{r=1} dC_{P_u} = \int_{r=0}^{r=1} \lambda dC_{T_u}, \quad (49.51)$$

and the profile part of the rotor power is given by

$$C_{P_o} = \frac{\sigma}{2} \int_0^1 C_d r^3 dr. \quad (49.52)$$

49.3.5.2 Bare Rotor Flapping Dynamics

Similar to that of the fixed-pitch coaxial case, the rotor flapping dynamics of the variable-pitch coaxial helicopter is also seen as a rigid disk which can tilt about its longitudinal and lateral axes. However, instead of directly linking the flapping angles' dynamics to the servo inputs, the flapping angles (a_i , b_i) are first related to the cyclic pitch angles ($\theta_{cyc,bi}$, $\theta_{cyc,ai}$) as intermediate variables. The presence of $\theta_{cyc,bi}$ and $\theta_{cyc,ai}$ is a joint consequence of servo inputs and the stabilizer bar flapping angles. The detailed description of the rotor equations is extremely complicated. Here, a simplified formulation is adopted, where the rotor forces and moments are expressed as a polynomial function of the rotor state variables (Mettler 2002).

By removing the higher-order terms of the TPP equation, the remaining first-order rotor dynamics could be expressed as

$$\tau \dot{b}_i = -b_i - \tau p + B_a a_i + \theta_{\text{cyc}, bi}, \quad (49.53)$$

$$\tau \dot{a}_i = -a_i - \tau q + A_b b_i + \theta_{\text{cyc}, ai}, \quad (49.54)$$

where

$$A_b = -B_a = \frac{8K_\beta}{\gamma \Omega^2 J_\beta}, \quad (49.55)$$

$$\tau = \frac{16}{\gamma_r \Omega} \left(1 - \frac{8e}{3R} \right)^{-1}, \quad (49.56)$$

$$\gamma = \frac{\rho c C_{l\alpha} R^4}{J_\beta}. \quad (49.57)$$

a_i and b_i are the first-order TPP flapping angles in the longitudinal and lateral directions for either the upper rotors or the lower rotors. τ and γ are the flapping time constant and the lock number of the rotor blades, respectively. J_β is the blade moment of inertia. $\theta_{\text{cyc}, ai}$ and $\theta_{\text{cyc}, bi}$ are the longitudinal and lateral cyclic pitch of rotor blade. The other terms are defined by the same symbols as that of the fixed-pitch coaxial helicopter analysis in Sect. 49.3.4. The approximate formulation in Eqs. 49.53 and 49.54 characterizes the crucial TPP responses with respect to rotor cyclic control inputs.

49.3.5.3 Stabilizer Bar Flapping Dynamics

The stabilizer bar, which is attached to the upper main rotor shaft via a free-teetering hinge, can be regarded as a third disk. It consists of two paddles and a steel rod. The stabilizer bar is not designed to produce thrust or moment on the main hub, whereas its main function is to adjust the helicopter dynamics via the Bell-Hiller mixer by augmenting the cyclic pitch command of the upper rotor. It serves as a feedback system which increases the helicopter robustness against wind gust and turbulence (Cai et al. 2011). The flapping dynamics of stabilizer bar can be expressed as two first-order differential equations:

$$\dot{\phi}_{\text{sb}} = -q - \frac{1}{\tau_{\text{sb}}} \phi_{\text{sb}} + \frac{C}{\tau_{\text{sb}}} \delta_{\text{ail}}, \quad (49.58)$$

$$\dot{\theta}_{\text{sb}} = -p - \frac{1}{\tau_{\text{sb}}} \theta_{\text{sb}} + \frac{D}{\tau_{\text{sb}}} \delta_{\text{ele}}, \quad (49.59)$$

where τ_{sb} is the stabilizer bar flapping time constant, and it can be calculated as

$$\tau_{\text{sb}} = \frac{16}{\gamma_{\text{sb}} \Omega}, \quad (49.60)$$

where γ_{sb} is the stabilizer bar lock number:

$$\gamma_{sb} = \frac{\rho c_{sb} C_{l\alpha, sb} (R_{sb}^4 - r_{sb}^4)}{I_{\beta, sb}}. \quad (49.61)$$

The free-teetering hinge does not constrain the flapping of the stabilizer bar; thus, there is no coupling between the longitudinal and lateral flapping motions. The augmented rotor cyclic pitch of upper rotor can be expressed as

$$\theta_{cyc, aup} = A_a \delta_{ele} + K_{sb} \phi_{sb}, \quad (49.62)$$

$$\theta_{cyc, bup} = B_b \delta_{ail} + K_{sb} \theta_{sb}, \quad (49.63)$$

where K_{sb} is the ratio of rotor blade cyclic pitch to stabilizer bar flapping.

49.3.5.4 Lumped Flapping Dynamics

In this variable-pitch coaxial configuration, the upper rotor and the lower rotor receive the same cyclic input (δ_{ail} , δ_{ele}) since the top swashplate and bottom swashplate are always parallel. To minimize the overall complexity of the model, the two counterrotating rotor disks are treated as one equivalent rotor disk with respect to flapping motions. This assumption is only valid when the helicopter does not perform rapid maneuvering. By making this assumption, the model can be simplified to a large extent yet maintaining reasonable fidelity. The imaginary rotor has equivalent longitudinal and lateral angles expressed as a_s and b_s . Combining Eqs. 49.53–49.63, the lumped flapping dynamics subsystem could be represented in the following state-space form:

$$\dot{\mathbf{x}} = \mathbf{A} \mathbf{x} + \mathbf{B} \mathbf{u}, \quad (49.64)$$

$$\dot{\mathbf{y}} = \mathbf{C} \mathbf{x}, \quad (49.65)$$

where

$$\mathbf{x} = \begin{pmatrix} p \\ q \\ a_s \\ b_s \end{pmatrix}, \quad \mathbf{u} = \begin{pmatrix} \delta_{ail} \\ \delta_{ele} \end{pmatrix}, \quad \mathbf{y} = \begin{pmatrix} p \\ q \end{pmatrix}, \quad (49.66)$$

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & L_b \\ 0 & 0 & M_a & 0 \\ 0 & -1 & -\frac{1}{\tau_s} & \frac{A_b}{\tau_s} \\ -1 & 0 & \frac{B_a}{\tau_s} & -\frac{1}{\tau_s} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 0 & A'_{lon} \\ B'_{lat} & 0 \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}, \quad (49.67)$$

$$L_b = \frac{mg H_{mr} + K_\beta}{J_{xx}}, \quad M_a = \frac{mg H_{mr} + K_\beta}{J_{yy}}. \quad (49.68)$$

49.4 Model-Based Parameter Identification

When model formulation of a certain type of aerial platform has been derived, the next step is to identify unknown parameters of the derived model for a particular case. This is commonly known as the model-based parameter identification. In this section, several common parameter identification methods will be introduced based on the case study of ESky Big Lama, belonging to the fixed-pitch coaxial helicopter. It will be seen that some of the model parameters can be directly measured, while the remaining ones need special test bench experiments or flight tests to be carried out. The identification procedures for the case of variable-pitch coaxial helicopter will not be repeated since similar methods can be applied. It is also hoped that the readers will try the suggested experimental setups on other types of aerial platforms if they face similar parameter identification problems in their UAV-related projects.

49.4.1 Direct Measurement

For the ESky Big Lama fixed-pitch coaxial helicopter, some of its model parameters, especially those inherently defined by the platform dimension, geometry, weight loading, and the operational environment, can be directly measured or algebraically calculated, for example, the total mass of the platform (m), the distance from the rotor hubs to CG ($|\mathbf{l}_{up}|$ and $|\mathbf{l}_{dw}|$), the air density (ρ), the rotor diameter (R), the effective drag area of the fuselage (S_x , S_y , S_z), and the moment of inertia of the upper and lower rotor system (J_{up} , J_{dw}). Table 49.4 shows all the parameter values that can be identified through direct measurement and simple calculation.

49.4.2 Test Bench Experiment

In most aerial vehicle modeling cases, the direct measurement method is only able to determine a small portion of the parameters. The remaining majority parameters have to be identified by additional test bench experiments or actual flight tests. In this subsection, some common test bench methods are introduced, and they are again illustrated based on the ESky Big Lama fixed-pitch coaxial helicopter case.

First of all, the diagonal elements of the helicopter moment of inertia matrix J_{xx} , J_{yy} , J_{zz} can be measured by the so-called trifilar pendulum method proposed in Harris (1996). The experimental setup is shown in Fig. 49.7. In this experiment, the coaxial platform is suspended by three flexible strings with equal length l . The horizontal distances between the attached points and the CG are l_1 , l_2 , and l_3 , respectively. One can slightly twist and release the platform around the z -axis and record the oscillation period t_l . The moment of inertia is then given by

$$J_{zz} = \frac{mgl_1l_2l_3t_l^2}{4\pi^2l} \cdot \frac{l_1 \sin \alpha_1 + l_2 \sin \alpha_2 + l_3 \sin \alpha_3}{l_2l_3 \sin \alpha_1 + l_1l_3 \sin \alpha_2 + l_1l_2 \sin \alpha_3}, \quad (49.69)$$

Table 49.4 Parameters determined via direct measurement

| Parameter | Physical meaning |
|--|--|
| $\rho = 1.204 \text{ kg m}^{-3}$ | Air density |
| $m = 0.977 \text{ kg}$ | Total mass of the platform |
| $R = 0.250 \text{ m}$ | Rotor radius |
| $g = 9.781 \text{ m s}^{-2}$ | Earth gravity |
| $S_{fx} = 0.00835 \text{ m}^2$ | Effective longitudinal fuselage drag area |
| $S_{fy} = 0.01310 \text{ m}^2$ | Effective lateral fuselage drag area |
| $S_{fz} = 0.01700 \text{ m}^2$ | Effective vertical fuselage drag area |
| $ l_{up} = 0.195 \text{ m}$ | Distance from platform CG to the upper rotor hub |
| $ l_{dw} = 0.120 \text{ m}$ | Distance from platform CG to the lower rotor hub |
| $J_{up} = 6.8613 \cdot 10^{-4} \text{ kg m}^2$ | Moment of inertia of the upper rotor with stabilizer bar |
| $J_{dw} = 3.2906 \cdot 10^{-4} \text{ kg m}^2$ | Moment of inertia of the lower rotor |

Fig. 49.7 The trifilar pendulum method

where α_1 , α_2 , and α_3 are the angles denoted in Fig. 49.7. Similar experiments can be done to obtain the moment of inertia around the y and z axes. Figure 49.8 shows the experimental setups to carry out this trifilar pendulum method to obtain the moment of inertia of the Esky Big Lama in all three axes.

Next, to identify the rotor thrust coefficient and torque coefficient ($k_{T,i}$ and $k_{Q,i}$), two self-designed test bench experiments were carried out

Fig. 49.8 The setups to test helicopter moment of inertia. (a) x -axis. (b) y -axis. (c) z -axis

(see Figs. 49.9 and 49.10). The main measurement sensors include a force meter and a tachometer. When different values of pulse width modulation (PWM) signals are given to the motors, the steady-state rotor rotational speed and the generated thrust/torque are recorded. For the thrust experiment, results are summarized in Fig. 49.11. There are four lines in the plot, in which two of them (solid lines) perfectly match. They represent the cases when only one rotor, either the upper rotor or the lower rotor, is rotating. The dashed line on the top is a numerical combination of the two solid lines, while the dash-dot line comes from the actual test with both rotors spinning at the same speed. The gap between the two lines shows a drop in thrust efficiency caused by aerodynamic interactions between the two rotors. According to Deng et al. (2003), for a coaxial helicopter operating in near-hover condition, the induced-velocity effect of the upper rotor to the lower rotor is significantly larger than that of the lower rotor to the upper rotor. Thus, the loss of thrust efficiency can be assumed to be fully absorbed by the lower rotor thrust coefficient. Hence, $k_{T,up}$ is the gradient of the solid line, and $k_{T,dw}$ is the gradient difference between the dash-dot line and the solid line. For the torque experiment, results are summarized in Fig. 49.12. The solid line represents the case when only

Fig. 49.9 Setup to investigate relation between rotor thrust and rotor rotational speed

Fig. 49.10 Setup to investigate relation between rotor torque and rotor rotational speed

Fig. 49.11 Data plot of thrust against square of rotor speed

the stabilizer bar is rotating, while the dash-dot line is for a single rotating rotor. The dashed line is generated with the upper rotor and the stabilizer bar spinning together. Unsurprisingly, it matches the numerical combination of the lower two lines. Thus, the gradient of the dashed line is $k_{Q,up}$, and the gradient of the dash-dot line is $k_{Q,dw}$.

The identification of parameters involved in the motor dynamics can be done via test bench experiments also. The method to determine motor time constant (τ_{mt}) is a bit tricky, as the transient response of the rotor speed with a step motor input is very difficult to be recorded in real time. As such, instead of examining the transient response of the rotor speed with motor step input, the transient response of the input voltage subject to the changes of the motor Back-EMF (voltage generated by the spinning motor) is recorded using an oscilloscope (see Fig. 49.13). In theory, the time constant of the two transient responses should be the same. On the other hand, m_{up} and m_{dw} can be identified by plotting the steady-state relationship between the rotor speed and the normalized motor input (see Fig. 49.14). m_{up} and m_{dw} are the gradients of the two fitted lines in the figure.

The headlock gyro forms the most inner-loop control in the helicopter yaw channel. As mentioned in Sect. 49.3.4, it is a PI controller with three parameters (K_a , K_P , K_I) to be identified. The identification of K_a can be done via a hovering

Fig. 49.12 Data plot of torque against square of rotor speed

Fig. 49.13 Estimation of time constant of motor speed dynamics

Fig. 49.14 Data plot of rotor speed against motor input

Table 49.5 Yaw rate against rudder input

| | | | | |
|------------------------|-------|-------|-------|-------|
| r (rad/s) | −1.50 | −2.50 | −2.60 | −3.50 |
| δ_{rud} (−1, 1) | 0.25 | 0.35 | 0.40 | 0.55 |

turn test of the coaxial helicopter with different steady-state yaw rates. This test belongs more to the test bench category instead of flight test because it can be done on a swivel table with minimal friction. Table 49.5 shows four sets of data recorded. By plotting the least-square-fit line (see Fig. 49.15) and calculating its gradient, K_a can be determined. For the identification of K_P and K_I , the helicopter is placed stationary on a table. K_P and K_I can be determined by observing the headlock gyro output signal (in pulse width modulation form) caused by a small known step inputs. The initial ratio between the output and the input is $K_P \cdot K_a$, while the climbing rate of the step response is $K_I \cdot K_a$.

Last but not least, test bench experiments are also capable of determining some of the model parameters involved in the rotor flapping dynamics. First of all, by tilting the helicopter suddenly with rotor rotating at hovering speed and observing the transient step response of the stabilizer bar TPP (see Fig. 49.16) by a high-speed camera, the time constant (τ_{sb}) can be found to be about 0.2 s. In addition, the on-axis parameters that appear in the rotor flapping equations ($A_{a,up}$, $B_{b,up}$, $A_{a,dw}$, and $B_{b,dw}$) can be roughly identified by measuring lengths and angles under

Fig. 49.15 Data plot of yaw rate against rudder input

extreme conditions (see Figs. 49.17 and 49.18) and assume a linear proportional relationship between each pair of them. It should be noted that the parameters related to rotor flapping dynamics are most critical to the whole coaxial helicopter model. The above rough measurements may not be good enough to finalized their values. However, they can be used as an initial guess and get fine-tuned later by a model-based numerical search method via in-flight test data. In the next subsection, this method will be explained in detail. Here, Table 49.6 only lists those parameters that are already finalized at this test bench experiment stage.

49.4.3 Flight Test

After the majority of parameters have been identified, the remaining ones and a few uncertain ones can be identified and refined by analyzing flight test data with input perturbations (frequency sweeping). The recommended software for this task is called “Comprehensive Identification from FrEquency Responses” (CIFER). It is a MATLAB-based software package developed by NASA Ames Research Center for military-based rotorcraft system identifications.

In this Esky Big Lama case, since the remaining unidentified parameters are all about rotor flapping dynamics, only aileron and elevator perturbations need to be done to collect the relevant data for CIFER analysis. However, CIFER and most other parameter identification tools can only handle linear models. Hence, linearization needs to be done first to relate the aileron and elevator inputs to

Fig. 49.16 Step response of stabilizer bar TPP motion (*top*: $t = 0$; *center*, $t \approx 0.2$ s; *bottom*, $t = \infty$)

Fig. 49.17 *Left*: maximum teetering angle of the lower rotor hub; *right*: maximum flapping angle of the lower rotor

Fig. 49.18 *Left*: maximum teetering angle of the stabilizer bar; *right*: maximum teetering angle of the upper rotor hub

the helicopter roll, pitch angular rates. By relating and linearizing all the model formulation related to roll-pitch rate dynamics and upper rotor flapping dynamics at the hovering condition, one can obtain the following fourth-order linear state-space approximation:

$$\begin{pmatrix} \dot{p} \\ q \\ a_{up} \\ b_{up} \end{pmatrix} = \begin{bmatrix} \frac{-X_{dw}B_{p,dw}}{J_{xx}} & 0 & 0 & \frac{X_{up}}{J_{xx}} \\ 0 & \frac{-X_{dw}A_{q,dw}}{J_{yy}} & \frac{X_{up}}{J_{yy}} & 0 \\ -A_{b,up} & -A_{a,up} & -\frac{1}{\tau_{sb}} & 0 \\ -B_{b,up} & -B_{a,up} & 0 & -\frac{1}{\tau_{sb}} \end{bmatrix} \begin{pmatrix} p \\ q \\ a_{up} \\ b_{up} \end{pmatrix} + \begin{bmatrix} \frac{X_{dw}B_{b,dw}}{J_{xx}} & \frac{X_{dw}B_{a,dw}}{J_{xx}} \\ \frac{X_{dw}A_{b,dw}}{J_{yy}} & \frac{X_{dw}A_{a,dw}}{J_{yy}} \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{pmatrix} \delta_{ail} \\ \delta_{ele} \end{pmatrix}, \quad (49.70)$$

where $X_{up} = T_{up}l_{up} + K_{\beta}$ and $X_{dw} = T_{dw}l_{dw} + K_{\beta}$. By treating δ_{ail} , δ_{ele} as the inputs and p , q as the outputs (all can be recorded during flight tests) and giving known

Table 49.6 Parameters determined via test bench experiments

| Parameter | Physical meaning |
|--|--|
| $J_{xx} = 0.0059 \text{ kg m}^2$ | Platform moment of inertia in the x -axis |
| $J_{yy} = 0.0187 \text{ kg m}^2$ | Platform moment of inertia in the y -axis |
| $J_{zz} = 0.0030 \text{ kg m}^2$ | Platform moment of inertia in the z -axis |
| $k_{T,\text{up}} = 1.23 \cdot 10^{-4} \text{ N s}^2 \text{ rad}^{-2}$ | Effective thrust coefficient of the upper rotor |
| $k_{T,\text{dw}} = 8.50 \cdot 10^{-5} \text{ N s}^2 \text{ rad}^{-2}$ | Effective thrust coefficient of the lower rotor |
| $k_{Q,\text{up}} = 4.23 \cdot 10^{-6} \text{ N ms}^2 \text{ rad}^{-2}$ | Effective torque coefficient of the upper rotor |
| $k_{Q,\text{dw}} = 3.68 \cdot 10^{-6} \text{ N ms}^2 \text{ rad}^{-2}$ | Effective torque coefficient of the lower rotor |
| $m_{\text{up}} = 106.90 \text{ rad s}^{-1}$ | Steady-state ratio between change of upper rotor speed and change of motor input |
| $m_{\text{dw}} = 106.45 \text{ rad s}^{-1}$ | Steady-state ratio between change of lower rotor speed and change of motor input |
| $\Omega_{\text{up}}^* = 203.38 \text{ rad s}^{-1}$ | Trimming rotational speed of the upper rotor |
| $\Omega_{\text{dw}}^* = 217.88 \text{ rad s}^{-1}$ | Trimming rotational speed of the lower rotor |
| $\tau_{\text{mt}} = 0.12 \text{ s}$ | Motor time constant |
| $\tau_{\text{sb}} = 0.2 \text{ s}$ | Stabilizer bar time constant |
| $K_a = 6.4267$ | Feed-forward gain of the headlock gyro system |
| $K_p = 0.667/K_a$ | Proportional feedback gain of the headlock gyro system |
| $K_I = 0.713/K_a$ | Integral feedback gain of the headlock gyro system |

constraints and reasonable initial values (on-axis values from Sect. 49.4.2 and off-axis values as zeros), CIPHER helps to search for optimal numerical solution based on frequency response matching. A stable result with good matching is obtained as follows:

$$\begin{pmatrix} \dot{p} \\ q \\ a_{\text{up}} \\ b_{\text{up}} \end{pmatrix} = \begin{bmatrix} -17.19 & 0 & 0 & 934.1 \\ 0 & -5.360 & 291.3 & 0 \\ 0.2745 & -0.49 & -5 & 0 \\ -0.49 & -0.2745 & 0 & -5 \end{bmatrix} \begin{pmatrix} p \\ q \\ a_{\text{up}} \\ b_{\text{up}} \end{pmatrix} + \begin{bmatrix} -102.48 & -38.08 \\ -11.73 & 31.95 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{pmatrix} \delta_{\text{ail}} \\ \delta_{\text{ele}} \end{pmatrix}. \quad (49.71)$$

With this numerical result, Figs. 49.19–49.22 show the corresponding comparison of frequency response between the data collected via actual flight tests and the CIPHER derived model fit. For both the on-axis and off-axis responses, the matching is very good, indicating a high-quality identification result. Next, by comparing Eqs. 49.70 and 49.71, all the parameters involved in angular rate and rotor flapping dynamics can be finalized. Table 49.7 shows the identification results that have been obtained via flight test. Till now, all unknown parameters in the fixed-pitch coaxial model have been identified.

49.5 Model Verification

It is always a good practice to verify a derived system model with actual input and output data. In this section, a comprehensive evaluation on the fidelity of the obtained nonlinear model of the ESky Big Lama (fixed-pitch coaxial helicopter) is shown. Four manual flight tests were carried out, which include:

1. Aileron channel perturbation with platform rolling left and right
2. Elevator channel perturbation with platform pitching forward and backward
3. Throttle channel perturbation with platform flying up and down
4. Rudder channel perturbation with platform yawing clockwise and anticlockwise

In each of these four flight tests, the pilot was asked to agitate only one of the four input channels. However, to make sure the helicopter position does not drift too much, minor off-axis inputs were also issued to lightly counter the cross-couplings between the channels. The time-domain results are shown from Figs. 49.23 to 49.26. Based on the recorded inputs, the transient response of the UAV attitudes, angular rates, and body-frame velocities are calculated by a MATLAB simulation program with the aforementioned nonlinear mathematical model (dashed lines in the figures). They are plotted together with the in-flight true data obtained by the onboard sensors (solid lines in the figures). The matching between the two is quite perfect. Note that for the roll and pitch angular rate dynamics, both the on-axis and the off-axis responses match very well, indicating a precise formulation of the coupling terms. Some minor mismatches are caused by the ignorance of high-frequency dynamics when formulating the model, especially for the motion of rotor flapping, which is theoretically highly complicated. Other discrepancies come from ground effect, wind disturbances, and measurement noises present in practical flight tests. In general, this is an accurate cross-coupled model for a fixed-pitch coaxial UAV with low maneuvering speed.

49.6 Conclusions

This book chapter has demonstrated the main procedures and challenges in modeling flight dynamics of aerial vehicles for the purpose of UAV development. By using the fixed-pitch and variable-pitch coaxial helicopters as examples, the model formulation, parameter identification, and model verification methods are explained in sequence with an adequate level of complexity for people with general engineering backgrounds.

For the model formulation, all analysis starts from the general working principle and model structure of the targeted systems. Formulas to describe the 6DoF kinematics and rigid-body dynamics are listed, and they are universal to all other types of UAVs. The general composition of forces and torques exerted on the UAV fuselage is more or less the same for the fixed-pitch and variable-pitch coaxial helicopters. However, the detailed formulation of individual force and torque generation are different and thus explained separately.

For the model-based parameter identification, the identification methods are categorized into three types, namely, direct measurement, test bench experiments, and flight tests. The ESKy Big Lama, belonging to the fixed-pitch coaxial helicopter, is chosen to be a case study to illustrate some useful test bench and flight test setups to determine the model parameters. After all, a nonlinear model of the ESKy Big Lama flight dynamics is fully derived with all parameters identified.

Finally, model verification is done to prove the feasibility of the whole methodology. By comparing simulation data with the actual in-flight data, the fidelity of the derived nonlinear model is guaranteed. It is also worth noting that the derived model has been actually used in control law design for an indoor coaxial UAV, and good hovering performance has been achieved (Wang et al. 2012).

It is believed that with the proposed systematic modeling methodology, the readers will get insightful knowledge about UAV modeling and parameter identification. Hopefully, these methods can be utilized and applied to other types of aerial platforms, too. It is also welcomed that more detailed aerodynamic formulations and other innovative parameter identification methods can be shared in future and thus complement this work.

Abstract

In this chapter, the mathematical modeling and simulation of the micro UAV with a payload is derived. When the load is slung underneath the UAVs by cable, the flight dynamics of the UAVs will be altered, which makes the stability of the UAVs disturbed. The unstable oscillation may occur to degrade the performance of the UAVs, and the accurate placement of the load will be affected. Unlike the external disturbance, the negative effects are related to the characteristics of the UAV and the payload. In order to make the UAVs have the ability to adopt the change of the system dynamics and reduce the effects caused by the swing of the load, one modeling method of micro UAVs with single slung payload is addressed. The slung payload is treated as a pendulum-like mass point, and the coupling factors between the UAVs and the payload are considered in the Lagrangian formulation. The conducted model can be used to estimate the

negative effects acting on the UAVs, and it also can be used to assist estimating the trajectory of the load, which provides the possibility to improve the accuracy of placement of the loads.

50.1 Introduction

In recent years, unmanned aerial vehicles (UAVs) have become useful mobile platforms in industrial and academic fields, and their potential applications in numerous areas and their scientific significance in academic research have attracted more attentions (MacKunis et al. 2010; Mahony et al. 2012). Among various UAVs, the micro UAVs can provide an added measure of safety, security, and convenience for different applications, specifically, the micro UAV helicopters are suitable for a limited area or application by using their specific characteristics such as hovering and vertical landing (Marconi et al. 2011; Ryll et al. 2012; Tayebi and McGilvray 2006). In this chapter, one typical micro UAV, quadrotor-type aircraft, is chosen as the platform for the research work.

As a versatile aerial vehicle, one of the potential tasks of the UAV is to carry loads hanging in cable underneath the vehicles. However, carrying a slung load will take a new challenge since the flight characteristics of the UAVs is altered. Besides increasing the mass of UAVs, the slung load will induce oscillations that degrade the UAV's performance. For example, unstable oscillations may occur at high speeds due to the different aerodynamics of the slung loads that results in the crash. Also, the stability of UAV will be disturbed by the slung load, which slows or prevents an accurate placement of the loads. For example, placing a suspended payload accurately on a desired location, the swing load will degrade the placement precision, also the swing load can couple with the vehicle motion leading to poor flight handling performance with a potential for instability. There is, therefore, an interest in the scientific community to develop technologies that can address the challenge in operating UAVs with slung loads (Cruz and Fierro 2012; Min et al. 2011).

The modeling and control for vehicles carrying external suspended loads have been paid attention since the 1950s (Fusato et al. 2001; Hoh and Heffley 2006). Previous work addressed for single-helicopter or multi-helicopter with slung loads (Cicolani and Kanning 1992; Ronen 1985; Theron et al. 2005). Due to the coupling between the helicopter and the loads, it may not be suitable to deal with the oscillation or the instability caused by the slung loads as the external disturbance or the parameter uncertainty directly (Yang et al. 2011), and the related works have explored the specific or general dynamic models of the helicopter system coupled with the swing of the loads, and the control methods are designed for the stabilization of the helicopter systems (Cicolani and Kanning 1992; Fusato et al. 2001).

With the development of the unmanned aerial vehicles over the last few years, the flight stabilization of the UAVs with slung loads poses novel problems for the research of UAVs (Bernard et al. 2008; Bisgaard et al. 2010). The characteristics of the UAVs are different with the conventional helicopters, which makes the available methods may not be shifted to the UAV systems directly (Thanapalan and Wong 2010; Zameroski et al. 2011). For the quadrotor used in this research platform, it is

a four-rotor helicopter, which can be treated as an underactuated, dynamic vehicle with four inputs (four rotors) and six output coordinates (Castillo et al. 2005a; Peng et al. 2009). Different with the conventional helicopters changing the pitch and roll control torques by swashplate, in a quadrotor, rotors are paired to spin in opposite directions so that the quadrotor-type UAV has high payload and relatively easily balanced venter of mass. The quadrotor can be controlled by varying the angular speed of each rotor and moving forward by pitching. These characteristics of quadrotor make it necessary to consider the modeling method of the micro UAVs with payload, which can be used to estimate the performance of the micro UAV systems and to improve the precision of the payload location by choosing the proper cable length, UAV/load mass ratios, etc.

In this chapter, the modeling of quadrotor flying with single slung load is addressed. The approach taken in this chapter is to develop a systematic analytical formulation for general micro UAV systems with slung payload. The micro UAV systems with payload are treated as a class of multibody dynamic systems consisting of two rigid bodies connected by massless cable, and the cable is considered as massless and inelastic link. Therein, the mathematical model is derived from the Newton-Euler equations for rigid bodies and the Lagrange's equations for general dynamic systems.

Besides the stabilization analysis of the micro UAV system slung payload, the position of the payload can be obtained by calculating the suspension angles of the payload, which is useful to estimate the position of the payload.

50.2 Modeling for Quadrotor UAV with Slung Payload

In this section, the derivation of a mathematical model of the micro UAV with slung load is presented. As an illustration, one quadrotor-type UAV with slung load is addressed. The quadrotor system with payload is treated as the rigid body motion of slung-load systems, and the effects caused by the pendulum-like behavior of the slung load are considered in the general simulation model. The modeling method discussed in this chapter is to develop a systematic analytical formulation for micro UAVs with slung payload, which can be utilized to improve the control performance of the UAVs. Firstly, the dynamic model for quadrotor is introduced briefly.

50.2.1 Quadrotor UAV Dynamic Model

Taking inspiration from the work addressing on the classical helicopter, a quadrotor UAV system is studied in this chapter (Castillo et al. 2005a; Min et al. 2011). As shown in Fig. 50.1, the fuselage dynamics and the coordinate system can be divided into an earth frame $\{E\}$ and a body frame $\{B\}$, which are used to describe the relative motions between the two coordinate frames. In order to simplify the highly nonlinear factors in quadrotor UAV system (Min et al. 2011), the following assumptions can be considered in developing the mathematical model of the quadrotor UAV, which are made based on the slower speed and lower altitude:

Fig. 50.1 Schematic of quadrotor UAV dynamics

Assumption 1. The center of mass and the body frame origin are assumed to coincide.

Assumption 2. Interaction with ground or other surfaces is neglected.

Assumption 3. The body is rigid and symmetrical.

Utilizing the above assumptions and considering the hovering and flying with low-speed situation, the quadrotor UAV dynamic model (50.1) can be derived via a Lagrange approach to describe a six-degree-of-freedom rigid body model (Alexis et al. 2011), driven by forces and moments as follows:

$$\begin{aligned}
 \ddot{x} &= \frac{U_1(\cos \phi \sin \theta \cos \psi + \sin \phi \sin \psi)}{M} \\
 \ddot{y} &= \frac{U_1(\sin \phi \sin \theta \cos \psi - \cos \phi \sin \psi)}{M} \\
 \ddot{z} &= \frac{U_1(\cos \phi \cos \theta)}{M} - g \\
 \ddot{\phi} &= \dot{\theta} \dot{\psi} \left(\frac{J_y - J_z}{J_x} \right) + \frac{l}{J_x} U_2 \\
 \ddot{\theta} &= \dot{\phi} \dot{\psi} \left(\frac{J_z - J_x}{J_y} \right) + \frac{l}{J_y} U_3 \\
 \ddot{\psi} &= \dot{\phi} \dot{\theta} \left(\frac{J_x - J_y}{J_z} \right) + \frac{1}{J_z} U_4
 \end{aligned} \tag{50.1}$$

where (x, y, z) are three positions; (θ, ϕ, ψ) three Euler angles; representing pitch, roll and yaw, respectively; g is the acceleration of gravity; M is the mass of the UAV; J_x, J_y, J_z are the inertia moments applied to the center of mass of UAV; and l is the distance between the propeller and the center of mass of UAV. The system inputs are posed U_1, U_2, U_3 , and U_4 , which can be defined as follows (Castillo et al. 2005a):

$$U_1 = F_1 + F_2 + F_3 + F_4$$

$$U_2 = F_3 - F_1$$

$$U_3 = F_4 - F_2$$

$$U_4 = F_1 + F_3 - F_2 - F_4$$

where F_1, F_2, F_3 , and F_4 represent control forces generated by four rotors, which are proportional to the square of the angle speed. U_1 is the sum of the individual thrusts of each rotor. U_2 and U_3 can change the roll torque and pitch torque, respectively. The yaw motion can be changed by U_4 while keeping U_1 as constant. The characteristics of the quadrotor make the quadrotor-type UAVs with good performance, such as the high payload and relatively easily balanced center of mass.

50.2.2 Modeling of External Slung Payload

In order to obtain the general system equations of motion, the underslung payload is considered as a point mass that behaves like a spherical pendulum from a single point in this chapter. As shown in Fig. 50.2, the payload is approximated as a point mass with an aerodynamic drag force acting on it (Chen 2009). The equations that describe the load dynamics are obtained by considering motion with reference to the longitudinal suspension angles α_x in the x - z plane and α_y in the y - z plane. The investigation of the dynamics of the payload is changed to discuss the motion of the mass point, and the position of the payload is determined by the length of the cable and the suspension angles α_x and α_y .

50.2.2.1 Payload Dynamics

Since the payload is modeled as a three-dimensional point mass pendulum, the position of the slung payload in the frame $\{\mathbf{B}\}$ can be defined as

$$r^B = \begin{bmatrix} 0 \\ 0 \\ L \end{bmatrix} \quad (50.2)$$

where L is the distance between the mass point of the UAV and the payload.

Remark 1. Based on Assumptions 1 and 3, the hook point is assumed under the mass point of the UAV, and the length of the hook with respect to the UAV L_d is considered as the distance between the mass point of the UAV and the UAV. Then, it

Fig. 50.2 The point mass slung payload model

has $L = L_t + L_d$, where L_t is the length of the cable. When $L_t \gg L_d$, the length of the cable L_t can be treated as L for convenience.

To make the payload independent of the UAV attitude change, the payload position will be derived using the earth-fixed coordinates, then the position of the payload with respect to the center of mass of UAV is

$$r = R \begin{bmatrix} 0 \\ 0 \\ L \end{bmatrix} \quad (50.3)$$

where

$$\begin{aligned} R = \text{Rot}(\alpha_y)\text{Rot}(\alpha_x) &= \begin{bmatrix} \cos \alpha_y & 0 & \sin \alpha_y \\ 0 & 1 & 0 \\ -\sin \alpha_y & 0 & \cos \alpha_y \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \alpha_x & -\sin \alpha_x \\ 0 & \sin \alpha_x & \cos \alpha_x \end{bmatrix} \\ &= \begin{bmatrix} \cos \alpha_y & \sin \alpha_x \sin \alpha_y & -\cos \alpha_x \sin \alpha_y \\ 0 & \cos \alpha_x & -\sin \alpha_x \\ -\sin \alpha_y & \sin \alpha_x \cos \alpha_y & -\cos \alpha_x \cos \alpha_y \end{bmatrix} \end{aligned} \quad (50.4)$$

and $\text{Rot}(\alpha_x)$ and $\text{Rot}(\alpha_y)$ are rotational matrices.

The position of the payload using earth-fixed coordinates is redefined as

$$r_L = \begin{bmatrix} x \\ y \\ z \end{bmatrix} + \begin{bmatrix} -L \cos \alpha_x \sin \alpha_y \\ -L \sin \alpha_x \\ -L \cos \alpha_x \cos \alpha_y \end{bmatrix} = \begin{bmatrix} x - L \cos \alpha_x \sin \alpha_y \\ y - L \sin \alpha_x \\ z - L \cos \alpha_x \cos \alpha_y \end{bmatrix} \quad (50.5)$$

then the absolute velocity \dot{r}_L of the payload is given by

$$\dot{r}_L = \begin{bmatrix} \dot{x} + L(\dot{\alpha}_y \cos \alpha_x \cos \alpha_y - \dot{\alpha}_x \sin \alpha_x \cos \alpha_y) \\ \dot{y} - L\dot{\alpha}_x \cos \alpha_x \\ \dot{z} + L(-\dot{\alpha}_x \sin \alpha_x \cos \alpha_y - \dot{\alpha}_x \cos \alpha_x \sin \alpha_y) \end{bmatrix} \quad (50.6)$$

To derive the dynamic model of the slung payload, the energy conservation property by means of Lagrange's equations is applied. The effects due to the motion of the quadrotor and the characteristics of the payload are involved in the investigation of the suspension angles.

Define the Lagrangian function Λ as

$$\Lambda = \Gamma - V \quad (50.7)$$

where $\Lambda = \Gamma - V$, Γ is the kinetic energy, and V is the potential energy.

The kinetic energy of the system Γ is the sum of the translational kinetic energy of the payload Γ_t and rotational kinetic energy of the payload Γ_r . Therein, the translational kinetic energy is defined as

$$\Gamma_t = \frac{1}{2} M_L \dot{r}_L^T \dot{r}_L \quad (50.8)$$

and the rotational kinetic energy is defined as

$$\Gamma_r = \frac{1}{2} M_L L^2 \dot{\alpha}_x^2 + \frac{1}{2} M_L L^2 \dot{\alpha}_y^2 \quad (50.9)$$

and the potential energy of the payload is $V = -M_L L \cos \alpha_x \cos \alpha_y$.

The equations of motion for the payload (no direct force acting on the payload) can be derived from the general form of Lagrange's equations as

$$\frac{d}{dt} \left(\frac{\partial \Lambda}{\partial \dot{\alpha}_x} \right) - \frac{\partial \Lambda}{\partial \alpha_x} = 0 \quad (50.10)$$

$$\frac{d}{dt} \left(\frac{\partial \Lambda}{\partial \dot{\alpha}_y} \right) - \frac{\partial \Lambda}{\partial \alpha_y} = 0 \quad (50.11)$$

where $\frac{\partial \Lambda}{\partial \dot{\alpha}_x}$ and $\frac{\partial \Lambda}{\partial \dot{\alpha}_y}$ are the momentum conjugate to α_x and α_y , respectively.

Based on the above definition of Lagrangian function Λ , each item $\frac{d}{dt} \left(\frac{\partial \Lambda}{\partial \dot{\alpha}_x} \right)$, $\frac{\partial \Lambda}{\partial \alpha_x}$, $\frac{d}{dt} \left(\frac{\partial \Lambda}{\partial \dot{\alpha}_y} \right)$, and $\frac{\partial \Lambda}{\partial \alpha_y}$ can be derived by using mathematical softwares, such as Maple.

Remark 2. Solving the equations defined in (50.10) and (50.11), the symbolic expressions for $\ddot{\alpha}_x$ and $\ddot{\alpha}_y$ can be calculated by software, which are the functions of α_x , α_y , $\dot{\alpha}_x$, $\dot{\alpha}_y$, \dot{x} , \dot{y} , \dot{z} , \ddot{x} , \ddot{y} , \ddot{z} , and L_c .

$$\begin{bmatrix} \ddot{\alpha}_x \\ \ddot{\alpha}_y \end{bmatrix} = \mathbf{F}(L, \alpha_x, \alpha_y, \dot{\alpha}_x, \dot{\alpha}_y, \dot{x}, \dot{y}, \dot{z}, \ddot{x}, \ddot{y}, \ddot{z}) \quad (50.12)$$

However, the expressions of $\ddot{\alpha}_x$ and $\ddot{\alpha}_y$ are too complicated to be implemented for the real-time application. Usually, the small-angle assumption $\sin \alpha_x \rightarrow \alpha_x$ and $\sin \alpha_y \rightarrow \alpha_y$ are used, then calculation of the angle acceleration of payload $\ddot{\alpha}_x$ and $\ddot{\alpha}_y$ can be simplified.

Remark 3. In some special cases, the high speed or high acceleration of the UAV may cause the high oscillation of the payload, the small-angle assumption is not applicable. For these cases, $\sin \alpha_x$ and $\sin \alpha_y$ can be expanded as Taylor series $\sin \alpha_x = \alpha_x - \frac{\alpha_x^3}{3!}$ and $\sin \alpha_y = \alpha_y - \frac{\alpha_y^3}{3!}$. Usually, the small-angle assumption is suitable for the regular operation of quadrotor flying with low speeds.

50.2.2.2 Dynamics of Micro UAV with Payload

As a motivational example to show the effects acting on the micro UAV, the dynamics of the quadrotor carrying single payload by cable is discussed in this section. The quadrotor and the payload are considered two separate rigid bodies and the force acting on the axes of quadrotor, respectively.

As shown in Fig. 50.3, the curvilinear motion of the payload will result in the force acting on the quadrotor, which can be separated in the tangential, normal directions. The formulation of the tangential acceleration a_τ and the normal acceleration a_n can be obtained, respectively, using the theorem of motion of center of mass law of conservation of momentum, which are calculated through the suspension angles α_x and α_y . Then, the forces caused by the payload in respective axes are derived as follows:

$$\begin{aligned} F_{ox} &= M_L a_{ox} = M_L a_{\tau x} \cos \alpha_x - M_L a_{nx} \sin \alpha_x \\ &= M_L \ddot{\alpha}_x L \cos \alpha_y \cos \alpha_x - M_L \dot{\alpha}_x^2 L \cos \alpha_y \sin \alpha_x \\ F_{oy} &= M_L a_{oy} = M_L a_{\tau y} \cos \alpha_y - M_L a_{ny} \sin \alpha_y \\ &= M_L \ddot{\alpha}_y L \cos \alpha_x \cos \alpha_y - M_L \dot{\alpha}_y^2 L \cos \alpha_x \sin \alpha_y \\ F_{oz} &= M_L a_{oz} - M_L g \end{aligned}$$

Fig. 50.3 System dynamics of quadrotor with pendulum-like payload

Fig. 50.4 Mechanical model of quadrotor with single payload

$$\begin{aligned}
 &= M_L \ddot{\alpha}_x L \cos \alpha_y \sin \alpha_x + M_L \dot{\alpha}_x^2 L \cos \alpha_y \cos \alpha_x \\
 &\quad + M_L \ddot{\alpha}_y L \cos \alpha_x \sin \alpha_y + M_L \dot{\alpha}_y^2 L \cos \alpha_x \cos \alpha_y - M_L g
 \end{aligned}$$

Using the Newton-Euler function, the mechanical model reflecting the force acting on the quadrotor is shown in Fig. 50.4. Therefore, the model of the quadrotor with payload can be expressed as

$$\begin{aligned}
(M + M_L)\ddot{x} &= U_1(\cos \phi \sin \theta \cos \psi + \sin \phi \sin \psi) - F_{ox} \\
(M + M_L)\ddot{y} &= U_1(\sin \phi \sin \theta \cos \psi - \cos \phi \sin \psi) - F_{oy} \\
(M + M_L)\ddot{z} &= U_1(\cos \phi \cos \psi) - Mg + F_{oz} \\
\ddot{\phi} &= \dot{\theta} \dot{\psi} \left(\frac{J_x - J_z}{J_x} \right) + \frac{l}{J_x} U_2 \\
\ddot{\theta} &= \dot{\phi} \dot{\psi} \left(\frac{J_z - J_x}{J_y} \right) + \frac{l}{J_y} U_3 \\
\ddot{\psi} &= \dot{\phi} \dot{\theta} \left(\frac{J_x - J_y}{J_z} \right) + \frac{1}{J_z} U_4
\end{aligned} \tag{50.13}$$

50.3 Simulation

In order to gain insight into the dynamics of the quadrotor with slung payload, the numerical simulation for the slung payload with quadrotor is presented in this section. The simulation parameters for the quadrotor are chosen as $M = 1.52$ kg, and its moments of inertia were estimated as 0.03, 0.03, and 0.04 kg · m² for the x , y , and z body axes, respectively. The distance L_d between the center of the quadrotor and the anchor point is 20 cm. In order to show the effects caused by the slung payload, the linear quadratic regulator (LQR) control laws (Castillo et al. 2005b) are used in the position controller and orientation controller, and the control parameters are kept as the same for different mass of payload and length of cable.

Remark 4. In this chapter, the main task is to discuss the modeling method of the micro UAV with payload, and the controller used in simulation has been discussed in the previous work for controller design of quadrotor- type UAV. As an illustration to show the system performance with slung payload, the controller used in this simulation can be replaced by other controllers for quadrotor UAV (Fig. 50.5).

50.3.1 Stabilization Analysis of UAV with Payload

In this section, the modeling method for the quadrotor with payload derived in the previous section is utilized to estimate the unknown effects caused by the payload. The simulation performs the motion of the quadrotor from position (0 m, 0 m, 1 m) to (1.75 m, 1.2 m, 2 m). The quadrotor system simulation response without payload is shown in Fig. 50.6.

In order to illustrate the coupling between the quadrotor and payload which is related to the length of the cable and the mass of the payload, the simulation is conducted with the same controller parameters working on the quadrotor without payload, then compare the simulation results by choosing different payload parameters listed in Table 50.1.

Figures 50.7 and 50.8 show the trajectory oscillation caused by the slung payload $M_L = 68\text{ g}$ with different cables $M_L = 10\text{ cm}$ and $M_L = 70\text{ cm}$. Based on the simulation results, the frequency of the oscillation caused by the slung load is related to the cable length, and the existence of the payload will cause the delay and the increase of the overshoot in z axis, when the controller keeps the same parameters.

Figures 50.9 and 50.10 show the trajectory oscillation caused by the slung payload $M_L = 108\text{ g}$ with the cable length as $L_t = 10\text{ cm}$ and $L_t = 70\text{ cm}$. Compared with the results in Figs. 50.7 and 50.8, the negative effects caused by the payload are increasing with the mass of the payload.

Fig. 50.7 The reference and UAV outputs with payload $M_L = 0.068$ kg and length of cable $L_t = 10$ cm

Fig. 50.8 The reference and UAV outputs with payload $M_L = 0.068$ kg and length of cable $L_t = 70$ cm

By constructing the dynamic model for the UAV with payload, the coupling effects related to the length of cable and mass of the payload can be considered in the system dynamics, and these characteristics can be addressed in the control approaches, improving the effectiveness of the control performance.

50.3.2 Estimation of Payload Position

Another purpose for modeling of UAV carrying payload is to estimate the position of the payload, improving the accuracy of placement of payload. Addressing this

Fig. 50.9 The reference and UAV outputs with payload $M_L = 0.108$ kg and length of cable $L_t = 10$ cm

Fig. 50.10 The reference and UAV outputs with payload $M_L = 0.108$ kg and length of cable $L_t = 70$ cm

task, the dynamics modeling for the quadrotor can be used to describe the motion of the payload. Following the definition in the earth-fixed frame $\{E\}$, the position of the payload can be obtained when the suspension angles of the payload α_x and α_y are determined. As an illustration, the trajectories of the payload are shown in Figs. 50.11 and 50.12, when the desired trajectories are set as $x_d = 1.2 \sin(0.1t)$ and $y_d = \sin(0.1t)$.

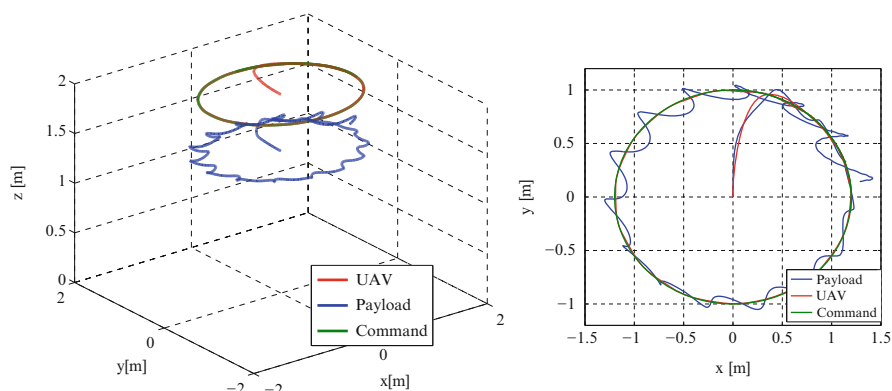

Fig. 50.11 The positions of the reference, quadrotor, and payload with $M_L = 0.068$ kg and $L_t = 37$ cm

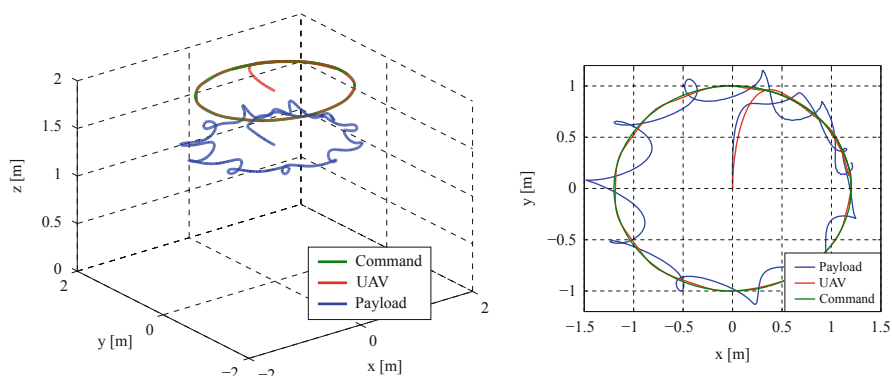

Fig. 50.12 The positions of the reference, quadrotor, and payload with $M_L = 0.108$ kg and $L_t = 37$ cm

50.4 Conclusion

One of the UAVs' tasks is to carry the payload by cable, and the negative effects caused by the slung load are coupled with the UAV systems, degrading the system performance and altering the flight dynamics of UAVs, which poses a new problem for the operating UAVs with slung payload. In this chapter, the model of single UAV with single payload is addressed. The slung payload is treated as a pendulum-like mass point, and the dynamics of the UAV with payload is obtained by formulating Lagrangian function. The derivation of the suspended angle of the payload makes it possible to estimate the position of the payload. The results discussed in this chapter can be utilized for further development of stabilizing and high-performance control laws.

Abstract

Motivated by Generals Rommel and Guderian’s innovative command and control techniques used in Europe in 1940, this chapter begins by using information theory to examine unmanned air vehicle (UAV) command and control (C2). The information-theoretic analysis provides a justification and uses cases for *autonomous* UAVs. An autonomous unmanned vehicle system “Organic Persistent Intelligence Surveillance and Reconnaissance” (OPISR) that is designed to duplicate Guderian’s innovations is introduced. OPISR is an autonomous unmanned vehicle system that combines the immediate response to tactical ISR needs provided by organic assets with the time-on-station, minimal logistics provided by persistent unmanned systems. OPISR autonomous vehicles collectively interpret real-time tactical intelligence surveillance and reconnaissance (ISR) objectives submitted by any number of disadvantaged users, gather the required ISR data, and return the needed intelligence directly to the affected user. OPISR is an ad hoc, decentralized system that requires no central base or authority and is capable of functioning in communications-denied environment. The chapter

D.H. Scheidt

e-mail: David.Scheidt@jhuapl.edu

describes a series of experiments including 2011 experiments in which 16 fully autonomous unmanned vehicles, including 9 unmanned air vehicles, were used to simultaneously support mounted, dismounted and maritime users. During these experiments users provided abstract mission-level ISR needs to the “vehicle cloud.” These needs were interpreted by the vehicles, which self-organized and efficiently achieved the user’s objectives.

51.1 Introduction

In the spring of 1940, the combined French, British, Dutch, and Belgian forces outnumbered their German counterparts in troops, mechanized equipment, tanks, fighter planes, and bombers. The ME109E German fighter aircraft was roughly equivalent to the British Spitfire, and the French CharB1 tank was superior to the German Panzer III. In addition, the allies were fighting on their home soil which greatly simplified their logistics. Yet in less than 6 weeks, the Belgians, Dutch, and French surrendered to the Germans, and the British retreated across the English Channel. Even though the allies had superior equipment and larger forces, they were defeated by the Germans who employed *Auftragstaktik*, a command and control technique that enabled “edge” war fighters to directly coordinate on tactical decisions using modern communications equipment (in WWII this was radio). Allied forces were forbidden to use radio because it “was not secure,” and allied maneuver decisions were made by generals at headquarters and based upon hand-couriered reports. German decisions were made on the fly by Panzer III commanders and JU-87 (Stuka) pilots conversing over the radio. By the time the French commanders met to decide what to do about the German advance, General Erwin Rommel and General Heinz Guderian’s Panzers had travelled over 200 miles and reached the English Channel.

As demonstrated repeatedly in military history, including the German advance in 1940, the speed at which battlefield decisions are made can be a deciding factor in the battle. A process model that describes military command and control is the Observe, Orient, Decide, Act (OODA) loop described by Boyd (Fig. 51.1). Boyd shows that, in military engagements, the side that can “get inside the opponent’s OODA loop” by more rapidly completing the OODA cycle has a distinct advantage. In their influential book *Power to the Edge*, Alberts and Hayes use the term agility to describe an organization’s ability to rapidly respond to changing battlefield conditions. Modern warfare case studies, such as the Chechens against the Russians, and not-so-modern warfare, such as Napoleon at Ulm, indicate that agile organizations enjoy a decisive military advantage. Alberts points out that a common feature of agile organizations is an empowerment of frontline forces, referred to as “edge” war fighters. Commanders facilitate organizational agility by exercising “command by intent,” in which commanders provide abstract goals and objectives to edge war fighters who then make independent decisions based upon these goals and their own battlefield awareness. This empowerment of edge war fighters reduces the OODA loop at the point of attack, providing the desired agility.

Fig. 51.1 Boyd's Observe, Orient, Decide, Act (OODA) cycle models the military decision-making process. Military organizations that perform their OODA cycle more rapidly than opponents gain a substantial competitive advantage

A distinguishing characteristic of the conflicts in Afghanistan and Iraq is the explosive growth in the use of unmanned air vehicles. Between the first and second Gulf Wars, unmanned vehicles transitioned from a novelty item to an indispensable component of the U.S. military. Field deployable organic unmanned air vehicles such as the AeroVironment Raven are essential equipment for the modern war fighter.

The agility provided by field deployable vehicles comes at a cost, as the use of field deployable units increases logistics and workload demands on frontline forces. When compared to larger unmanned vehicles, field deployable units such as the Raven (Fig. 51.2) offer limited sensing and time-on-target capabilities. Medium-sized vehicles, such as the Boeing-Insitu ScanEagle and AAI Shadow, offer longer time on station and more capable payloads. Medium-sized vehicles also do not make logistics or workload demands on the edge war fighter. Large unmanned vehicles such as the General Atomics Reaper and Northrup Grumman Triton offer still more capable payloads and increased time on station and also do not increase edge war fighter logistics or workload. However, providing timely edge war fighter access to intelligence products produced by medium and large vehicles is a challenge because medium- and large-sized unmanned air vehicles produce massive amounts of data that is difficult to process and disseminate from centralized command posts. In fact, as reported by Ariel Bleicher, "In 2009 alone, the U.S. Air Force shot 24 years' worth of video over Iraq and Afghanistan using spy drones." The trouble is there aren't enough human eyes to watch it all. The deluge of video data from these unmanned aerial vehicles, or UAVs, is likely to get worse. A single Reaper drone can record 10 video feeds at once, and the Air Force plans to eventually upgrade that number to 65. John Rush, chief of the Intelligence, Surveillance and Reconnaissance Division of the U.S. National

Fig. 51.2 An AeroVironment Raven being launched

Geospatial-Intelligence Agency, projects that it would take an untenable 16,000 analysts to study the video footage from UAVs and other airborne surveillance systems. The intelligence, surveillance, and reconnaissance (ISR) capability represented by medium- and large-scale unmanned vehicles represents a tremendous potential for the edge war fighter if only the information could be processed and distributed in time. For the edge war fighter to take advantage of the ISR capability represented by these assets, information relevant to that specific war fighter must be gleaned from the mass of information available and presented to the war fighter in a timely manner. This presents a challenge as crews analyzing UAV payload data (far fewer than Rush's 16,000 analysts) are not apprised of the changing tactical needs of all war fighters, nor do the war fighters have access or the time required to select and access data from UAV sources. Currently, operation centers are used to gather and disseminate information from persistent ISR assets. This centralized information management process introduces a delay between the observation and transmission to the war fighter which reduces force agility and operational effectiveness. While U.S. soldiers are empowered to operate on "command by intent," their ISR systems are all too frequently centralized systems reminiscent of the French command structure. For U.S. forces to become a fully agile force, the ISR systems supporting the U.S. soldier must be as agile as the soldier it supports. Agile unmanned vehicle systems require that some decisions are made at the edge nodes; therefore to become agile, unmanned vehicles must become autonomous.

51.2 Autonomous Unmanned Air Vehicles

UAVs currently in use are described as unmanned strictly because no human rides inside the air vehicle; however, the manual labor required to operate an air vehicle

remains largely unchanged as ground-based UAV pilots perform similar tasking to airborne pilots. Because flight procedures have not evolved to match the removal of the human from the air vehicle, the manpower required to operate an UAV equals or exceeds the manpower required to operate a manned aircraft. Because UAV pilots, by definition, fly the vehicle remotely, there is no longer a requirement that a pilot be co-located with the UAV area of operations, and it is not uncommon particularly for large, expensive UAVs for the UAV pilot to operate the vehicle from an office-like environment thousands of miles from the operating area. As the size, range, and capability of a UAV diminish, its use becomes more tactical, and the UAV pilot is located closer to the operating area with medium-sized UAVs such as the Boeing ScanEagle and AAI Shadow being controlled from forward operating bases and the AeroVironment Raven being controlled by a tactical unit in the field. Clearly remote vehicle operations significantly reduce pilot risk when compared to manned aircraft, yet this risk reduction comes at the cost of tactical awareness and involvement. Remote UAV pilots, when emplaced in a hierarchical command structure, have a reduced ability to assist in agile operations; without being immersed in the environment and able to, when required, communicate with actors outside of the current command structure, UAV pilots cannot support tactical operations as well as a JU-87 pilot from 1940.

Automated aircraft control techniques are emerging that allow UAV designers to design and field UAVs with varying degrees of autonomy. For the purpose of discussion, three general levels of autonomy are defined: tele-operation, which is essentially no automation at all; automatic, in which UAVs perform simple actions that can be fully enumerated and tested during design; and autonomy, in which the vehicle independently devises a course of action in response to complex operating conditions. The distinction between automatic and autonomy is subtle but important. Most UAVs being used today are automatic. Engineers of automatic UAVs have designed in action-based commands for pilot use (e.g., follow this path, loiter here, land there), the response matrix has been exhaustively enumerated and tested by development engineers, and the task of managing uncertainty, and complexity, lies with the pilot. Autonomous UAVs, which are not currently in service, are capable of devising a course of action in response to a complex, uncertain situation that was not, in detail, examined by the engineer during design or by the pilot. In other words, an automatic UAV is capable of following a path; an autonomous UAV is capable of finding a path.

The technology required to build autonomous UAVs is available today. Prototype autonomous UAVs that exhibit a variety of complex autonomous behaviors have been developed at academic institutions and industry research centers. Demonstrated capabilities involve relatively simple tasks including search, interdiction, tracking, obstacle avoidance, path planning, logistics, communications, launch, and recovery. While vehicle tasking remains simple, the complex unpredictable nature of the operating environment represents a complex problem requiring an autonomous, not automatic, solution. The bulk of autonomous UAV efforts are conducted at a relatively low technology readiness level (TRL) using low-cost rotorcraft in a laboratory (Kumar and Michael 2012; Bethke et al. 2008). More mature demonstrations

of autonomous tier 1 and tier 2 UAVs have been demonstrated outdoors at U.S. government ranges (Scheidt et al. 2004; Kwon and Pack 2011; Tisdale et al. 2008). Arguably the most mature autonomous UAV effort is the DARPA Heterogeneous Airborne Reconnaissance Team (HART) program, providing automatic unmanned air vehicles with an autonomous tactical decision aide (TDA). In these systems simple actions such as waypoint following are performed independently by each UAV, and complex decisions are performed by the TDA algorithm located on the pilot's computer. Prior to execution, the pilot reviews and approves (or disapproves and modifies) the plan. Proponents of HART correctly argue that the pilot is allowed to "auto-approve" plans, effectively making HART an autonomous system; however, the requirement to continually enable the pilot to review and approve all flight plans profoundly impacts the UAV system architecture and performance by delaying the exchange of information between the sensor and the UAV controller. The U.S. Army planned on partial fielding of HART in 2012 (Defense Systems staff 2012).

51.2.1 The Case for Autonomous Systems

Technological availability does not mean that autonomous UAVs will, or should, be used in the field. Autonomous UAV use requires that, when compared to manned aircraft or tele-operated/automatic UAVs, autonomous UAVs provide some tangible benefit to the organization deploying the autonomous UAV. Three general benefits are commonly offered that could justify the use of autonomous UAVs: first, by reducing the manpower required to fly/operate the UAV, autonomous vehicles are less expensive to fly; second, because autonomous UAVs do not require constant communications with a base, they are less vulnerable to electronic warfare attacks and capable of electromagnetic stealth; and third, by making better, more timely decisions, autonomous UAVs can, in certain circumstances, provide more effective performance. This third argument that autonomous unmanned vehicles can improve mission performance and that this performance can be understood and predicted by viewing autonomy as a command and control technique is the central theme of this chapter.

51.2.2 C2 Fundamentals

In *Power to the Edge*, command and control (C2) is defined as the "common military term for management of personnel and resources" but also gives the formal definition of command as found in the Joint Chiefs of Staff Publication, which subsumes some portions of control in that definition. Viewed as a black box the purpose of the C2 system use observations to produce decisions. C2, including UAV C2, involves the production and execution of decisions that, when executed, change the world in which the UAV is operating in ways that benefit the operator. That world (X) is described as a set of states, $X = \{x_1, x_2, \dots, x_n\}$, each one of which represents a unique configuration of actors and attributes within the natural world in which

the UAV operates. The command and control system can be viewed as a transfer function ($f(x_i) \rightarrow x_j$) that produces a state change in the world. The “quality” of each state can be determined by applying a mission-based fitness criteria to elements within the state. For example, if a UAV mission is to track a target, then states in which the target is within the field of view of the UAV’s sensor are evaluated as of higher quality than those states in which the target is not seen by the UAV, and an effective C2 system would cause state transitions that are of high quality when compared to alternative transitions. C2 is a constant battle between chaos and order, with order being state transitions designed to achieve mission goals that are instigated by the C2 system and chaos being unanticipated state transitions produced by adversaries, poorly coordinated teammates or random acts.

C2 can be best understood as an information-theoretic problem. This is apropos as both the situational awareness upon which decisions are based as well as the decision products can be viewed as information-theoretic messages and both the C2 process and the natural world can be viewed as information transfer functions. For an interesting, albeit somewhat off-topic, discussion on the information-theoretic nature of physics, see Wheeler (1990).

The information content (S) of a message (m) is defined by Shannon (1948) as:

$$S(m) = \log_2(1/P(m)) \quad (51.1)$$

The more improbable the message being received, the larger the information content. For example, barring a highly improbable change to celestial mechanics, a message stating “tonight it will be dark” has zero information content because the a priori probability that it would be dark is one. By comparison, “tonight it will rain” has positive information content because the a priori probability that it would rain during a given evening is less than one. Information content is measured in bits, which are real numbers. Note that the term “bit” is overloaded, and information theory bits are not the same as computer science bits, which are integers.

The *state space* (p) of the world in which our UAVs operate is the amount of bits required to uniquely identify all possible states in the world, which is referred to as the *state space* of the world.

$$p = \log_2 |X| \quad (51.2)$$

Completely describing the world requires a message of length p . A communication that completely describes the natural world would require a message whose length would be effectively infinite as the natural world includes each blade of grass, molecule of air, quantum states of ions within each atom, and so forth. Fortunately, effective C2 of UAVs does not require such detailed knowledge, and effective UAV control can be provided using artifacts that are abstract, limited, and while potentially quite large in number, expressible in messages that are small enough to be used within a modern computer network. In fact, military C2 systems routinely express tactical “worlds” in finite languages such as the protocols used by the *Global Command and Control System* and the *Link16* network. In practice, the size of a UAV’s world as represented by the C2 system can be dynamic, with the state

space of the tactical world changing as artifacts enter, or leave, the operational area. That the complexity of a UAV's world, as represented by the state space of the current situation, is subject to change is important to understanding how to control UAVs.

Knowledge of the UAV's world is rarely complete, and UAVs are expected to operate in the presence of varying degrees of uncertainty. Uncertainty in tactical information can be produced by errors in sensor systems, gaps in sensor coverage, or approximation error, which is the difference between the actual ground truth and the coding scheme selected. For example, if the unit representation of a coding scheme used to represent linear position is 1 m, then an approximation error of 0.5 m is unavoidable. Consider the message (m) that encapsulates a C2 systems' current situational awareness (SA). When $S(m) \neq p$, uncertainty exists and additional information is required to produce complete SA. Now consider a second message (m') that contains all of the missing information required to reduce uncertainty to zero. The information content of m' is information entropy (H) of m , shown as

$$S(m') = H(m) = \sum P(x) \log \frac{1}{P(x)}$$

where x is the assemblage of information contained in m (51.3)

The information content of m is "negentropy" (N) or "order," Command and control is a battle between the forces of order and chaos, in which the command and control system seeks to generate order by forcing the world into the most beneficial state for the commander and the uncontrollable forces within the world, which may include adversaries, continuously generates entropy that moves the world away from the commander's ideal state.

Together, the information content of m and m' represents the total amount of information potential within the system s.t:

$$S(m') = p - S(m) \quad (51.4)$$

For each bit of order produced by the C2 system, entropy is reduced by a bit. Likewise, each bit of entropy produced by unanticipated change reduces order by 1 bit.

As demonstrated by Guderian and Rommel, C2 systems are temporally sensitive. As time elapses the information content of a message that describes a dynamic scene decreases in proportion to the unpredictable change in the scene. An example of this are unexpected maneuvers made by a target after a sensor observation was made but before the execution of an response to the observation. The loss of information over time is defined as *entropic drag* (Γ) which is expressed mathematically by Scheidt and Schultz (2011) as:

$$\Gamma(x, t, t_0) = \frac{H(x(t) | x(t_0))}{t - t_0} \quad (51.5)$$

Note that entropic drag is specific value for each state. Control of UAVs operating in an uncertain world in which multiple states are feasible requires a consideration of all admissible states. The measurement of entropic change that incorporates all feasible states is the normalized form of entropic drag (Γ_{norm}) that is the average entropic drag for all states within the system:

$$\Gamma_{norm}(t) = \sum_{\forall x_i} \frac{H(x_i(t) | x_i(t_0))}{(t - t_0) \cdot |X|} \quad (51.6)$$

UAVs acquire, process, and share information over a control infrastructure that includes onboard network and processing, radio downlinks and uplinks, and off-board processing. When processing information, two key characteristics of the control infrastructure are *latency* (δ_0), which is the unavoidable delay in processing an information packet regardless of packet size, and *bandwidth* (β), which is the rate in bits per second at which bits of information can be processed irrespective of the latency. The delay time (δ) required to process a message m of information can be viewed as

$$\delta_m = \delta_0 + \left(\frac{\text{size}_m}{\beta} \right) \quad (51.7)$$

When communicating information from a sensor to a user over a communications link, large amounts of information take more time to transmit and process than small amounts of information. If the information observed by the sensor is a dynamic scene, which is often the case for UAVs, increases in information gathering cause an increase in processing delays that, in turn, cause an increase in entropy. This presents a paradox with respect to attempts to increase information content by increasing the quantity of data. This paradox is defined by the relationships between Eqs. (51.5) and (51.7) that was described by Scheidt and Pekala (2007) and is shown in Fig. 51.3. The figure shows uncertainty as a function of the unit resolution used to describe a dynamic scene using a constant cognitive bandwidth and also assuming that all sensor data is correct. In the plot the highest unit resolution (e.g., least precision) is shown on the right, while the smallest unit resolution (most precision) is shown on the left. Interpreting the plot from right to left shows, as one might expect, that initially increasing the information content of a message substantially reduces uncertainty. As precision increases, the time requires to communicate and process the information increases, which increases information loss due to the entropic drag. Eventually an uncertainty minima is reached at which the information gain from additional information content within the initial message equals the information loss due to entropic drag. Any attempt to use additional precision beyond the minima produces net loss in information content.

If the function of the UAV is intelligence, surveillance, and reconnaissance (ISR), then mission goals are to provide information on targets of interest with minimal uncertainty. Counterintuitively, transmitting all possible information on a target may not be the best approach for an ISR system. The plot in Fig. 51.3 provides a guide as to the optimal amount of data that should be gathered, processed, and

Fig. 51.3 When information describing a dynamic (changing) scene is sent over, a network uncertainty can be minimized by using the optimal resolution (shown by the local minima). The local minima shown is the balance point where the rate of information gain equals the rate of entropy (entropic drag)

Table 51.1 The complexity and rate of unpredictable change vary by mission class

| Use case | Description | Complexity, $P(x)$ | Entropic drag, $\Gamma(t)$ |
|--------------------|---|--------------------|----------------------------|
| Strategic | Strategic missions are dedicated to acquiring information on standing infrastructure | – | None |
| Operational | Operational missions are dedicated to acquiring information on the general movement and condition of large units (e.g., company size or larger) | Low | Low |
| Focused tactical | Small units (individuals, squads, or platoons) performing tightly defined, focused missions in isolation | Low | High |
| Multiunit tactical | Small units operating as part of a large engagement that involves multiple units | High | High |

provided from a UAV to the UAV operator. The local minima in the plot represents the optimal amount of information that should be transmitted. UAV system that transmit too much information, represented by high-resolution data on the left of the graph, reduces the net information provided due to the large loss of information across all data due to entropic drag. To further understand this relationship, let us examine bandwidth from Eq. (51.7) and its relationship to Eqs. (51.5) and (51.6) in more detail. This is accomplished by viewing canonical ISR missions and operating conditions through information theory and applying these views to differing forms of UAV control. Table 51.1 describes four general classes of ISR missions for UAVs and defines, in general terms, the complexity and entropic drag associated with those missions.

Recall that UAVs may be controlled using three general methods: tele-operation, automatic control, and autonomous control. Descriptions of these methods are:

- Tele-operation – The most common form of UAV control is tele-operation. Tele-operated UAVs use a ground-based pilot to fly the UAV using techniques that are identical those of human-piloted aircraft. Tele-operated UAVs utilize low-level control features found in an airplane cockpit as well and onboard sensor data on the pilot's ground station that are duplicates of those found in the cockpit of a piloted aircraft. All decisions used to control tele-operated planes are made by the ground-based human pilot.
- Automatic flight – UAVs that contain autopilots are capable of *automatic* flight. Automatic UAVs use autopilots to assure stable-controlled flight. The pilots of automatic UAVs provide waypoint locations that direct the path of the UAV. In addition to flying to pre-defined waypoints, automatic UAVs may be preprogrammed to handle simple changes in operating conditions; however, management of complex or unanticipated changes are handled by a ground-based pilot.
- Autonomous flight – UAVs that contain an autopilot and an onboard, intelligent controller are capable of *autonomous* flight. Similar to automatic UAVs, autonomous UAVs provide stable flight between waypoints; however, unlike automatic UAVs, the intelligent controllers onboard an autonomous UAVs define new waypoints in response to unanticipated changes in operational conditions.

Autonomous UAVs fundamentally change the relationship between the human and the UAV because autonomous UAVs, unlike tele-operated UAVs, automatic UAVs, and manned aircraft, do not require pilots. Autonomous UAVs do use human supervision; however, that supervision is performed at a higher level than the typical plane-pilot relationship. The relationship between an autonomous UAV and the supervising human resembles the relationship between a human pilot and an air traffic controller or, for Navy pilots, the Air Boss. Autonomous UAV operators supervise their UAVs by providing abstract, mission-level objectives as well as rules of engagements that are equivalent to the instructions provided to human pilots prior to a mission. During the mission autonomous UAVs devise a course of action aligned with these instructions in response to the current situation. As conditions change during the course of a mission, an autonomous UAV constantly modifies the course of action in accordance with the mission-level objectives. Unlike automatic UAVs, autonomous UAVs respond to complex situations that were not explicitly considered during UAV design.

The different forms of UAV control demand different levels of communications. Direct control of UAV control surfaces requires that tele-operated UAV pilots use low-latency, high quality of service communications to command UAVs. For tele-operated UAVs even small perturbations in service run the risk of loss of control and catastrophic failure. Automatic UAVs are more forgiving, as the pilot is only required to provide guidance at the waypoint level. The communications requirement for automatic UAVs is determined by the rate of change of those operational elements that dictate the mission pace. For example, if the UAV is engaged in an ISR task to track a specific target, the UAV communications

infrastructure used to control the UAV must be capable of providing target track data to the pilot prior to the target exiting the UAV's field of view. Depending upon the nature of the target, the response time required for automatic UAVs can range from sub-second intervals to minutes. Autonomous vehicles are the most forgiving of communications outages and delays. In fact, autonomous vehicles are capable of performing without communication to human operators during an entire mission. The ability to function without continual human supervision changes operator and designer perspectives on UAV communications from being a requirement to being an opportunity. When autonomous UAVs can communicate, either to humans or other vehicles, mission performance is improved by the sharing of information and collaborating on decisions; however, when communications are not available, autonomous UAVs are still capable of fulfilling the mission. A synopsis on the communications availability, in terms of latency and bandwidth, for four different classes of conditions is provided in Table 51.2.

When considering whether a UAV control decision should be made by a human operator or by a control processor onboard a UAV, three criteria should be considered: (1) what is the quality of decisions made by the human/machine, (2) what are the ethical and legal requirements for making decisions, and (3) what accessible information is available to the human and the machine? There are ethical and legal advantages and disadvantages for both human and machine decision-making. Arkin provides an excellent overview of the legal and ethical issues, concluding that no consensus exists that would favor human control over machine control or vice versa (Arkin 2009). Regarding the ability to make higher-quality decisions, anecdotal evidence suggests that there exist problem sets for which humans provide better quality decisions and problem sets for which intelligent control algorithms provide better decisions. For example, few would argue that the path planning algorithms provided by Mapquest and Google find superior paths over complex road networks in times unmatched by humans. On the other hand, even the most sophisticated pattern recognition algorithms are incapable of matching small children in rapidly identifying and manipulating common household items in a cluttered environment. The neuroscience and psychology communities have long-studied human cognitive abilities, and computer science, particularly the subfield of complexity theory (Kolmogorov 1998), has been used to study the performance of cognitive algorithms as a function of the problem space being addressed; however, a comparative understanding between human and machine cognition (or even the tools necessary to achieve this understanding) does not exist at this time.

In order to move the discussion of UAV C2 into a manageable space, two simplifying assumptions are asserted: first, decisions should be made using the maximum amount of information, and (51.2) given equivalent information, it is preferred that decisions be made by a human. These simplifying assumptions allow us to focus on the availability of information as the primary driver for command and control. While it is somewhat disconcerting to ignore the quality of the decision-maker and ethical issues, our focus on information as the driving factor in C2 is consistent with the lessons learned from Guderian and Rommel earlier.

Table 51.2 Communication availability experienced by UAVs during a mission can vary greatly. Depending upon the operational conditions, latency and bandwidth can vary greatly

| Communications availability | Description | Latency (δ_0) | Bandwidth (β) |
|-----------------------------|--|------------------------|-----------------------|
| Dedicated communications | Dedicated infrastructure whose access is tightly controlled and not contested by environmental or adversarial activities | Very low | Extremely high |
| Uncontested broadband | Standing infrastructure that is broadly used that is not contested by environmental or adversarial activities | Very low | High |
| Contested communications | Standing infrastructure that is broadly used and is not contested by environmental or adversarial activities that produce periodic outages and/or reduction in service | Low | Low |
| Over the horizon | Operations that involve periodic movement in areas that are beyond communications range or involve periodic, planned communications blackouts | High | Moderate |

Having narrowed our focus into the information used to make a decision, three information-theoretic distinctions using between an operator and an onboard computer to determine a course of action are identified. These distinctions are as follows: (a) the complexity of the scene that must be described to make a decision, which dictates the size of the packets that must be communicated and the run time of decision processes; (b) the entropic drag of the system being represented by the data, which dictates the time for which the information is valid; and (c) the communications delay time provided in Eq. (51.7) which defines the earliest time at which the decision could be made. These values may be combined to form an information value $g(x)$ that defines the UAV control problem. The information value is defined as the product of the complexity of the UAV’s world and the entropic drag of the world’s unpredictable change divided by the delay associated with communicating the world state to the decision-maker s.t:

$$g(x) = \frac{P(x)\Gamma(t_m)}{\delta_m(x)}$$

(51.8)

The information value correlates to the utility of the autonomous, automatic, and tele-operated controls approaches. When the world the UAV operates in provides an information value that is high autonomous control dominates, when the world the UAV operates in provides an information value that is low tele-operated control dominates and automatic control is preferred in the midrange. Mapping this relationship to the UAV use cases and communications conditions

Table 51.3 The appropriate conditions for using tele-operated, automatic, or autonomous UAV control are defined by the operational criteria and available communications

| Dominant control technique | Dedicated communications | Uncontested broadband | Contested broadband | Over the horizon |
|----------------------------|--------------------------|-----------------------|---------------------|------------------|
| Strategic | Tele-operated | Tele-operated | Automatic | Automatic |
| Operational | Tele-operated | Tele-operated | Automatic | Autonomous |
| Focused tactical | Tele-operated | Tele-operated | Automatic | Autonomous |
| Multiunit tactical | Autonomous | Autonomous | Autonomous | Autonomous |

defined earlier, operational scenarios that are appropriate for autonomous, auto-
matic, and tele-operated UAV control are defined and enumerated in Table 51.3.
As Table 51.3 indicates, there exist real-world circumstances in which UAV C2
should be tele-operated, automatic, or autonomous. Not surprisingly, those times
which autonomous C2 is dominant are complex, dynamic situations. Exactly the
sort of situation faced by Guderian and Rommel. So, having identified that complex,
constantly changing scenarios is best supported by autonomous UAVs, how might
we develop such as system.

**51.2.3 The Organic Persistent Intelligence Surveillance and
Reconnaissance System**

OPISR autonomous UAVs utilize a software and communications subsystem that
is designed to support the rapid, autonomous movement of information across
a tactical force. Commander and/or operators interact with OPISR as a system.
When using OPISR, war fighters connect into the OPISR “cloud,” task OPISR with
mission-level ISR needs and are subsequently provided with the intelligence they
need (Fig. 51.4). This capability provides intelligence directly to the war fighter
without requiring the war fighter to personally direct or, even know about, the
OPISR assets gathering the information. OPISR is autonomous. As a system, OPISR
seeks out relevant information, pushing key tactical information directly to impacted
soldiers in real time. OPISR is capable of rapidly managing large complex, dynamic
situations because it utilizes a decentralized, ad hoc organizational structure.
Systems that use decentralized structures such as OPISR are known to be more
effective at the timely coordination of complex systems (Scheidt and Schultz 2011).
OPISR tracks the location and ISR needs of all blue forces, maintaining a contextual
awareness of the war fighter’s current tactical needs.

As relevant tactical information becomes available, OPISR presents it directly to
the war fighter through an intuitive handheld device. The information requirements
that are used to determine information relevance are defined by the war fighter
through the same handheld interface. This interface supports abstract queries such as
(1) patrol these roads, (2) search this area, (3) provide imagery of a specific location,
(4) track all targets of a specific class on a specific route of location, or (5) alert me
whenever a threat is identified within a certain distance of my location. Information

Fig. 51.4 OPISR's concept of operation allows UAVs of various sizes to communicate with each other, with users, and with commanders through an ad hoc, asynchronous cloud. The cloud communicates goals from users to vehicles and sensor observations from users to vehicles

that matches these queries is sent by the system to the handheld device. The handheld interface provides a map of the surrounding area that displays real-time tracks and detections and imagery metadata. The imagery metadata describes, at a glance, the imagery available from the surrounding area. OPISR-enabled vehicles are autonomous; if the information required by the war fighter is not available at the time the query is made, OPISR unmanned vehicles autonomously relocate so that their sensors can obtain the required information. OPISR-enabled unmanned vehicles support multiple war fighters simultaneously, with vehicles self-organizing to define joint courses of action that satisfy the information requirements of all war fighters.

Because war fighters are required to operate in harsh, failure-prone conditions, OPISR was designed to be extremely robust and fault tolerant. OPISR's designers viewed communications opportunistically, designing the system to take advantage of communications channels when available but making sure to avoid any/all dependencies on continual high quality of service communications. Accordingly, all OPISR devices are capable of operating independently as standalone systems or as ad hoc coalitions of devices. When an OPISR device is capable of communicating with other devices, it will exchange information through networked communications and thereby improve the effectiveness of the system as a whole. However, if communications are unavailable each device will continue to perform previously

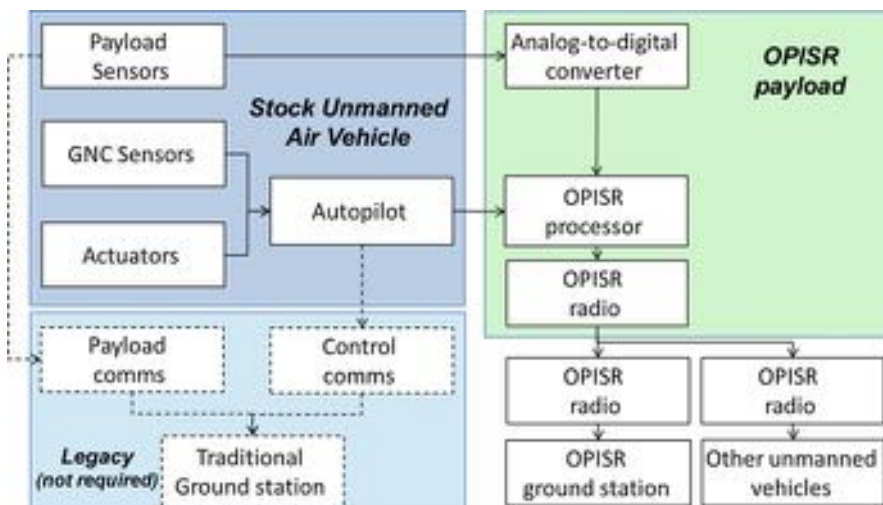

Fig. 51.5 OPISR's hardware architecture is based on a modular payload that can be fitted onto different types of unmanned vehicles

identified tasks. When multiple devices are operating in the same area, they will self-organize to efficiently perform whatever tasks have war fighters have requested.

51.2.3.1 OPISR Hardware

Off-the-shelf unmanned vehicles and unattended sensors can be incorporated into the OPISR system by adding the OPISR payload. As shown in Fig. 51.5, the OPISR payload consists of three hardware components: an OPISR processor that executes the OPISR software, an OPISR radio that provides communications to other OPISR nodes including OPISR's handheld interface devices, and an analog to digital converter that is used to convert payload sensor signals into digital form. Unmanned vehicles that have an onboard autopilot capable of providing stable flight can be modified to become *autonomous* vehicles by connecting the autopilot to the OPISR processor. When the vehicle is operating autonomously, the autopilot sends guidance and control (GNC) telemetry to the OPISR processor. The processor using the GNC data to devise a continual stream of waypoints are sent to the autopilot to follow. The OPISR processor also uses the GNC telemetry to produce metadata that is associated with the sensor data. The combined sensor data and metadata is then used by the OPISR system as a whole.

In service unmanned vehicles frequently use separate communications channels for control and imagery. Since OPISR devices perform both image processing and control onboard the device, these communications channels, and the traditional pilot-ground station, are no longer required. Effectively OPISR devices are capable of operating fully independent of direct human supervision. Note that OPISR devices are still responding to war fighter requests; however, these devices accomplish this without requiring continual communications with the war fighter

being serviced. While OPISR does not require traditional control and payload communications, OPISR devices do support these legacy capabilities. Because the OPISR nodes communicate over a separate channel, OPISR functionality may be provided in tandem with traditional control. This is in keeping with the OPISR dictum that OPISR is an entirely additive capability; unmanned vehicle owners lose no functionality by adding OPISR. However, OPISR vehicles are responsive to commands from human operators and will, at any time, allow an authorized human operator to override OPISR processor decisions. Likewise, legacy consumers of information will still receive their analog data streams. Note that even when the OPISR processor is denied control by the UAV pilot, the OPISR system will continue to share information directly with edge war fighters as appropriate.

51.2.3.2 OPISR Software

OPISR is based upon a distributed multi-agent software architecture. Each software agent serves as a proxy for the device on which it is located, and all devices within OPISR have their own agents including unmanned vehicles, unattended sensors, and user interfaces. Each agent is composed of four major software components (Fig. 51.6): a distributed blackboard, which serves as a repository for the shared situational awareness within the agent system; an agent communications manager, which manages the flow of information between agents; a cSwarm controller, which determines a course of action for those devices that are capable of autonomous movement; and a payload manager, which manages the sensor information from the device's organic sensors. All devices within the system, including the war fighter's handheld device, are peers within OPISR.

51.2.3.3 Distributed Blackboard

In the 1980s, Nii (1986) described a method for multi-agent systems to communicate between each other in an asynchronous manner called a blackboard system. Like its namesake in the physical world, blackboard systems allow agents to post messages for peer agent consumption at an indeterminate time. Each OPISR agent contains a personal blackboard system that maintains a model of the agent's environment. Three types of information are stored on each agent's blackboard: beliefs, metadata, and raw data. Raw data is unprocessed sensor data from a sensor within the OPISR system. Metadata is information that provides context to a set of raw data including sensor position, pose, and time of collection. Beliefs are abstract "facts" about the current situation. Beliefs include geo-spatial artifacts such as targets, blue force locations, or search areas. Beliefs can be developed autonomously from onboard pattern recognition software and data fusion algorithms or asserted by humans. Mission-level objectives, the goals that drive OPISR, are a special class of belief that must be produced by a human. The storing and retrieval of information to and from agent blackboards is performed by the blackboard manager. The blackboard manager accepts stores and retrievals from sensors onboard the agent's device, other agents, or pattern recognition/data fusion software contained within the agent. The integrity of the data stored on the blackboard is maintained by a truth maintenance system (TMS). The TMS performs two functions. First, the TMS resolves conflicts between beliefs. The simplest form of conflict resolution is

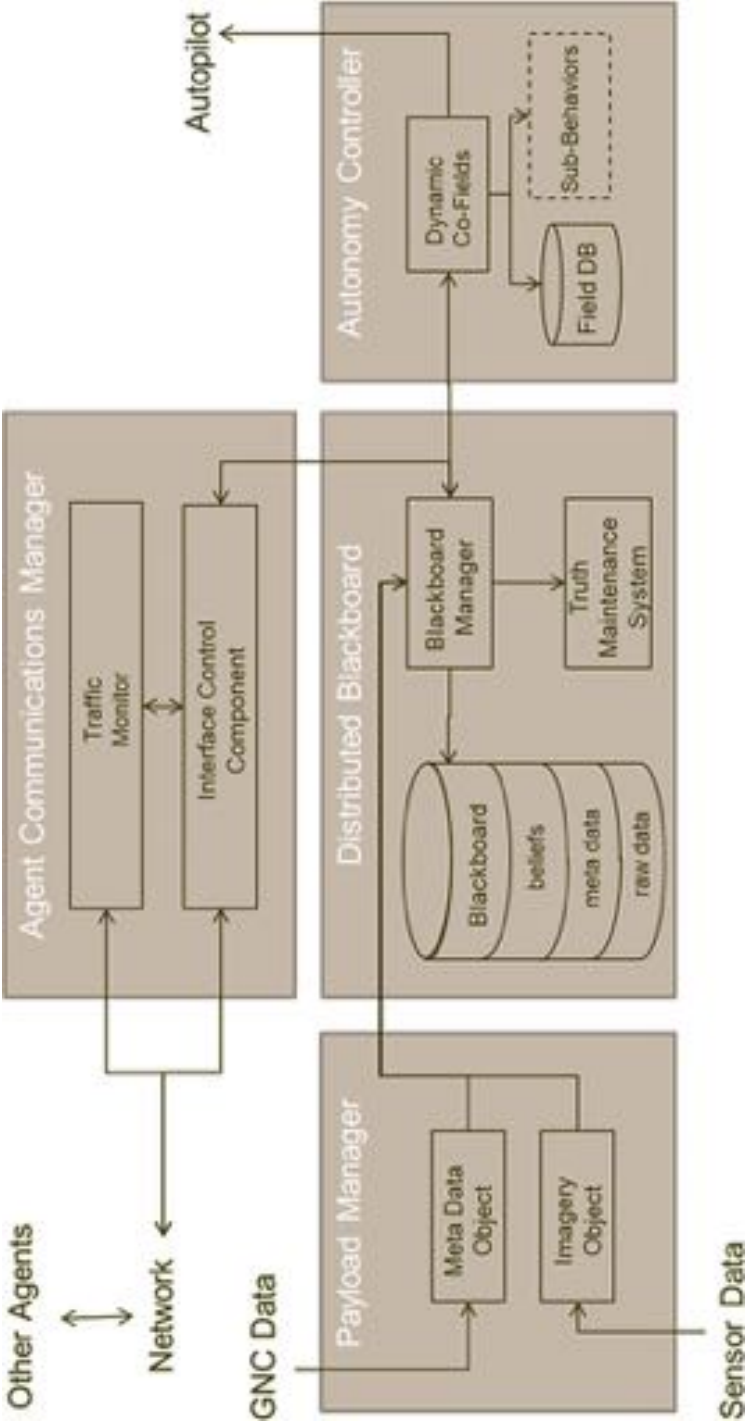

Fig. 51.6 Each OPISR node contains a four major software components that manages information flow and decision-making

accomplished by storing the belief with the more recent time stamp. For example, one belief might posit that there is a target at grid $[x, y]$ at time t_0 , and a second belief might posit that there is no target at grid $[x, y]$ at time t_1 . More sophisticated conflict resolution algorithms are scheduled to be integrated into OPISR in 2012. The second TMS function is the efficient storage of information within the blackboard. When performing this task, the TMS caches the most relevant timely information for rapid access, and when long-lived systems generate more data than can be managed within the system, the TMS removes less important information from the blackboard. For caching and removal, the importance of information is defined by the age, proximity, uniqueness, and operational relevance.

Coordination between agents is asynchronous, unscheduled, and completely decentralized, as it has to be, for any centralized arbiter, or scheduled communications introduce dependencies that reduce the robustness and fault tolerance that is paramount in the OPISR design. Because agent communication is asynchronous and unscheduled, there is no guarantee that any two agents will have matching beliefs at an instance of time. Fortunately, the control algorithms used by OPISR are robust to belief inconsistencies. Cross agent truth maintenance is designed to the same criteria as agent-agent communications: *Information exchanges between agents seek to maximize the consistency of the most important information but does not require absolute consistency between agent belief systems.* Information exchange between agents is performed by the agent communications manager. When communications are established between agents, the respective agent communications managers (ACM) facilitate an exchange of information between their respective blackboards. When limited bandwidth and/or brief exchanges limit the amount of information exchanged between agents, each ACM uses an interface control component to prioritize the information to be transmitted. Information is transmitted in priority order with priority being determined by information class (beliefs being the most important, followed by metadata), goal association (e.g., if a war fighter has requested specific information that information is given priority), timeliness, and uniqueness.

51.2.3.4 Autonomous Control

OPISR's autonomous unmanned vehicles use dynamic co-fields (DCF), also known as stigmergic potential fields, to generate movement and control actions. DCF is a form of potential field control. Potential field control techniques generate movement or trigger actions by associating an artificial field function with geo-spatial objects. In OPISR, the objects that are used to derive fields are beliefs. Fields represent some combination of attraction and/or repulsion. By evaluating the fields for all known beliefs at a vehicle's current location, a gradient vector is produced. This gradient vector is then used to dictate a movement decision. Developed in 2003 (Scheidt et al. 2005), DCF extends an earlier potential field approach called co-fields (Mamei et al. 2002) by making the potential fields used dynamic with respect to time and also making vehicle fields self-referential. Self-referential fields are fields that induce vehicle decisions that are generated by the vehicle's own presence. Adding these dynamic qualities is key to managing two well-known problems with potential fields

approaches: namely, the tendency of vehicles to become stuck in local minima and the propensity to exhibit undesired oscillatory behavior. As implemented in OPISR, DCF is used to effect specific behaviors such as search, transit, or track, as well as behavioral selection. The DCF algorithm is encoded in the cSwarm software module. All unmanned vehicles in OPISR execute cSwarm. DCF behaviors specific to unique classes of vehicle are produced by tailoring the field formula which is stored in a database within cSwarm. OPISR autonomous unmanned vehicles is a variety of behaviors including:

- Searching contiguous areas defined by war fighters.
- Searching linear networks such as roads.
- Transiting to a waypoint.
- Blue-force over-watch.
- Target tracking.
- Perimeter patrol.
- Information exchange infrastructure, in which unmanned vehicles maneuver to form a network connection between an information source, such as an unattended sensor, and war fighters that require information on the source. Note that the war fighter is not required to specify this behavior; the war fighter need only specify the information need, and the vehicle(s) utilizes this behavior as a means to satisfy the need.
- Active diagnosis, in which vehicles reduce uncertain or incomplete observations through their organic sensing capabilities. For example, a UAV with a sensing capability capable of classifying targets will automatically move to and classify unclassified targets being tracked by a cooperating radar.

In addition to the mission-level behaviors enumerated above, OPISR vehicles exhibit certain attributes within all behaviors. These universal attributes are:

- Avoiding obstacles or user-defined out-of-bounds areas.
- Responding to direct human commands. OPISR unmanned vehicles are designed to function autonomously in response to mission-level objectives; however, when operators provide explicit flight instructions, OPISR vehicles *always* respond to the human commands in preference to the autonomous commands.

51.2.3.5 Experimentation

The current OPISR system is the culmination of a decade-long exploration in autonomous unmanned vehicles. Experimentation with DCF began in 2002 as part of an effort to investigate agent-based control of unmanned vehicles to support the U.S. Army's Future Combat System. These early efforts focused predominantly on cooperative search, the results of which are described by Chalmers (Scheidt et al. 2004). Since 2002 thousands of simulated engagements have been conducted with DCF. These simulations have shown that DCF's computational load is independent of the number of vehicles cooperating to solve a mission. Two-hundred vehicle real-time simulations have been run on a single-Pentium class processor. Simulations from a variety of ISR missions have repeatedly shown that vehicle behavior is robust to perturbations in the number of vehicles or the lay-down of those vehicles.

Hardware in-the-loop experimentation with DCF began in 2003 under a joint effort between the Johns Hopkins University, the Army Research Laboratory and Altarum, Inc. In the summer of 2004, this effort conducted a series unmanned air and unmanned ground vehicles experiments at the Aberdeen Proving Grounds (APG). Low-level control was provided by MicroPilot autopilots (air vehicles) and iRobot Mobility (ground vehicles). High-level control of these vehicles was provided by DCF and Altarum's pheromone-based swarming algorithm (Parunak 1997). The distributed blackboard system was used to facilitate sharing between the ground vehicles, although centralized data sharing was used to support UAV control. High-level ground vehicle control software was located onboard the vehicles while high-level air vehicle control software was located onboard a ground station that communicated with the onboard autopilot over a 900 MHz communications link. The air vehicles used in these experiments were Army Mig-27 target drones (Fig. 51.7). These drones have a 6-foot wing span and are capable of air speeds of 60 knots. The ground vehicles used were iRobot ATRV, ATRV-JR, and mini robots. This effort concluded in an October 2004 demonstration in which two air vehicles and four ground vehicles conducted a multi-objective mission at APG. The air vehicles were equipped with GPS for localization and notional EO sensors for target detection and tracking. Mission objectives were provided by three independent human users. Objectives included are as follows: (1) patrol the base, (2) protect the moving convoy, (3) search operator-defined areas, (4) track unclassified targets, (5) classify unclassified targets, and (6) interdict targets classified as threats. AUVs supported objectives 2, 3, and 4. The demonstration started with UGVs patrolling the base and UAVs searching the engagement area. A convoy entered the engagement area with the intention of transiting to the base. The officer leading the convoy requested protection, causing the UAVs to change mode to cover the convoy en route. While patrolling the area in front of the convoy, the UAVs detected a number of dismounts loitering at a road intersection in the convoy's path. This information was relayed to the convoy, causing the human driver to stop prior to the intersection. This same information was relayed to the UGVs, causing the UGV with the acoustic sensor payload to approach the intersection. Once in range of the intersection, the acoustic UGV classified a subset of the dismounts as hostile targets. This information caused the UGVs to pursue the hostile targets, which then fled the area. Once the intersection was cleared, the convoy completed its transit to the base. This demonstration, and variants of it, was successfully performed a number of times. During one demonstration a UGV suffered a hardware fault and went off-line. The other vehicles recognized the sudden absence of their peer, adapting their actions to maintain overall operational effectiveness.

A similar set of experiments were conducted at the Department of Energy's Nevada Test Site in the summer of 2005. These experiments used three Procerus Unicorn UAVs and infrared unmanned ground sensors (UGS). In these experiments all of the vehicles used DCF as their high-level control policy. The UAVs performed area search, road search, target tracking, and, for the first time, airborne information exchange. The engagement consisted of two mounted blue-force patrols,

Fig. 51.7 The first UAVs to fly using OPISR's DCF were modified U.S. Army Mig-27 drones

a single-dismounted aggressor, and two-mounted aggressors. The UGS, using onboard automated target recognition algorithms, detected and identified the dismounted and mounted adversaries. These detections caused the UAVs to track the adversaries and relay the contact information to the blue-force patrols. These experiments were the first in-flight uses of the previously described active-metadata framework.

Also in 2005, DCF was successfully used in experiments to control UAVs detecting, taking samples from and tracking atmospheric plumes. These experiments used three AeroVironment Dragon-eye UAVs. The plume detection experiments were motivated by a desire to provide first-responders with an ability to rapidly identify aerosol contaminants emanating from an industrial accident and to understand and predict the location of those contaminants. These experiments were conducted at a Department of Homeland Security facility in Michigan.

From 2006 to February 2008, DCF has been used regularly in the Naval Postgraduate School's TNT experiments held at Camp Roberts, CA. These experiments have deployed as many as six Procerus Unicorns a fully mission-based swarm. The UAVs used for TNT are fully independent, as the high-level control, a variety of sensors, and the automated target recognition algorithms have been moved onboard the UAVs. Additional behaviors have also been demonstrated at TNT including automated obstacle avoidance (fixed and airborne) and communications. In a 2007 experiment six vehicles cooperated to provide streaming video of arbitrarily defined objects from over the horizon to human users.

DCF has been used as a control metaphor in sea-based experiments conducted predominantly in littoral environments. Starting in 2005 DCF has been used to control several types of unmanned sea surface vehicles conducting search and track n'trail missions at speeds of up to 40 knots with no man in the loop. In 2007 and 2008 OPISR software was used to control unmanned undersea vehicles on search and track missions.

Between 2002 and 2010 twenty hardware experiments were conducted using elements of the OPISR system, including DCF (Scheidt et al. 2005), the distributed blackboard (Nii 1986; Hawthorne et al. 2004), delay-tolerant communications

Fig. 51.8 OPISR vehicles from the 2011 Webster field demonstration including one (of four) ScanEagles, two custom surface vehicles, one (of six) Procerus Unicorns, and an OceanServer Iver2 undersea vehicle

(Bamberger et al. 2004), and simultaneous support for multiple end users (Stipes et al. 2007). As successful as these experiments have been prior to 2011, the full suite of OPISR capabilities described in this chapter had not been demonstrated on a large disparate set of vehicles. In September 2011 a multi-vehicle system consisting of 16 OPISR-enabled nodes, including 9 UAVs in support of 3 users, was conducted at Webster Air Field in St. Inigoes, MD, and the surrounding Chesapeake Bay. The 2011 demonstration mixed air, ground, and sea ISR needs with surveillance being conducted under the water, on the water, and on and over land. The autonomous unmanned vehicles included four Boeing ScanEagles, six Procerus Unicorns, a Segway RMP ground vehicles, custom surface vehicles, and an OceanServer Iver2 undersea vehicle. The air, surface, and undersea vehicles are shown in Fig. 51.8. These vehicles used a wide range of payload sensors to detect, classify, and track waterborne vehicles, land vehicles, dismounts, and mine-like objects, including EO, IR, radar, AIS, passive acoustic, side-scan sonar, and LIDAR. ISR tasking was generated by three proxy operators, two of which were on land (one mounted and one dismounted) and one of which was on the water. ISR tasks requested required the use of all of the vehicle behaviors previously described.

The OPISR capabilities demonstrated by OPISR UAVs at St. Inigoes included a set of six enabling autonomous submission capabilities, which are:

1. Area search – When user(s) requests that one or more contiguous areas should be searched, the autonomous vehicles respond by searching those areas.
2. Road network search – When user(s) request that one or more roads should be searched, the autonomous vehicles respond by searching those roads. This is functionally identical to performing an area search over an area that is confined to (or focused on) roads of interest.
3. Overwatch – A convoy protection mode that when a user requests “overwatch” protection, one or more vehicles circle the protected user. This is functionally identical to track a moving target, except that the $U \times V$ sensors will be directed at the region surrounding the convoy, rather than directly at a target.
4. Communication relay – When an area to be searched (see behavior #1) is farther from the user interested in the area than the vehicle-user communications range, one or more vehicles autonomously form a communications chain to relay data from the searched area to the user.
5. Obstacle avoidance – Obstacles that are known by a vehicle are avoided. Note that obstacles may include physical obstacles detected by vehicle sensors (e.g., trees) and/or abstract obstacles provided by users such as no-fly zones.
6. Behavior switching – Vehicles are capable of exhibiting multiple behaviors depending upon current user goals and circumstances.

One highlight of the experiment was the indirect access to time-sensitive data from a remote camera sensor – located well outside the direct communication ranges of the C2 ground stations and their radios – to OPISR users by autonomous UAV communications chains. This communications link was formed fully autonomously, even to the extent that there was no specific command given to the ScanEagle UAV that it forms a communications chain. The ScanEagle was tasked to patrol the region, and as it became aware of sensor data, it relayed that data to the user, who immediately had the sensor data available on his display.

Another key OPISR feature that was demonstrated in St. Inigoes was the OPISR UAV ability to coordinate on tasks that it (the UAV) cannot satisfy without recruiting other vehicle types. Very importantly in this experiment, command was shown not only from one ground station to multiple heterogeneous vehicle platforms but also commands from multiple users at multiple ground stations could set the goals of any and all OPISR components.

During experimentation sensor and mission information was delivered to both C2 user stations both directly and via UAV communications chaining. This delivery occurred both automatically and in response to specific user requests. All relevant mission data was made available and reported to the C2 user, including the status of assigned search missions, represented as “fog of war” over the map geo display; detections from the various UGS, the two USVs, and the UUV; and camera imagery from the various platforms. Within the flight time windows available, over 65,000 images were collected by the various camera sensors, including onboard UAV payload sensors and relayed to the C2 stations, available to any of the notional war fighter users as their ground node was connected to cognizant portions of the mesh network.

51.3 Conclusion

The OPISR system is a framework that provides a capability through which numerous unmanned platforms simultaneously provide real-time actionable intelligence to tactical units, provide abstract manageable situation awareness to theater commanders, and provide high-quality forensic data to analysts. OPISR is a demonstrated system that includes a distributed self-localizing camera payload that provides imagery and positional metadata necessary to stitch information from multiple sources, a distributed collaboration system that is based upon robust ad hoc wireless communications and agent-based data management, and a user interface that allows users to receive real-time stitched imagery from unmanned vehicles that does not require users to directly control (or even expressly be aware of) the unmanned vehicles producing the imagery. OPISR is a bold vision that presents an innovative approach to ISR, an important enabler emphasized in the Quadrennial Defense Review and other key policy documents, and gives the laboratory an enhanced ability to help sponsors address future capability gaps in this critical area.

MAVs and Bio-Inspired UAVs

Robert C. Michelson

Kimon P. Valavanis and George J. Vachtsevanos

MAVs and Bio-inspired UAVs addresses the emerging UAV area of Micro Aerial Vehicles (MAVs) and bio-inspired MAVs and UAVs. Research and development activities in MAVs have accelerated significantly over the past years, driven by a need for small autonomous vehicles that can execute a variety of tasks, such as Intelligence, Surveillance, and Reconnaissance (ISR) in complex urban environments, search and rescue operations, and security and border patrol, among other applications. A substantial component of the MAV research is inspired by the exceptional flying behaviors of biological species, i.e., birds and insects. MAVs can be operated by a single person offering low weight and cost, extreme maneuvering capabilities, and rapid response times to requests for visual observations. Innovative MAV concepts are motivating advanced research and development sponsored by the government and industry.

► **Micro Air Vehicles** by R.C. Michelson addresses challenges related to the design of MAVs. Such challenges span across aerospace, electrical, mechanical, and computer engineering because of flight regime in which these tiny aircrafts operate. Aerospace designers must contend with issues surrounding low Reynolds number flight, while electrical and mechanical designers are concerned with issues of energy storage, behavior of materials at small scales, and non-scaling items. The missions at which MAVs excel demand increased levels of autonomy, forcing computer engineers to create innate onboard intelligence exhibiting high bandwidth and

superior abilities to interpret obstacle-rich environments not usually encountered by larger flying machines.

► **Survey of the Human-Centered Approach to Micro Air Vehicles** by S. Michelson presents a detailed overview of some of the Human Systems Integration (HSI) and Human Factors Engineering (HFE) issues involved with MAVs. The importance of a total systems engineering approach to MAV design, how MAVs fit into commonly accepted Human Systems Integration domains, and an exposure of some emerging issues with MAVs that require further research are discussed. The unique attributes of MAVs in terms of their size and control methods, combined with the challenges of the dynamic operational environments where they are deployed, represent HFE issues exclusive to the MAV platform that require special consideration. The importance of designing for the human operator is paramount for successful outcomes with MAV platforms. Specifically highlighted are some areas where currently researched HFE issues are particularly applicable to MAVs as opposed to large-scale systems.

► **Development of Insect-Sized MAVs** by Sunada, Liu, Tokutake, and Kubo describes a prototype bio-inspired flapping MAV with flexible wings, with a specific focus on the flexible-wing aerodynamics. The flapping-wing MAV has a weight of 2.4–3.0 g and a wingspan of 10–12 cm, which is comparable to hawk moths and hummingbirds. The MAV's flexible-wing aerodynamics is analyzed by combining an *in-house* computational fluid dynamics (CFD) method and wind tunnel experiments (EXP). In addition, fixed-wing and rotary-wing MAVs with elements that enable the miniaturization of an aerial vehicle are introduced.

► **Flapping-Wing Propelled Micro Air Vehicles** by Jones and Platzer presents a brief history of the major discoveries in the scientific exploration of flapping-wing flight. This is followed by a short review of the basic concepts of lift generation on wings in low-speed, steady flight, which leads into a discussion of the generation of thrust due to the flapping of wings. The aerodynamics of single flapping wings in forward and hovering flight, of flapping tandem and biplane wings, and of dual wings using the clap-and-fling effects are discussed. The chapter concludes with an overview of the major characteristics of five representative flapping-wing propelled MAVs developed to date, including models developed at the AeroVironment Company, Naval Postgraduate School, Wright State University, and Delft University.

► **Inventing a Biologically Inspired, Energy Efficient Micro Aerial Vehicle** by Ratti and Vachtsevanos introduces a novel framework for the design and control of a MAV, where the conceptual design is based on biologically inspired principles and emulates a dragonfly. The chapter addresses the design and control features of the proposed design and gives an overview on the developmental efforts towards the prototyping of the flyer. The potential applications for such a high endurance vehicle are numerous, including air deployable mass surveillance in cluster and swarm formations. The disposability of the vehicle helps in battlefield deployment as well, where such an MAV is made available to soldiers for proximity sensing and threat-level assessment. Other applications include search and rescue operations and civilian law enforcement.

► **Issues Surrounding Communications with Micro Aerial Vehicles** by C. Michelson seeks to answer many of the communications-linked questions that MAV designers have and gives a high-level overview of the factors that affect MAV data and control links. Challenges related to communications with MAVs are because of their size and very limited payload capabilities. Limited payload capacity leads to considerable constraints on power sources, sensors, and communication systems. Power sources are by far the most weight-inefficient components on an MAV. MAV designers are forced to look elsewhere to optimize their designs. The best way to do so in lieu of focusing on improving battery technology is to optimize the systems that draw power, thereby increasing endurance. Motors, onboard processing, and communications transceivers are the largest three power consumers on MAVs today. While motors and embedded processing are important to optimize, the sheer number of available communications options may leave MAV designers unsure how to proceed. By building an MAV around its onboard communications system, designers increase reliability, endurance, and capability with little or no added cost. Care must be taken to ensure that the end result meets the power, aerodynamic, and electromagnetic requirements for the particular MAV and its particular mission.

Collectively, the chapters in this section refer to all aspects of MAV design, control, communications, operation, and applications.

Abstract

The design of micro air vehicles (MAV) presents one of the most formidable engineering challenges, not only to aerospace, but electrical, mechanical, and computer engineers because of flight regime in which these tiny aircraft operate. Aerospace designers must contend with issues surrounding low Reynolds number flight, while electrical and mechanical designers will be concerned with issues of energy storage, behavior of materials at small scales, and non-scaling items. The missions at which MAVs will excel demand increased levels of autonomy, forcing computer engineers to create innate onboard intelligence exhibiting high bandwidth and superior abilities to interpret obstacle-rich environments not usually encountered by larger flying machines. This section deals with MAVs that conform to the original Defense Advanced Research Projects Agency (DARPA) definition (15 cm and smaller), rather than the larger UAVs which many are prone to label as “micro air vehicles,” but in reality are just small-scale UAVs. Topics covered in this section are somewhat unique relative to typical MAV discussions

in other texts dealing with MAVs that focus primarily on the air vehicle rather than the system. Not only is the air vehicle covered here but also issues of MAV deployment which are all too often neglected in discussions of MAV operations (e.g., communications and operational issues).

53.1 Introduction

“No other air vehicle design space has presented the mix of challenges as that of miniature flight platforms. By definition these tiny platforms are unmanned and endeavor to invade the flight regime of birds and insects. In order to do so, the creators of these aerial robots must address the same physical design constraints which have already been mastered by the world of airborne biology, including low Reynolds number aerodynamics, high energy density, and extreme miniaturization” (Michelson 2004).

Critical issues arise when working at this scale, energy storage being one of the most significant. Nontraditional aerodynamics in low Reynolds number regimes complicate flight efficiency, driving designs toward the biologically inspired and away from the conventional. Due to the inability to scale all systems as a result of basic physics-based constraints, normally simple telemetry systems are constrained to operate at short ranges and high frequencies due to limitations on antenna structures. Further, teleoperated operation becomes impractical as the tiny MAV fades from view over fairly short distances. This leads to designs requiring greater or full autonomy – but an entirely new set of issues arise with fully autonomous MAVs and their potential for emergent behaviors that are difficult to predict and test.

The following sections of this introductory MAV chapter will put these issues into perspective and show their interrelation.

53.2 Historical Perspective

Interest in tiny flying machines had its origins with the notion that a small insect-like flying platform could be devised for covert operations. The U.S. Central Intelligence Agency (CIA) experimented with the creation of a remotely-controlled pneumatic “dragon fly.” In 1993 a RAND Corporation study discussed the potential use of sensor-carrying insects and the concept of truly “micro” air vehicles (Hundley and Gritton 1994). Japanese researchers attempted to stimulate motor neurons in cockroaches to control the insect trajectory by a radio link (BBCi Sci/Tech 1998). Tiny airplanes powered by biological motors (large flies glued to a fixed-wing fuselage) have been demonstrated recently but was actually a subject of experimentation at the turn of the twentieth century by Nikola Tesla (Cheney 1981).

“Micro Air Vehicle (MAV) is a most unfortunate name given to this class of air vehicles because none are truly ‘micro’ and the original (ca. 1995) official DARPA vehicle definition requiring a maximum 15 cm (6 in.) dimension confirmed the name to be a total misnomer” (Michelson 2006). DARPA defined MAVs as “being less

than 15 cm” because this represented the juncture at which low Reynolds number effects begin to dominate and beyond which, integration of energy, propulsion, aerodynamic structures, and intelligence is a necessity (Michelson 2004).

Initially (ca. 1997), DARPA’s vision for MAVs was that the individual soldiers at the platoon, company, or brigade level would use such vehicles for reconnaissance and surveillance, battle damage assessment, targeting, emplacing sensors, communications relays, or for sensing chemical, nuclear, or biological substances. The 15-cm vehicles would be able to conduct real-time imaging, have ranges of up to 10 km, and speeds of up to 30 miles per hour for missions that are 20 min–2 h long. By 2012, this vision has been realized, but not without many operational impediments.

53.3 The Energy Barrier

In order to realize the endurance envisioned by DARPA, energy sources of significant energy density had to be developed. Various MAV concepts using high energy density battery technology, fuels (both combustion and catalyst-based), as well as energy harvesting techniques have been explored. Battery technologies exist that exhibit amazing energy densities; however, most of these are primary cells (nonrechargeable) and because of the greater danger of explosion from rapid overheating due to internal or external shorting of the cells, these battery types have not been fielded in MAVs. Presently, the most common high energy density battery chemistry in common use is the lithium polymer (LiPo) battery. LiPo technology allows for the creation of relatively high energy density secondary (rechargeable) cells and is the most widely used energy source for electric flight propulsion at present.

Electric propulsion is almost exclusively by means of electric motors driving propellers/rotors or flapping wing mechanisms. Synthetic muscle technologies such as piezoelectric elements, shape-memory alloys, rheological fluids, and electro-polymers offer an array of electrically controlled actuators which have been touted as a potential source of power for biologically inspired aerial robots, but all have yet to demonstrate sufficient efficiency to lift even the best high energy density battery (Michelson 2004).

Researchers have also considered the use of chemical power sources due to the higher energy density contained in fuels of various types. Stored energy becomes a significant impediment as MAV mission duration increases. The present state of the art in battery technology does not allow for long endurance MAV missions, though it is hoped that someday improved electrical storage media (carbon-air, fuel cells, etc.) will result in the energy densities required for useful long endurance missions in MAV-sized vehicles. Near-term solutions to onboard energy storage will come from chemical or fossil fuels because of their superior energy density. As a point of comparison, consider the amount of releasable energy stored in a drop of gasoline compared to that which can be stored in a battery the size of a drop of gasoline (Michelson 1998). Further, as the mission progresses, a fueled propulsion system

gets lighter, whereas a battery-operated propulsion system remains just as heavy at the end of the mission as the beginning. One example of a chemically fueled MAV concept is the Entomopter, a flapping wing MAV that was under development by DARPA and NASA. The “Entomopter” (*entomo* as in entomology + *pteron* meaning wing or a “winged insect machine”) uses a liquid monopropellant such as high-concentration hydrogen peroxide or hydrazine in the presence of a catalyst to create gas for reciprocating actuation of flapping wings.

A third approach to powering MAVs for longer endurance missions is energy harvesting. Small birds and insects are consumed with the task of energy harvesting: the search for food. Hummingbirds, the smallest of all avians, feeding on dilute nectar can ingest nearly three times their body mass in nectar per day to sustain life and mobility (Powers and Nagy 1988; McWhorther and Martinez del Rio 1999). Their small bodies cannot carry large amounts of food, so to improve efficiency they choose high energy foods that provide immediate energy access (sugars) as do many insects. Tiny aerial robots suffer from the same need for readily available energy. The energy density of the best battery technologies currently available still cannot match that which is locked chemically in various compounds such as sugars. Some have advocated energy harvesting through the use of solar panels on MAVs. Unfortunately, the efficiency of current solar cells (roughly 5 % for common cells, ranging up to 28 % for some of the best triple-junction gallium arsenide space-qualified cells) in sizes that could be carried by a MAV is insufficient for sustained flight (Dornheim 2003). The extra weight of such cells negates their use as an endurance extender, and their low voltage output is incompatible with many of the electronic actuators proposed (e.g., piezoelectric, electro polymers). Finally, night operation or flight through shadows is precluded.

Research has been conducted in leaching power from power lines by UAVs, and a ground vehicle known as “slugbot” was developed to consume organic matter and digest it to produce energy for locomotion. In both cases, the amount of energy harvested and the time taken to process the energy made the application impractical.

53.4 Biological Inspiration

MAVs have been demonstrated as fixed, rotary, and flapping wing vehicles. As the size of the MAV decreases and the vehicle operates in lower and lower Reynolds number regimes, the efficiency for flight moves away from classical fixed-wing aerodynamics toward flapping wing solutions. It is no accident that all insects use flapping wings to fly. A number of MAVs such as the Entomopter mentioned above and various other unconventional flappers have been demonstrated. Some of these designs are “biomimetic” (copying nature), while others are “biologically inspired” (taking principals from nature but implementing them in a way that goes beyond what is found in nature). Examples of both approaches are discussed in detail in the subsequent chapters ► [Development of Insect-sized MAVs](#) and ► [Flapping-Wing Propelled Micro Air Vehicles](#).

53.5 Mission Effectiveness and Payload

One area that is usually glossed over in most texts dealing with MAVs involves issues surrounding communications with micro air vehicles. Because of their small size, MAVs are restricted not only in the power that they can carry to support telemetry, but they are also hampered by the physical constraints placed on radiating elements. Operation at greater ranges is enhanced by the use of lower frequencies. The same is true when attempting to transmit through obstacles such as buildings or foliage. Unfortunately, lower frequency operation becomes inefficient as the antenna apertures shrink in size. Increasing transmitted power is not an effective solution due to the limited energy carried onboard the MAV as well as the mismatch between a low-frequency transmitter and a miniature antenna. As a result, higher-frequency telemetry is desirable from an emissions standpoint, but not from an attenuation standpoint. Specific consideration must be given to transmitter power, data and command link design, amplifier types, modulation techniques, simultaneous communications, and antenna aerodynamics. Various techniques to deal with these conflicting MAV telemetry design parameters are discussed in chapter [►Issues Surrounding Communications with Micro Aerial Vehicles](#).

53.6 The Man and the Machine

Certainly one of the least discussed topics relating to MAVs is the human interaction with the MAV system. A prime example of an MAV-specific human interaction problem is the fact that as the MAV flies away from the operator, even at only short ranges, useful visual feedback is lost due to its tiny size. Further, if the MAV mission involves the penetration of a building, visual feedback is lost. As briefly discussed in the prior section, teleoperation via a data link is problematic for any number of reasons, none the least of which is the cost in onboard stored energy.

Another significant issue arises when autonomy is used to relieve the operator from having to control the MAV remotely. A fully autonomous MAV, while very desirable for many reasons, is highly difficult to test because of the unpredictable potential for emergent behaviors (Michelson 2008).

Chapter [►Survey of the Human-Centered Approach to Micro Air Vehicles](#) discusses these issues as well as how to effectively incorporate a human-systems integration approach to the design of MAVs in light of a valid MAV concept of operation. Automation, situation awareness, and workload issues are discussed, as are the test, evaluation, and training considerations particular to MAV operators.

53.7 Conclusion

The genesis of the micro air vehicle concept and the initial funding by DARPA to push the technology forward have resulted in many MAV configurations using

fixed, rotary, and flapping wing propulsion. The critical element preventing greater performance over the past 20 years has been high energy density propulsive power, and this remains true to this day. Battery and chemical fuel power sources, with few exceptions, have not progressed at a rate which allows MAVs to have the endurance of birds of similar size. Biomimetic control systems have been developed in laboratory settings, but the ability to control a MAV with the agility of a small bird, much less than that of a dragonfly, still eludes designers.

When considering the best communications architecture for MAVs, designers must remember that everything is a trade-off when balancing miniaturization with high bandwidth remote non-line-of-sight telemetry. RF characteristics are largely bounded by the universal constraints of physics and are therefore not controllable by the designer. Remaining mindful of the distinction between human systems integration and human factors engineering with regard to MAV development is pivotal to correctly accounting for the human in the design process. The uniqueness of the MAV and its deployment is creating the need for a new understanding of man-machine systems in the unique operational environment of the MAV.

MAVs are still in their infancy 20 years after the DARPA vision for such a vehicle, largely due to technical challenges. It is not that one does not understand the design issues; rather, one lacks the component efficiency and level of mechanical miniaturization necessary to compete with biological systems. Since fully 50 % of a MAV's gross takeoff weight is consumed in stored energy, one of the areas in which future MAV designers will reap the greatest gains will come from advances in propulsive energy density.

Abstract

A detailed overview of some of the Human Systems Integration (HSI) and Human Factors Engineering (HFE) issues involved with the newest and perhaps fastest growing research area in unmanned systems, micro air vehicles (MAVs), will be presented. This work will be useful to those studying MAV system concepts and designs, managers of HSI programs, users of MAV systems, and those who design MAVs and the resources to support them. The importance of a total systems engineering approach to MAV design, how MAVs fit into commonly accepted Human Systems Integration domains, and an exposure of some emerging issues with MAVs that require further research are discussed.

S. Michelson
Human Systems Integration Division, Georgia Tech Research Institute, Atlanta, GA, USA
e-mail: stuart.michelson@gtri.gatech.edu

The unique attributes of MAVs in terms of their size and control methods, combined with the challenges of the dynamic operational environments where they are deployed (such as the battlefield), represent HFE issues exclusive to the MAV platform that require special consideration. The importance of designing for the human operator is paramount for successful outcomes with MAV platforms.

Literature currently addressing HFE issues with unmanned platforms generally lump all flying systems together, making no distinction between the large high-altitude platforms and smaller ones, despite there being a unique set of challenges that are specific to smaller platforms. Specifically highlighted are some areas where currently researched HFE issues are particularly applicable to MAVs as opposed to large-scale systems.

54.1 Introduction

Successfully implementing micro air vehicle (MAV) programs requires one to maintain a total systems approach, and Human Systems Integration (HSI) must be an integral part of that approach. These are presuppositions to the remainder of the content in this work. Acquiring a human-centered approach to analyzing the observable problems with unmanned systems is essential, but one might feel inclined to question what the human has to do with such systems at all, especially when the hallmark of the domain is the absence of humans. While it is important to comprehend that the human is an integral part of the design of any unmanned system, humans are particularly important to the MAV platform where operators are thought to have more active roles in commanding the craft, and systems have a wider spread across the levels of automation. This reality can complicate system design and function allocation. A failed systems approach that deemphasizes the human in the loop will result in human-related challenges such as unmanageable operator workload or poor situational awareness (SA) culminating in compromised safety for warfighters.

The Defense Acquisition Guidebook indicates that a total system approach “includes not only the prime mission equipment, but also the people who operate, maintain, and support the system; the training devices; and the operational and support infrastructure” (United States Department of Defense 2012). It would be a grave error for designers to assume that just because a human is not physically present onboard the vehicle that they do not need to be knowledgeable about human attributes and limitations. Testing and evaluating these attributes and limitations is a major aspect of Human Factors Engineering (HFE), and given the uniqueness of the manner in which MAVs are deployed, special design considerations must be given to elements such as human anthropometry and cognitive, physical, and sensory abilities. While not every engineer needs to be an expert in these areas, they should at least be able to discuss them intelligently with HFE/HSI practitioners and understand their extreme importance to successful system design, as it is their job to guarantee that the human is considered throughout every portion of the design process.

54.2 Terms

Introducing system designers and operators to HSI and HFE considerations associated with MAVs requires one to recognize the finer distinctions between commonly used terms within the systems engineering domain.

A brief discussion of terms used in this work is necessary for clarity since many use some of the common terms interchangeably while the author does not. Note that while there are many definitions of Human Systems Integration, the author ascribes to the United States Air Force's definition of Human Systems Integration which is "the integrated and comprehensive analysis, design, and assessment of requirements, concepts and resources for system manpower, personnel, training, environment, safety, occupational health, habitability, survivability, and human factors engineering, with the aim to reduce total ownership cost, while optimizing total mission performance" (United States Department of Defense 2009). While different branches of the armed forces emphasize varying arrangements of domains (see MANPRINT, for example), the underlying theme is that HSI is a vital element that optimizes system design to enhance system performance while maximizing the abilities and mitigating the limitations of humans. In so doing, the abilities of the warfighter are enhanced and total ownership costs of a system are reduced (Air Force Human Systems Integration Office 2009). It is important to emphasize that HSI from an engineering standpoint not only deals with requirements and concepts but people and equipment. In this way, HSI should be understood to be a broader concept than HFE although many incorrectly use the two terms interchangeably. The major motivation for incorporating HSI into MAV programs is to control total ownership costs while maximizing system effectiveness.

Note that Human Factors Engineering is included as one of the domains of HSI. HFE deals more exclusively with the realization of design criteria, psychological elements of human behavior, as well as physical and mental limitations of humans. By understanding human attributes (anthropometry, for example), HFE analysis seeks to enhance performance (to required levels), increase safety, and increase user satisfaction (Wickens et al. 2003). The science of human factors can be said to rest upon generalization and prediction. With respect to unmanned systems, researchers should be interested in generalizing common problems and predicting solutions – all while accounting for the humans in the loop and reducing design-induced failures.

The importance of incorporating HSI and HFE analyses into the design process early cannot be stressed enough. The Department of Defense specifies that design changes can cost 1,000 and 10,000 times more in initial production phases than the same change would cost during a product's earlier design phases (United States Department of Defense 2005). While the human element is a vital consideration throughout the entirety of the design process, it has been shown time and time again that design changes made early are less costly because they do not involve the modification of existing hardware and software. A human-centered approach to MAV development should be early and iterative but also should span throughout the entirety of the design process.

54.3 Incorporating an HSI-Centric Design Approach

A proper approach to system design must include HSI as a consideration of prime importance. So much so that the Department of Defense's acquisition policy indicates that HSI should be central to the formation of integrated product teams (IPTs), which are a vital part of the integrated product and process development method. The Defense Acquisition Guidebook states that the product and process development method is a "management technique that integrates all acquisition activities starting with capabilities definition through systems engineering, production, fielding/deployment and operational support in order to optimize the design, manufacturing, business, and supportability processes. At the core of the IPDD technique are IPTs. Human Systems Integration should be a key consideration during the formation of IPTs" (United States Department of Defense 2012). It is important for HSI experts who are considering the human element for each HSI domain to be included as members of the various IPTs so that the human element is considered throughout the entire design process. This design concept places those charged with including the human element in positions to comprehensively impact the system's design (United States Department of Defense 2012). HSI professionals should be included in the development of a MAV platform's concept of operations rather than being invited into the design later to comment. In reality this rarely occurs, but doing so allows HSI considerations to impact the concept of operations and in turn create systems where total ownership costs are reduced and system effectiveness is maximized.

It is not to be unexpected for engineers to resist the involvement of HSI professionals. Those that do are likely victims of a bad definition of HSI and do not understand how it will positively impact their work, or they think it is an unnecessary cost not realizing that without it their program will be more expensive. Unfortunately, many engineers treat HSI and HFE as checkboxes for after their work is considered complete. A tendency may exist among some engineers to place less emphasis on designing for the human when managing unmanned systems programs such as MAVs. The development of an HSI plan is one way to make sure that human considerations are not deemphasized. Managers must develop an HSI strategy for their program. This takes the form of an HSI plan that should be established early in the design process before any manufacturing takes place (United States Department of Defense 2012). Each phase of the program should include how the HSI plan will address issues associated with each HSI domain. In systems where new technologies are expected to replace or supplement human activities, HSI plans should anticipate the possibility that delays in development might still prevent such measures from being implemented, and therefore, program managers should have alternatives that still account for appropriate levels of human operator workload.

While the finer points of the accepted defense acquisition strategy are beyond the scope of this work, a brief understanding of the context in which MAVs are being developed is valuable. Within the unmanned systems category, incorporating good HSI plans is particularly important for MAVs where typically more involvement is expected of the human operator in terms of direct control of the craft.

This distinction of the MAV platform requires a close look at all of the HSI domains but specifically those that deal with the cognitive, physical, and sensory abilities of humans and their knowledge, skills, abilities, and experience levels as system operators (the personnel, training, and human factors engineering domains).

54.4 MAV Concept of Operations

In contrast to larger, more traditional unmanned systems being widely deployed around the world, MAVs are deployed in a distinctive manner. DARPA's definition of a MAV specifies that the vehicle be smaller than 15 cm (about 6 in.) in any dimension (McMichael and Francis 1997). The MAV was originally thought to be a military asset that could be included in every warfighter's loadout, enabling him/her to engage in intelligence, surveillance, and reconnaissance (ISR) missions while in the field (Michelson 2008). This methodology stands in contrast to larger-scale systems with expansive ground control stations used with popular unmanned aerial vehicles (UAVs) such as Northrop Grumman's Global Hawk or General Atomics' Predator. In such systems, multiple human operators are involved in the command and control of the system from either homeland-based command centers or mobile trailer style units.

From a technical standpoint, MAVs, being craft measuring in mere centimeters, represent a number of issues that have been written about in detail elsewhere. Some of these issues include robustness in inclement weather, endurance, antenna aperture, and strains on command and control due to limited storable energy on board the craft. While these are very real challenges deserving consideration, one cannot look to solve these problems while ignoring or merely paying lip service to the importance of a human-centered approach to design of MAV platforms. The aforementioned issues should be handled considering their effects on humans, but there are other specific issues that are perhaps not often thought of regarding the human's interaction with MAV systems. The remainder of this chapter is dedicated to addressing some common considerations to MAV design and implementation from a human-centered perspective while comparing and contrasting their uniqueness against larger high-altitude UAV systems. HSI professionals involved in the development of a MAV's concept of operations should emphasize that a system is driven by humans. Unmanned systems should be just as concerned with designing for the human in the loop as manned systems. The main difference between the two is that a human is not physically onboard the craft, but UAVs such as Predator have hundreds of humans involved in their operation, maintenance, and support.

54.5 MAVs and the Man-Machine System

As the popularity of UAVs has increased, so has the interest in shrinking their size. This reduction in size has expanded the range of applications for which humans can utilize them. No longer are UAVs limited to outdoor flight at altitude.

Recent developments in research and technology have afforded MAVs the prospect of flying into buildings, down hallways, through air ducts, sewer systems, or even acting as micro spies no bigger than a housefly on the wall. All of these abilities present new challenges not only to the MAV platform's hardware and software but also to the human system designers and operators. The challenges associated with indoor flight such as obstacle avoidance and navigating environments without the assistance of GPS are difficult to overcome and are only enhanced by difficulties such as transmitting valuable location information back to human operators from inside of a structure.

Engineers may feel inclined to meet these challenges with a reductionist approach to systems design. This traditionally popular approach is characterized by a focus on each physical and technical component of a system alone while not emphasizing the behavioral components of systems. This approach has been associated with catastrophic system failures on the order of magnitude of oil spills and commercial aircraft crashes because it does not consider the interaction among all of a system's parts and does not view system components in terms of their relation to accomplishing overall system goals (Czaja and Nair 2012). The best way to avoid this pitfall is to incorporate a good HSI plan which dictates that all the various domains of HSI are considered together.

Since HFE is concerned with enhancing the interactions between humans and all other components of a system, good systems theory sees the understanding of the entirety of a system's components being in concert as implicit to good systems design (Czaja and Nair 2012). As the levels of autonomy continue to increase with MAVs, the complexities of automation and the system components required to support them also increase. As the emphasis continues to be on advancing the state of MAV technology, equal consideration in the realm of system design must be given to the human element or systems will underperform. This is an accepted tenant within the HFE field (Czaja and Nair 2012).

While there are many ways to classify a system, classifying MAV systems in terms of levels of feedback mechanisms is particularly useful to the characterization of the platform. A closed-loop system provides feedback to an operator that is continuous for error correction. This type of system provides human operators with real-time information so that they can determine the difference between actual and desired system states. An open-loop system does not afford an operator the feedback necessary for continuous control (Czaja and Nair 2012). MAVs exhibit levels of autonomy ranging across the spectrum from 100 % remotely piloted robots to entirely autonomous robots making their own decisions in real time based on their environment apart from a human operator. For this reason, MAVs as a category can be closed-loop systems, open-loop systems, or both.

This can complicate the design strategy one should employ since open- and closed-loop systems require varying design strategies. Designers should pay close attention to the consequences of dynamic function allocations to ensure that realistic expectations are being placed on human operators in certain circumstances where the human has more control. Extensive experimentation and testing using realistic scenarios that cover the breadth of possible human and computer workload should be undertaken to mitigate potential workload-related errors. For a more full

discussion of scenario development strategies and workload analysis techniques that extend beyond the scope of this work, see *Mental Workload and Situation Awareness* (Vidulich and Tsang 2012).

When considering the capabilities and limitations of humans for MAV systems, it is important to recognize the way in which advancing vehicle autonomy has changed the nature of man-machine systems. Not only have new technologies enhanced the manner in which human operators can control their vehicles (spoken commands, for instance), but also the capacity for intelligence of the vehicles themselves has changed the relationship between the human and the system. This trend will continue as flying robots are increasingly able to perform more tasks previously restricted to humans. Historically the model for human machine interfaces has been based around control. Humans were said to interact with a system by controlling it. Under such circumstances, the system was subservient to the human. The current state of affairs is that intelligent MAVs are evolving into entities that can extend the capabilities of their human partners (Czaja and Nair 2012). With respect to MAVs, the robot should be viewed and treated as a member of the team working to accomplish the stated goals of the system. This reality of the human's relationship with MAVs will only be enhanced further as each human operator becomes responsible for swarms of MAVs in the future.

Perhaps the most prominent example of MAVs advancing the state of the art in robotic flight behavior is the International Aerial Robotics Competition. It has consistently highlighted the importance of the interdependent relationship of human operators and their aerial robots to accomplish tasks. Starting in 1991, the International Aerial Robotics Competition is the longest ongoing university-based robotics competition in the world. In addition to exposing the next generation of aerial robotics engineers to the process of system design from concept to reality, the competition has always been driven by pushing the advancement of autonomous robotic technology to levels previously unattainable by governments or industry. While earlier competition challenges involved outdoor flight tasks including mapping hazardous environments, searching for disaster survivors, collecting and moving objects, locating specific buildings and their attributes, and transmitting information back to command and control stations, the most recent challenges have involved smaller flying robots that are tasked with penetrating structures and negotiating confined spaces full of obstacles with no GPS guidance. Small air vehicles are designed to penetrate openings in structures, deactivate security systems, read signs (in languages foreign to the human operators), avoid obstacles (furniture and debris), negotiate disturbances to the airspace (such as fans), and successfully retrieve and replace an object that must be located in a limited amount of time.

These advanced robots systems are fully autonomous, making decisions on their own with no human operator control inputs, and are typical of the relationship between humans and their MAVs because they assist the human to accomplish a task that cannot be achieved without both entities working together. An attribute typical of all International Aerial Robotics Competition missions has been using unmanned technology to enhance the capabilities of humans by going places and doing things that are either not possible or too dangerous for humans to attempt. In this way,

the missions when accomplished become excellent case studies exemplifying the relationships of man-machine systems that can extend the capabilities of humans.

For a detailed examination of some considerations that can assist one to create, test, and evaluate autonomous systems that are designed to extend human capabilities and not merely mimic human attributes, the author recommends *Ten Challenges for Making Automation a “Team Player” in Joint Human Activity* (Klein and Bradshaw 2004). This essay highlights the importance of focusing research objectives on promoting healthy human robot teamwork, not merely on how to make systems more autonomous.

54.6 Automation, Situation Awareness, and Workload

It has been established that human operators and MAVs should be thought of as team members working toward the satisfaction of mission goals. But how does one determine what should be an automated function and what should not with MAV systems? Traditionally, designers might reference a Fitts List (an exhaustive list outlining the abilities of humans against the abilities of machines) to attain an overall understanding of the types of activities humans excel at versus the types of activities at which machines excel. However, one should do so with caution, making sure that by examining individual activities their interrelation as a whole within the system is not overlooked.

There are several primary reasons why a function might be considered a good candidate for automation. The first is when a task is considered too dangerous for a human to attempt without resulting in bodily harm or death. Another is when the nature of a task is something at which humans do not excel. A final example is when the safe and successful operation of a system requires a reduction in the workload of the human operator. To achieve optimal system performance, the capacity of the human to take on tasks successfully as well as the system's limitations must ultimately direct which functions should be allocated to which team member and when (Hopcroft et al. 2006).

Recent studies in the area of workload and adaptive automation have revealed that automation should be thought to redistribute workload, not reduce it (Vidulich and Tsang 2012). Too much automation on the other hand could lead to operator boredom, which could separate the human operator from the current state of the system resulting in difficulty for the human if they had to take over control to mitigate unusual crisis events. The concept behind adaptive automation is to implement automation that negotiates the fine balance between appropriate workload levels for human operators (the author advocates 75–80% workload as a rule of thumb) without inhibiting situational awareness (SA) (Vidulich and Tsang 2012). Particularly when human operators are monitoring MAVs in flight, it is essential that ground control stations provide solid feedback in real time lest the operator lose track of actions taken by the vehicle resulting in incorrect mental models of the system state. Such a situation enhances the likelihood of errors and reduces human

trust in automation. Conversely, human trust in automation might be too high due to poor feedback resulting in less attentive monitoring and the overlooking of error (Hopcroft et al. 2006).

Advocates of adaptive automation prescribe that predetermined fixed (or static) allocations do not compliment complex dynamic systems because individual factors can rapidly and unexpectedly change confounding human operators (Vidulich and Tsang 2012). This is a particularly important observation for MAVs deployed on the battlefield where the operational environment can quickly change not just in terms of threats from enemy combatants but also from environmental changes such as sandstorms or blinding rainfall.

Since MAV operators on the battlefield may be involved in direct and supervisory control of aerial robots during a firefight, one should expect that the cognitive workload demands are enhanced greatly as a variety of stressors have the opportunity to overwhelm the operator (Parasuraman et al. 2009). In such cases, automation should be employed effectively to support the human's performance with the system. Limitations such as mistrust in automation, a poor balance of workload between the human and the system, overreliance, and SA reductions are just a few of the challenges that can prevent automation from successfully aiding the warfighter in such high-stress operational environments (Parasuraman et al. 2009).

Dynamic environments such as battlefields are excellent case studies for why static function allocations are not ideal. The solutions to the limitations the warfighter faces in the operational environment with MAVs can be addressed with proper adaptive automation where conditions in which the system intervenes are not fixed but rather avail themselves at the appropriate time depending on the context of the battlefield environment. This sort of context-sensitive system assistance can be triggered by mission events, human operator performance levels, or even the human operator's physiological status (Parasuraman et al. 2009). For a further discussion of adaptive automation, reference *Adaptive Automation for Human Supervision of Multiple Uninhabited Vehicles: Effects on Change Detection, Situation Awareness, and Mental Workload* (Parasuraman et al. 2009). It encompasses a more thorough examination of the means of deploying effective adaptive automation with unmanned systems in general for warfighters on the battlefield.

To fully understand the relationship between SA and workload for warfighters remotely piloting vehicles on the battlefield, human operators who have sent MAVs inside of structures that they cannot see, or human operators who are piloting MAVs that have left their line of sight outdoors, a brief discussion of what SA entails is warranted. The author's description of SA offered below is designed to familiarize the reader with the basic concepts of SA, which is a topic that has been widely researched and written about. For a more full discussion of SA and the common challenges associated with it, reference *Situation Awareness* (Endsley 2012).

SA is a human attribute derived from cognitive processes and is therefore not an attribute of computers. Endsley's widely accepted definition of situational awareness is "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the

near future” (Endsley 1995). Using this definition, one must accept that situational awareness has three vital elements (perception, understanding, and prediction) and that each of them must be applied to exact circumstances.

Each of the three elements of situational awareness (perception, understanding, and prediction) requires different levels of human operator skill. Perception relies on selective attention, understanding relies on working and long-term memory, and prediction encompasses plan generation based on processed cues. Operator expertise is a major factor in SA (Endsley 2012). Applying the elements of situational awareness to the task of MAV flight monitoring, evaluators should expect to consider the following human tasks:

1. The assimilation of new information into preexisting knowledge bases within the human operator’s working memory
2. The perception of relationships and their significance
3. The projection of what will occur in the future given current information so that appropriate actions can be taken

It is being suggested that evaluations studying ground control station effectiveness address each of the three tasks in order by representing information so that it can be comprehended, depicting relationships among stimuli and integrating with heuristics to aid the human in making predictions about future system states. Human cognition naturally attempts to organize and make sense of visual and auditory stimuli. Human cognition is attuned to spatial and temporal relationships. Specifically with regard to perception, the human mind organizes stimuli into sources and streams that have identity and continuity over time (Endsley 2012). Harnessing these tendencies to create appropriate system feedback and data presentations to the human operator is important. In assessing successful user outcomes, it is important to highlight that good SA is not the same as good performance. Good SA is measured as appropriate and timely responses to unexpected events taking place within the system being studied.

An appropriate framework that considers the team members within a man-machine system working toward the accomplishment of mission goals must be adopted if one is to effectively manage the issue of automation with varying degrees of SA with a MAV system. One such framework has been proposed, which underscores the importance of considering which team members need awareness of other team members’ states. Using the warfighter as an example, human operators need information about the MAV’s state, humans need to know about each other (other soldiers involved with the mission), the MAV needs to know about the human’s state, and MAVs need to know about each other (Drury and Scott 2008). The human-UAV awareness framework should “accommodate the asymmetrical information needs of people and UAVs, be independent of any particular instantiation of a UAV, and be specific to the types of information needed in the UAV domain” (Drury and Scott 2008). While geared toward UAVs at large, the framework is well suited to MAVs and even refers to specific MAV platforms. The framework does well to address a common pitfall of SA analyses which is to paint an entire system’s human interface as either having good or bad SA because it considers a deeper level analysis of the

types of awareness various agents exhibit and require within a system in the context of levels of automation (Drury and Scott 2008).

As stated earlier, HFE is concerned with generalization and prediction. One challenge worth noting with regard to conducting workload and SA analyses on MAV systems is that generalizing can be challenging. In the example of the warfighter, while one can simulate weather effects to some degree, it is not possible to simulate the stresses of live fire from a battlefield into one's HFE evaluation protocol when studying a MAV system. Therefore, the actual levels of workload and stress observed during system evaluation cannot be considered to mirror what actual conditions would be. This reality is furthered by individual differences in human operator's skill and SA needs in a given situation.

Another generalization issue associated with MAVs is that one should be careful not to generalize workload assessments conducted on large-scale UAV platforms to MAV platforms because the concept of operations and the manning concepts are different. For instance, researchers at the Georgia Tech Research Institute have conducted workload analyses of large-scale high-altitude UAV platforms to determine the optimal crew size and workload levels under varying conditions for realistic operational scenarios (Georgia Tech Research Institute 2008). It would not be appropriate to generalize their findings about crew size and workload to a MAV because MAV flights are shorter in duration and typically do not involve handoffs of control as one would expect to see with a crew shift in order to support a large system for days at a time. Human operators within the large control centers serving UAVs such as Global Hawk find themselves in a more routine work cycle than the warfighters launching ISR missions with backpack MAVs from dynamic battlefields to see what is over the next hill. Depending on the MAV platform, soldiers may find themselves handing control off to one another to accomplish a mission, but this would not be because of operator fatigue like in large command and control centers. Two elements of workload that are often overlooked are what other routine tasks an operator was already involved in prior to the introduction of a new set of tasks for the MAV system, and how the introduction of the MAV system effects other agents (maintainers for example). Conducting a detailed task/job analysis as part of a good HSI plan should mitigate such an error.

54.7 Test, Evaluation, and Training

A unique attribute of MAV platforms distinguishing them from their larger unmanned counterparts is their low risk in terms of testing and evaluation. The testing of MAV platforms begins in wind tunnels but progresses to outdoor test flights much more rapidly than larger platforms that can ill afford costly crashes (Michelson 2008). AeroVironment's Wasp MAV with a radius of just 5 nm was selected for Disruptive Technology Fund by the Navy which, among others things, specified a cost goal of 5,000 USD per vehicle (United States Department of Defense 2005). Using the Wasp as an example, testing a vehicle with this price point is a very

affordable prospect. For perspective, the popular large platforms being deployed today cost well over 10 million USD. At such a nominal cost in comparison, one could crash thousands of Wasps before equaling the cost of one of those systems.

The affordability of test flights with MAVs is an advantage to the platform that is uniquely suited to its needs. Assessments of MAV performance during flight tests is generally completely reliant on stored information from testing instrumentation because the vehicle's responses to control prompts become unobservable to operators on the ground. Fine-tuning stability can often be a trial and error process (Michelson 2008), and therefore the ability to crash early test flights with fewer financial consequences is an advantage of the platform. The often-repeated mantra of "crash early, crash often" can be adopted with MAVs, allowing designers and researchers to conduct a higher number of test flights early on in the design process than with larger-scale unmanned systems.

Although there are advantages to testing with the MAV platform in comparison to larger craft, there are drawbacks. Perhaps one of the most challenging drawbacks is how one handles test instrumentation. As mentioned previously, MAVs generally have to rely on test instrumentation onboard to store flight data. It is often difficult to outfit MAVs with this special test instrumentation, and given that the majority of them operate with 50 % of the gross takeoff weight dedicated to propulsion and energy and the other 50 % to airframe and payload (Michelson 2008), some MAVs have very little payload to spare. The test instrumentation needs to be unique in size and weight, which has numerous implications on its cost, power, and versatility. In this way, MAV test instrumentation exists at the cost of fuel and endurance.

Because these platform-specific challenges to test and evaluation are unique, program managers need to have tasked HSI practitioners to address human concerns for each of the domains of HSI. Testing and evaluation falls within the bounds of the HFE domain because it deals not only with the satisfaction of design criteria but also with making sure that systems operation, maintenance, and support are appropriately suited to the capabilities and limitations of human operators and maintainers of the system (Air Force Human Systems Integration Office 2009). Due to the technical and manning requirements specific to MAVs, one should never attempt to reuse or adjust an existing test plan for a larger system and apply it to a MAV system. Doing so could result in major deficiencies in the test plan resulting in key attributes not being tested appropriately or at all.

When considering the training and selection for UAV operators, it is important to note that there are no common standards across the branches of the U.S. military. The Air Force restricts UAV pilots to military pilots only, while the Navy, Marines, and Army require a pilot to have only a private pilot's license. While human factors research has shown that appropriate levels of positive knowledge transfer is possible from manned flight to UAV control, further research is required to ascertain whether manned flight experience should be required (McCarley and Wickens 2004). These questions surrounding training standards and qualifications become more complex for MAVs where the desired model may be to place the common foot soldier in command of one or many vehicles. Further analysis, and ethnographic research,

for instance, should be required to determine what levels of training is appropriate for the piloting of MAVs from the battlefield. Manned flight experience may prove to be unnecessary as novel approaches to the command and control of MAVs are developed. Ideally, ground control station interface designs should incorporate good usability attributes that enhance the operator's ability through good affordances to remotely pilot vehicles without extensive prior flight experience.

54.8 MAV Ground Control Station Considerations

If the design of a new system or product is to be successful, a considerable amount of time must be spent trying to understand who the users will be and what their needs are. Failure to do so will result in products that do not accommodate their intended users or their environments. One of the greatest pitfalls for designers is to design for themselves and fail to consider their actual users. Ground control stations for MAVs are more mobile in nature compared to other UAV platforms. Many of them are carried in backpack rigs by soldiers or deployed from trunks of vehicles. Further, a real possibility exists that MAV ground control stations will be used in harsh outdoor battlefield environments. Although incorporating solid user interface design principles into ground control station concepts, such as element recognition over recall, clear affordances, and continuous feedback, is crucial for successful outcomes in general, this section is concerned with addressing a few of the unique challenges that MAV ground control stations have to overcome in order to be successful.

The most popular types of ground control stations serving MAVs are laptop-style designs. These come in many forms, and some of them are packed into ruggedized plastic boxes to prevent damage to system components. An advantage to the laptop style as a design is that training can be reduced because operators most likely already have familiarity with laptops in general. This style system is also advantageous because it can be rapidly deployed if necessary.

Recently, there has been an interest within industry to develop universal ground control stations that promote interoperability. Achieving interoperability increases the efficiency of MAV systems and capabilities of military units to share information. Designers should pay attention to preexisting standards and requirements for interoperability established by various branches of the armed forces as well NATO's standardization agreement (STANAG) when developing their own ground control station requirements.

Even the best interoperable ground control station designs are subject to degradation under certain conditions. In bright urban environments or desert battlefields, direct sunlight can render a ground control station's display useless. While hoods and shields can be helpful, they come at the cost of safety to the operator. If a MAV operator has his/her head buried in a display to interpret it or to maintain direct control over the vehicle, they can no longer observe their immediate physical surroundings. On battlefields or other environments where threats to the operator may abound, flying a MAV can be a high-risk activity. Minimally, the operator's

colleagues will have to guard the operator. In other situations, the operator may be able to operate the MAV from within an armored vehicle, offering protection as well as reduction in direct sunlight on the display. Designers should consider how obvious their ground control station designs make an operator to potential enemies in order to avoid increasing their likelihood of becoming a special target. Therefore one should not discount the manner in which the introduction of MAVs at the platoon level impacts the operators' preexisting job descriptions. Accounting for HSI early in a program (during the development of the concept of operations) can deter design induced manning and safety issues.

There are other environmental concerns apart from sunlight. Ground control stations can fall victim to excessive heat, cold, moisture, sand, and dust to name a few. These sorts of design considerations are often addressed in standards and guidelines. Designers should reference these when making sure that their hardware is appropriately engineered to handle these sorts of threats to functionality. What might be overlooked however is that the human operator interacting with the ground control station is also subject to the adverse effects of those elements. Soldiers, for instance, may not have the luxury of choosing their operational environment, and their performance can be limited due to these elements degrading their sensory and physical abilities. As mentioned previously, proper human interface design principles can help to reduce these negative effects by ensuring that displays and controls are simple to use.

It is important for designers to remember that the human operator while remotely piloting a MAV from a ground control station is separated from the sensory inputs that pilots receive in manned aircraft. This means that displays showing flight information need to be easy to read and operators should be able to trust them because their physical bodies are not actually feeling the effects of the forces that the vehicle is. For this reason, one should never assume that findings from studies about workload and cockpit control layout are scalable from manned aircraft to MAV ground control stations. The MAV ground control station should be considered as a unique entity with its own challenges in terms of workload and design layout.

While a pilot's inability to feel the forces of flight can be seen as a disadvantage, it can also be seen to enable the human operator, who may be able to remain calmer in riskier situations where his/her physical well being is not tied to the fate of the MAV. Designers might consider implementing haptic feedback to augment the physical effects that the MAV may be encountering. This can greatly enhance flight condition feedback to the operator.

The display of ground control stations should not overburden a human operator's mental resources. Selective attention and working memory are required because these two processes are particularly important to enhancing SA (Vidulich and Tsang 2012). An important consideration for MAVs that will be remotely piloted is the viewpoint that the display will show the operator. There are advantages and disadvantages to choosing an egocentric (one where the viewer sees what they would see as a pilot physically sitting in the vehicle) versus exocentric (a view from directly behind the vehicle) display, and one should consider the tradeoffs carefully. From one point of view, the environment is moving and the vehicle is

seen to be stationary, and from another, the environment is fixed and the vehicle is moving. An egocentric display may be preferable for obstacle avoidance, while an exocentric display may be better for acquiring an overall awareness of the terrain and environment (Vidulich and Tsang 2012). When designing for certain applications, it may be possible and advisable to create a display that affords the user both views simultaneously or the ability to switch easily. Whichever display type is selected, the design should support the human by accounting for his/her cognitive resources.

Another consideration for designers of ground control stations is the design of controls. Designing for gloved operation is normally a good idea for joysticks, buttons, and latches. Any testing and evaluation of a system should reflect as closely as possible the actual operational environment in which the system will be deployed, and therefore test participants should be outfitted with all their equipment for an appropriate context including gloves or other elements which could inhibit mobility or fine motor control required for delicate articulation. For some applications, the adherence to certain MILSPEC guidelines and standards might be required with regard to design features such as gloved operation, button size, and spacing.

In certain environments where the warfighter will be launching and commanding MAVs, light and noise discipline may hinder ground control station effectiveness. Systems that rely on light and audio to function are poor designs for this application. One should not design command and control to be limited to a single type of control input such as speech recognition. Alerts and alarms should not be audible in such conditions and displays should be designed to consider the potential for immediate muting. The necessity of night vision integration may also prove useful in certain applications. Another element to consider for the battlefield is that if the recognition of audible alerts and alarms is vital to proper system use, they can easily be muffled by the sounds produced by a firefight.

54.9 Ruggedization

The primary attribute of MAVs that distinguish them from other man-made flying things is their small size. This means that MAVs are more fragile than other UAVs, and how they transported and deployed in unforgiving environments such as the battlefield is worthy of consideration. Many MAVs are designed to fit into protective bags and cases that can be attached to the warfighter's loadout. Many MAVs are designed to be packable within the standard Modular Lightweight, Load-carrying Equipment (MOLLE) system.

Providing bags for compatibility with common equipment attachment methods is desirable but does not guarantee the level of protection that may be necessary to protect the smallest and most fragile MAVs. In the future, MAVs are going to continue to shrink in size, and it stands to reason that their fragility will continue to increase. This reality presents a challenge for the future as manufacturers of military components have had difficulty in the past keeping up with the speed of the evolution of commercial off-the-shelf components. Components get smaller, faster, and more rugged, while military systems can get bogged down in expensive

and time-consuming tests to make sure they meet military standards (Military and Aerospace Electronics 2004).

Applied Research Associates' Tactical Mini-Unmanned Air Vehicle (TACMAV) was a novel approach to storage and carrying. TACMAV had a 20.9-in. wingspan, and its flexible wings folded up around its carbon fiber fuselage. The entire system was storable in a 22×5 in. tube that attached to a soldier's backpack and weighed 0.8 pounds (United States Department of Defense 2009).

Designers should consider not only the vehicle itself but its ground control station's protection for harsh environments. The ruggedness of a MAV system should be driven by its intended use. Systems deployed inside of structures should be seen in contrast to those deployed outdoors. Standards and guidelines can be useful to designers as they determine to what degree a system's packaging needs to repel water, heat, cold, or other elements. When examining ruggedization from an HSI perspective, one should consider the survivability domain and its interdependence on the other HSI domains.

54.10 Conclusion

Remaining mindful of the distinction between Human Systems Integration and Human Factors Engineering with regard to MAV development is pivotal to correctly accounting for the human in the design process. The uniqueness of MAVs and how they are deployed is forging a new understanding of man-machine systems as their intelligence expands the capabilities of humans in diverse operational environments. Teamwork in the future among humans and MAVs will depend on systems appropriately accounting for operator-specific elements such as workload, situational awareness, and training. Developing and implementing a Human Systems Integration Plan throughout acquisition is part of a total systems approach and will ensure that the human is considered throughout the entire design process.

While specific design choices regarding ground control station interfaces or ruggedization will vary from system to system, one must remember that Human Factors Engineering is comprised of a series of tradeoffs. The individual choices made should support the operational performance objectives set forth for a specific MAV system to accomplish its mission. The relative merits of the issues discussed in this work are driven by how a particular system is intended to be deployed. For example, MAVs intended for urban combat environments will require a different set of design criteria than ones intended for agricultural surveying.

As civilian and military operators continue to appreciate the valuable differences MAVs can make in protecting human life and accomplishing formidable missions, much of the focus moving forward will be on meeting the technical and political challenges of achieving interoperability, enhancing communications, managing system affordability, furthering autonomous behavior, increasing endurance, and integrating into national airspace. MAVs will no doubt continue to be an

increasingly popular solution for warfighters as they operate in dynamically challenging environments, and therefore the means of further integrating MAVs at the platoon level will be a concern. In a time when so much of the media attention surrounding MAVs is focused on advances in technical capability and policy considerations, one must not forget to pay attention to the needs, wants, and desires of human operators within the design space. How well designers implement a human-centered approach to MAVs in the future will largely dictate the platform's success.

Abstract

MAVs (micro air vehicles), with a maximal dimension of 15 cm and nominal flight speeds around 10 m/s, operate in a Reynolds number regime of 10^5 or lower, the same as that of most natural flyers, including insects, bats, and birds. Due to the light weight and low flight speed, the MAV's flight characteristics are substantially affected by environmental factors such as wind gust and demonstrate distinguished features with fixed, rotary, and flapping wings. Like natural flyers, the wing structures of MAVs are often flexible and tend to deform during flight. Consequently, the aero/fluid and structural dynamics of these flyers are closely linked to each other, making the entire flight vehicle difficult to analyze. In this chapter, a prototype bio-inspired flapping MAV with flexible wings is described with a specific focus on the flexible-wing aerodynamics. The flapping-wing MAV has a weight of 2.4–3.0 g and a wingspan of 10–12 cm, which is comparable to hawk moths and hummingbirds. The MAV's flexible-wing aerodynamics is analyzed by combining an *in-house* computational fluid dynamics (CFD) method and wind tunnel experiments (EXP). In addition, fixed-wing and rotary-wing MAVs with elements that enable the miniaturization of an aerial vehicle will be introduced.

55.1 Introduction

A large earthquake occurred in the Tohoku area of Japan on March 11, 2011. A devastating tsunami caused by the earthquake then hit the area, destroying all the power supplies at the nuclear power plant at Fukushima. The plant subsequently lost the ability to cool down the reactor core. The building covering the reactor vessel was destroyed by the explosion of H_2 , and a great amount of radioactive materials were released from the power plant. Various methods have been undertaken to clean up after this accident. Acquiring visual information of the power plant from a high altitude using a small aerial vehicle is instrumental in this regard. The Global Hawk (Northrop Grumman Corporation), an airplane of the Fuji IMVAC Corporation, and the T-Hawk (Honeywell Corporation), a ducted-fan air vehicle, were used for this purpose. A photograph taken by Air Photo Service, Inc. by using the Fuji IMVAC Corporation airplane is shown in Fig. 55.1. The importance of unmanned aerial vehicles was confirmed by the activities of these meter-sized aerial vehicles.

Smaller aerial vehicles, in particular, the micro air vehicle (MAV), have also been studied and developed. MAVs are now the subjects of an active and well-integrated area of research, attracting participation from a wide range of talent. With a maximal dimension of 15 cm and nominal flight speeds of around 10 m/s, MAVs are desired for performing missions such as environmental monitoring, surveillance, and assessment in hostile situations. MAVs normally operate in a Reynolds number regime of 10^4 – 10^5 or lower, the same as that of most natural flyers, including insects, bats, and birds. The prominent feature of the MAVs' aerodynamics, in general, is characterized by a large-scale vortex flow structure and, hence, is highly unsteady

Fig. 55.1 Overview of the nuclear power plant at Fukushima after the earthquake on March 11, 2011 (Courtesy of Air Photo Service, Inc.)

(Shyy et al. 2007). Further, with the flexible wing structures and wing deformation of MAVs, the aero/fluid and structural dynamics of these flyers are closely linked to each other, making the entire flight vehicle difficult to analyze and design. In the past decade, there has been a remarkable increase in the research and development of MAVs, and numerous vehicle concepts, including the fixed wing, rotary wing, and flapping wing, have been proposed (Mueller 2001; Platzer et al. 2008; Stanford et al. 2008; Liu et al. 2010).

AeroVironment, Inc. has developed a very tiny aerial vehicle with flapping wings, the NANO hummingbird. Keennon et al. (2012) at AeroVironment state about the NANO hummingbird as follows: The NANO hummingbird differs from other ornithopters in its ability to control attitude in roll, pitch, and yaw during hover through the actuation of the same flapping wings it uses for propulsion, whereas other hovering ornithopters have used large tail surfaces to deflect the wake of the main wings. By performing flight and control with its wings alone, the NANO hummingbird moves one step closer to nature's flyers, which commonly demonstrate the ability to hover without large tail areas or large tail deflections.

According to online documents about the NANO hummingbird (<http://www.avinc.com/nano>), this flapper can:

1. Demonstrate precision hover flight
2. Demonstrate hover stability in a wind gust flight that requires the aircraft to hover and tolerate a 2-m/s (5 miles per hour) wind gust from the side without drifting downwind more than 1 m

3. Demonstrate a continuous hover endurance of 8 min with no external power source
4. Fly and demonstrate a controlled transition flight from hover to 11 miles per hour fast forward flight and back to hover flight
5. Demonstrate flying from outdoors to indoors and back outdoors through a normal-size doorway
6. Demonstrate flying indoors “heads-down” where the pilot operates the aircraft looking only at a live video image stream from the aircraft, without looking at or hearing the aircraft directly
7. Fly in hover and fast forward flight with a bird-shaped body and bird-shaped wings

The NANO Hummingbird has high flight capabilities, as stated above. When its flight abilities are increased, it will be used to accomplish a true mission. Is this high performance of the NANO Hummingbird caused by the flapping wings? At the present stage, one cannot deny the possibility that a tiny aerial vehicle with a configuration other than an entomopter/ornithopter has high performance flight capabilities. The following flights are required for a tiny aerial vehicle to accomplish a real mission:

1. Flights under a wide range of forward velocities including hovering
2. Flights with high acceleration and angular acceleration
3. Flights that are very robust to wind gusts

Independent of configuration, when an aerial vehicle becomes smaller, it is strongly affected by wind gusts, and the frequencies of some oscillated motions are larger, while the time constants of some converged/diverged motions are smaller. By considering these characteristics of reduced-size aerial vehicles, insect-sized aerial vehicles, which can accomplish the flights stated above, must have the following abilities:

1. Large and quick control force/moment
2. Small variations of aerodynamic force/moment when wind gusts are encountered
3. Sensors and actuators with short time-delay and high accuracy

In this chapter, recent studies and developments of the tiny entomopter/ornithopter and an aerial vehicle with other configurations that are thought to be suitable for downsizing will be introduced.

55.2 Flapping Wing

An airplane, which flies with a fixed wing, and a helicopter, which flies with a rotary wing, are the primary human-passenger aircrafts. Flying living creatures, such as birds and insects, fly with flapping wings. What type of aircraft is suitable for an insect-sized airplane? One answer might be an ornithopter, which is a vehicle with flapping wings. This is because birds and insects with very high flight capabilities have flapping wings. Sigthorsson et al. (2012) showed by their analysis that the flapping-wing vehicle is less sensitive to velocity perturbations in all aerodynamic forces and moments than the rotorcraft, except for the forward/backward

direction force. The following are the presumed advantages over an airplane with a propeller(s):

1. An ornithopter does not require a thruster because flapping wings can generate thrust as well as lift. This contributes to reducing the total weight of the vehicle.
2. A propeller generates pitching and yawing moments when it encounters side and vertical winds, respectively (Ribner 1943). This disturbs the attitude of an airplane with propellers. This does not happen when an ornithopter encounters side and vertical wind gusts.

Moreover, Iida pointed out at 2011 Annual Meeting, Japan Society of Fluid Mechanics that the lift generated by an ornithopter is independent of turbulence. On the other hand, lift on a fixed wing at a small angle of attack of 6 deg is decreased as turbulence is increased. Though more research is required, this result raises the possibility that an ornithopter is more robust to turbulence than a fixed-wing airplane.

All of the successful flapping-wing MAVs developed up to this point have flexible and light wings such as those observed in natural biological flyers (Wootton 1981), which indicates that wing flexibility is likely to have a significant influence on the resulting aerodynamics, as well as the flight stability (Young et al. 2009; Mountcastle and Daniel 2009; Shyy et al. 2010; Liu et al. 2010). In a sense, flapping flexible-wing aerodynamics is of great importance not only in uncovering the novel mechanisms of insect and bird flight but also in designing efficient flapping flight vehicles. Recently, a biologically inspired flapping-wing MAV is developed, which has four flexible wings. In this prototype MAV, the clap and fling mechanism is applied and achieved by a prototype crank system, not only because such a mechanism is observed in insect flight and thought to be capable of enhancing the aerodynamic force generation (Weis-Fogh 1973) but also because such physical interaction can affect the in-flight deformation of flexible flapping wings and, hence, aerodynamic performance.

55.2.1 A Hummingbird-Sized Flapping-Wing MAV

A prototype flapping MAV developed at Chiba University (Nakata and Liu 2011; Nakata et al. 2011) is illustrated in Fig. 55.2a. The wingspan is designed to be around 12 cm – the size observed in hawk moths and hummingbirds. The wing has a semielliptic planform that is made of a polyethylene film with a thickness of 0.03 mm and a carbon rod with a diameter of 0.3 mm at the leading edge. The wing length is 60 mm, and the wing chord length is 30 mm at the wing base. The mean chord length is calculated as 23.6 mm. Two pairs of wings are attached to a crank system that is designed to achieve the clap and fling mechanism (Weis-Fogh 1973). As illustrated in Fig. 55.2b, the wings touch thrice in a wing beat on the top by upper wings and on the side by upper and lower wings. The gearbox is fabricated by cutting the acrylonitrile-butadiene-styrene (ABS) resin so as to ensure a nice match with the motor (MK04S-10, DIDEL), the gears, and the wing hinges. A 12-tooth pinion gear made from polyacetal with a module of 0.3 is attached to the motor.

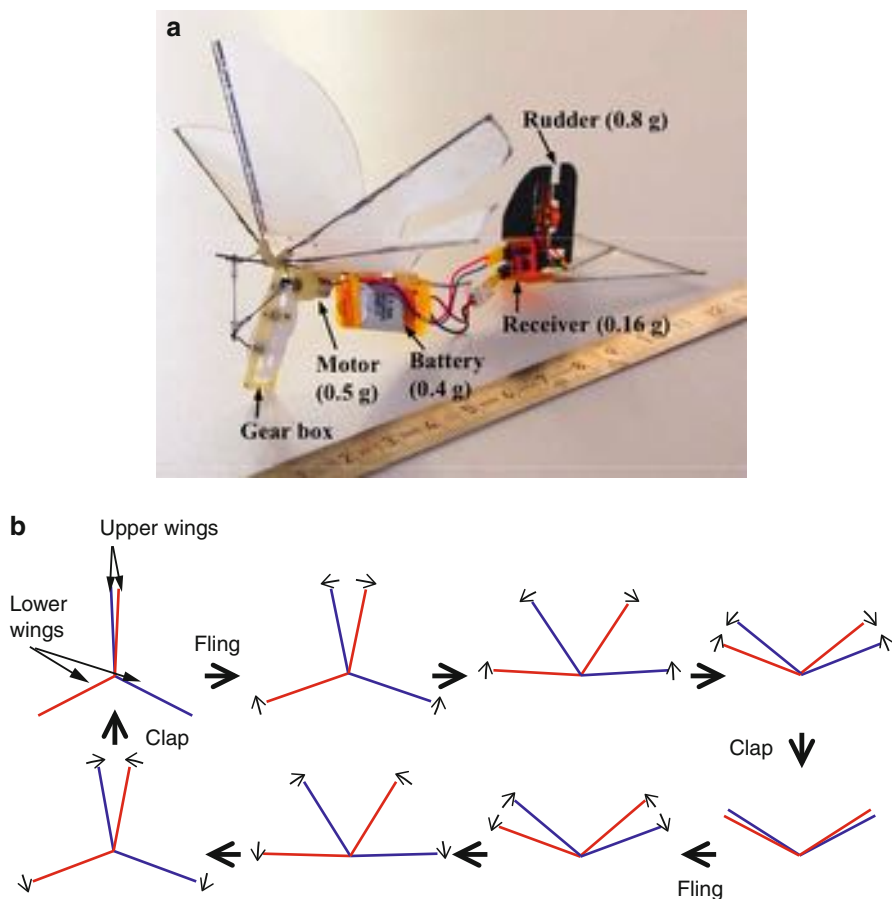

Fig. 55.2 (a) A prototype flapping micro air vehicle (MAV): a bio-inspired MAV. (b) Schematic of wing kinematics in an X-type wing MAV (viewed from the leading edge)

With a speed-reduction ratio of 60/12 teeth of the idler gear, the crank is mounted to link and actuate the two pairs of wings on the 60-tooth final gear. The gearbox system, the crank, and the wings are connected by a carbon rod with a diameter of 0.5 mm with the tail, the rudder, the receiver, and the remote control. The rudder is controlled by a magnetic actuator (hinge act, Plantraco) that moves laterally, weighs 0.23 g, and can provide sufficient control power. The remote control with infrared ray offers two channels to control both the motor frequency and the rudder angle. A rechargeable lithium polymer battery (FR30SC, Fullriver) is utilized as the power source. With all the parts mounted together, their flapping MAV weighs less than 3 g in toto and is able to fly with a time duration of up to 6 min, a maximum height over 10 m, and a region of 20×20 m.

55.2.2 The MAV's Flexible-Wing Kinematics

The flexible-wing aerodynamics is measured with a high-speed camera filming system as depicted in Fig. 55.3a–d by tracking the body-wing motions and deformations during tethered flapping flights. Three high-speed cameras (Miro, Vision Research Ltd.) with an image of 800×600 pixels at a frequency of 1,000 Hz are synchronized and operated for 2 s. Given that the MAV's flapping frequency normally varies over a range of 20–35 Hz, the recorded image sequences are able to provide sufficient temporal resolution for the current flexible-wing kinematics. Calibration is done in a global three-dimensional system by a right-angled portable calibration frame, as shown in Fig. 55.3b, c. The markers (the white dots) are arranged in an array with an interval of approximately 100 mm, which is sufficient to reasonably resolve the flexible-wing kinematics during a complete wing beat.

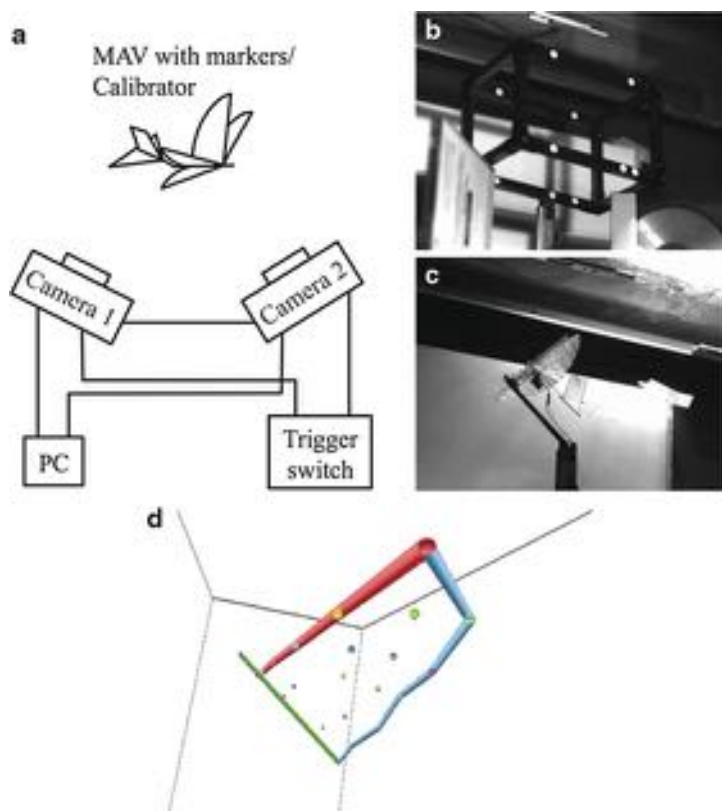

Fig. 55.3 (a) High-speed camera filming system for wing kinematics measurement. (b) A right-angled portable calibration frame. (c) An image of the flapping MAV captured by a high-speed camera. (d) Reconstructed coordinates on the wing surface based on a sequence of images in a complete beat cycle

The recorded image sequences are then downloaded to a computer, and the three-dimensional coordinates of these marked points are reconstructed utilizing commercial software, DippMotion (Ditect) (Fig. 55.3d).

A realistic kinematic model of the MAV's flexible wing is constructed by interpolating the reconstructed coordinates of the markers on the flapping wings. The displacements $\mathbf{u}(t, x, y)$ at some point of the wing (x, y) (Fig. 55.4d) are interpolated by using a function of Fourier series, such as

$$\mathbf{u}(t, x, y) = \sum_{l=0}^{n_x} \sum_{m=0}^{n_y} \sum_{n=0}^n (\mathbf{a}(l, m, n) x^l y^m \cos(n\omega t) + \mathbf{b}(l, m, n) x^l y^m \sin(n\omega t)), \quad (55.1)$$

where terms \mathbf{a} and \mathbf{b} are derived by the least square method. A realistic morphological model of the MAV's wing for computational fluid dynamics (CFD) analysis is constructed by tracing the outline of the wing planform. A uniform thickness is defined, but with elliptic smoothing at the leading and trailing edge, as well as at the tip. Figure 55.4b illustrates the computational geometric models and grid systems of the MAV. The CFD analysis is performed by introducing a symmetric plane as depicted in Fig. 55.4b under the assumption that the left and right wings move and deform symmetrically.

Figure 55.5b shows the time courses of both the upper and lower wings at a wing cross section of $0.7 R$ from the wing base (Fig. 55.5a), in which the cross sections at the stroke reversal are shown by a dotted line. Note that those markers where the coordinates cannot be reconstructed due to the overlapping of upper and lower wings are excluded (Fig. 55.5b). Since the crank system can only generate the one-axial flapping motion, the wing rotation or the feathering motion is apparently induced passively due to the wing flexibility. The angles of attacks of both the upper and lower wings are, however, observed to somehow be in good timing, contributing to the lift force production during each half stroke. The upper wing is nearly vertical to the horizontal axis at both stroke reversals, which implies a “symmetric” rotational phase of the upper wing (Dickinson et al. 1999), and hence is likely a result of the clap and fling at each stroke reversal. The lower wing keeps the attitude throughout the half stroke while showing some “phase delay” at the stroke reversal, which may lead to lowering the aerodynamic performance of flapping wings.

55.2.3 The MAV's Flexible-Wing Aerodynamics

55.2.3.1 CFD Modeling of Flexible Flapping Wing

Evaluation of the aerodynamic performance of the bio-inspired flapping MAV is conducted by using an insect dynamic flight simulator (Liu 2009; Liu et al. 2010; Nakata and Liu 2011) that is designed to integrate the modeling of realistic wing-body morphology, realistic flapping wing and body kinematics, and unsteady aerodynamics in biological flight. The CFD study is performed under the assumption of

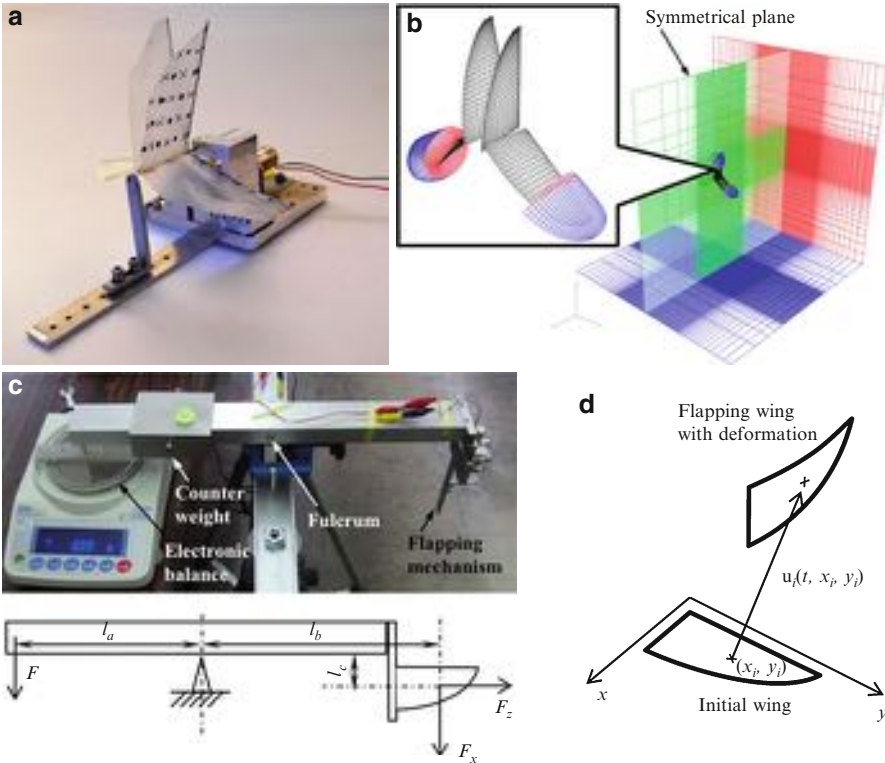

Fig. 55.4 (a) A mechanical flapping-wing MAV model. (b) A computational fluid dynamic model of MAV wings and a multiblock grid system (single wing grid: $33 \times 37 \times 19$, background grid: $89 \times 129 \times 81$). (c) Force measurement system for the mechanical flapping-wing MAV model. (d) Definition of displacement \mathbf{u} at point (x_i, y_i) on the wing surface at time t

a hovering flight condition. Given the mean chord length c_m as the reference length L_{ref} and the mean wing tip velocity in hovering flight as the reference velocity U_{ref} , which is proportional to $U_{\text{ref}} = \omega R$, where R is the wing length and ω is the mean angular velocity of the wing ($\omega = 2\Phi f$, where Φ is the wing beat amplitude and f is the flapping frequency), the Reynolds number in hovering flight can be reformed as

$$\text{Re} = \frac{U_{\text{ref}} L_{\text{ref}}}{\nu} = \frac{2\Phi f R c_m}{\nu} = \frac{\Phi f R^2}{\nu} \left(\frac{4}{\text{AR}} \right), \quad (55.2)$$

where the aspect ratio AR is in the form of $\text{AR} = (2R)^2/S$ with a wing area of $S = 2Rc_m$. Note that the Reynolds number here is proportional to the wing beat amplitude, Φ , the flapping frequency, f , and a square of the wing length, R^2 , but proportional inversely to the aspect ratio of the wing, AR.

Fig. 55.5 (a) Definition of angle position ϕ . (b) Time courses of both *upper* and *lower wings* at a wing cross section of $0.7 R$ from the wing base

The reduced frequency that normally characterizes rotational versus translational speeds is defined in the case of hovering flights as

$$k = \frac{\pi f L_{\text{ref}}}{U_{\text{ref}}} = \frac{\pi c_m}{2\Phi R} = \frac{\pi}{\Phi \text{AR}}. \tag{55.3}$$

Note that the reduced frequency k is proportional inversely to the beat amplitude Φ and the aspect ratio AR of the wing. According to the measured data of the MAV’s mechanical model ($c_m = 23.6 \text{ mm}$, $R = 60 \text{ mm}$, $F = 1 \text{ rad}$, $f = 18.5 \text{ s}^{-1}$, $n = 1.5 \times 10^{-5} \text{ m}^2/\text{s}$), Re and k are calculated to be about 3,400 and 0.59, respectively.

The CFD modeling of unsteady flows around the MAV’s flexible wings undergoing flapping is performed for a single flexible-wing model in which realistic geometric and kinematic models are utilized, as described in the preceding sections. The CFD-based results show that a leading-edge vortex (LEV) and, hence, a strong negative pressure region are generated on the upper and lower wings during both half strokes (Fig. 55.6a). As observed in insect flapping flight (Ellington et al. 1996),

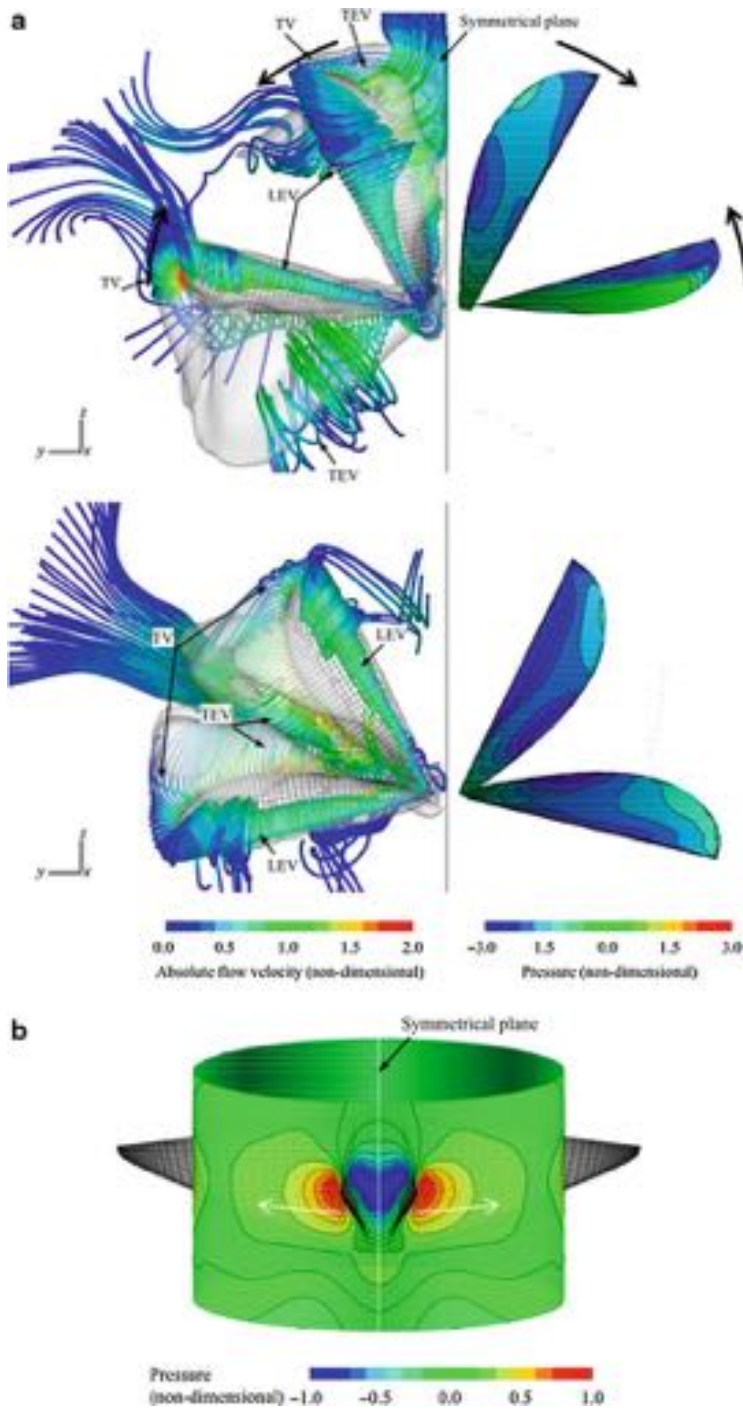

Fig. 55.6 (continued)

Fig. 55.6 (a) Instantaneous streamlines, iso-vorticity surface, and pressure contours on the upper surface of flapping wings at each half stroke. (b) Pressure contours on a virtual cylindrical surface at $2.0 c_m$ from the wing base. (c) Wake topologies at the end of each half stroke. Velocity vectors and contours are visualized at a virtual cylindrical surface at $2.0 c_m$ from the wing base

this LEV apparently plays a crucial role in the lift and/or thrust force production in the MAV flight. The vortex rings that are formed from the LEV, the tip vortex (TV), and the trailing-edge vortex (TEV) are also observed, showing a similar pattern to those of insect flight (Liu and Aono 2009). Obviously, strong negative pressure regions are detected between the upper right and left wings, as illustrated in Fig. 55.6b, which are likely induced by the clap and fling mechanism.

Figure 55.6c illustrates the wake topology on a virtual cylindrical surface at the end of each half stroke. An intense downwash is generated behind the path of the wings identical to the center of the vortex rings (Liu 2009). The downwash disks are connected by the clap and fling with a pitching up motion, resulting in a pronounced downwash in the far wake below. In contrast, it is interesting to see that the downwash generated by the lower wings without the clap and fling is rather weak and there is almost no high-speed zone visible downward in the far wake.

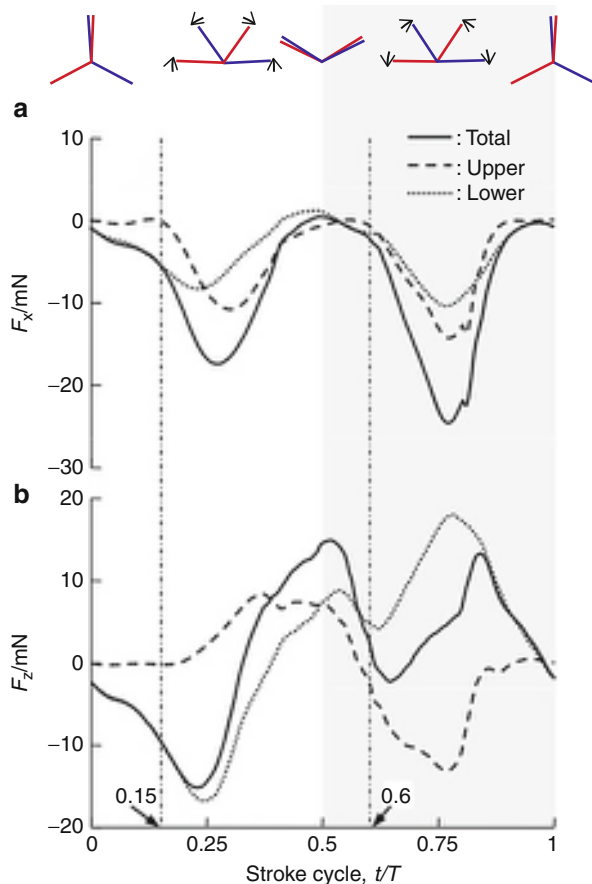

Figure 55.7 shows the time courses of aerodynamic forces generated by the upper and lower wings in a wing beat. Clearly, the upper wing generates very few aerodynamic forces until $0.15 T$ after the clap and fling (the vertical dashed line in Fig. 55.7), while the aerodynamic forces generated by the lower wing show a stable increase after the stroke reversal. However, the horizontal force F_x by the upper wing shows a subsequent rapid rise having a higher peak than the lower wing. Then, force F_x continues to decrease to a low level until $0.6 T$ after the next stroke reversal (the vertical dashed line in Fig. 55.7), while the upper wing shows a larger peak again at the half stroke. Since the present flapping-wing mechanism generates large forces at each half stroke, one peak in the total F_x is observed at each half stroke.

Furthermore, the mean aerodynamic force is calculated to be 23.3 mN, which is in good agreement with the measurement of a value of 26.46 mN acting on the electronic balance. The mean force components of F_x and F_z generated by the upper wing are -4.2 and 0.2 mN and those by the lower wing are -3.8 and 2.0 mN, respectively. The mean aerodynamic power consumed by the upper and lower wings is estimated to be 14.2 and 14 mW, respectively.

55.2.3.2 Wind Tunnel Experiments: Lift, Drag, and Flexible-Wing Kinematics

The aerodynamic performance of the present prototype MAV (Fig. 55.3b, c) and a mechanical flapping-wing MAV model (Fig. 55.4a, c) that can measure forces is evaluated by means of wind tunnel experiments. The forces acting upon the MAV undergoing the tethered flight are measured by utilizing the load cells. Figure 55.8 shows the mean lift and drag forces plotted against the body inclination angle of q_b , which varies from 0 to 70 deg. The lift force is seen to increase with increasing the body angle, the flapping frequency (with two frequencies of 10 and 20 Hz), and the wind velocity (when q_b is greater than 40 deg), which reaches a value of 25 mN at a flapping frequency of 20 Hz and a wind velocity of 1.6 m/s, very close to the MAV's weight. The drag force also shows an increase with increasing the body angle, but a negative drag force, i.e., the thrust force, is observed when the body angle is less than 50 deg. Note that the thrust force is generated merely in the case of no wind velocity and turns to the drag force at the larger wind velocity of 3.0 m/s.

Fig. 55.7 Time courses of force components (a) F_x and (b) F_z on the right wings of the four-winged MAV

One key reason that the present MAV utilizes the X-type wing (Fig. 55.2) with four wings is because it can generate more lift and/or thrust forces than a two-winged MAV. Comparison of the lift forces between the two MAV types indicates that the present four-winged MAV does generate more lift force at almost twice the lift forces of the two-winged MAV when q_b is greater than 40 deg. However, two times the lift force by the two-winged MAV with the thin Mylar wing shows a larger value than that of the present four-winged MAV.

55.2.3.3 The Clap and Fling Mechanism in Four-Winged MAVs

The flapping-wing mechanism utilizing an X-type wing with four wings is employed for the present four-winged MAV, which is inspired by the smart two-winged natural flyer, the hummingbird, but obviously has crucial differences. Though there is a great variety of biological flyers, such as insects, bats, and birds, most fly with one pair of wings. The present flapping-wing mechanism is quite unique

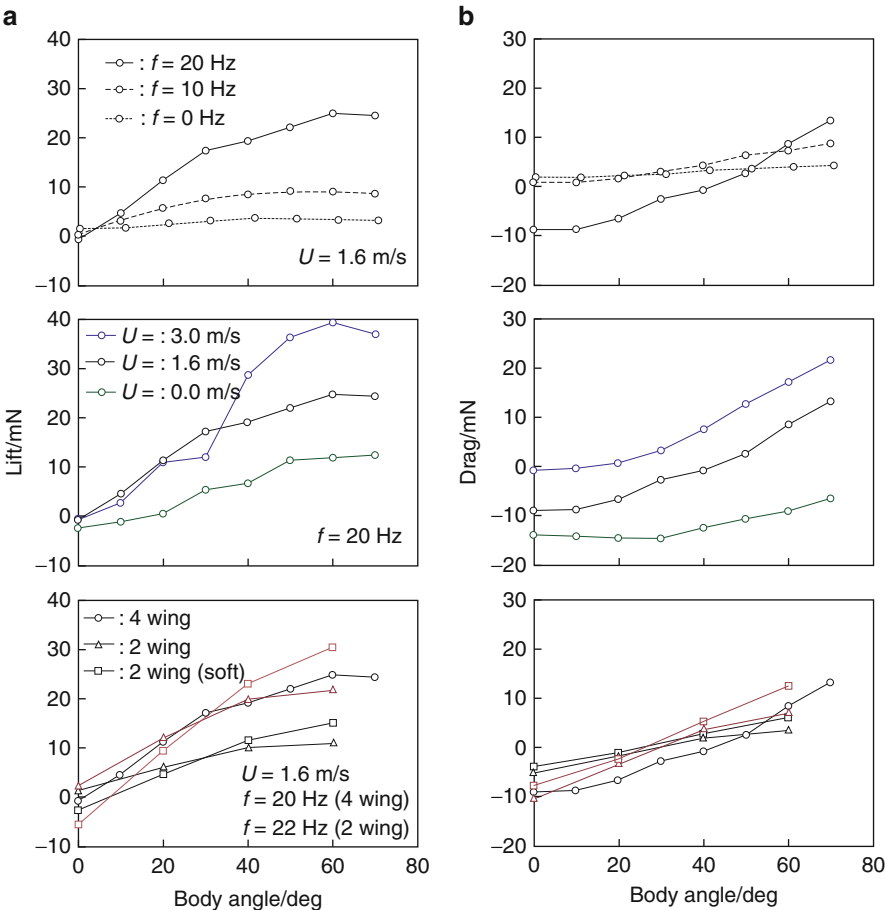

Fig. 55.8 (a) Lift and (b) drag forces plotted against body angles for four-winged and two-winged MAVs. The red line represents two times of lift and drag forces generated by the two-winged MAV

because of the multiple physical interactions in a wing beat cycle. Here, it is found that the four-winged MAV is able to generate two times greater lift force than that of a two-winged MAV at body angles larger than 40 deg where the MAV actually flies (Fig. 55.8). This implies that the present flapping-wing mechanism very likely utilizes the clap and fling mechanism effectively and hence enhances force production more than the two-winged flapping mechanism. On the other hand, it is seen that a two-winged MAV with a softer Mylar wing generates even more lift force than the four-winged MAV in the case of body angles larger than 30 deg (Fig. 55.8), which further points to the importance of the choice of an appropriate wing structure in the MAV design (Heathcote and Gursul 2007; Heathcote et al. 2008).

55.3 Rotary Wing

A lot of meter-sized rotary-wing unmanned aerial vehicles (UAVs) are helicopters with attitudes controlled by cyclic pitch. The following two types of rotary-wing UAVs without cyclic pitch control seem to be successful.

55.3.1 Ducted-Fan UAV

A ducted-fan MAV is a vehicle having a lift-augmented ducted fan driven by a reciprocating engine or an electrical motor at the center of the vehicle and aerodynamic surfaces (vanes) close to the outlet of the duct for flight control. This entails less danger to the operator and has an acoustic signature rather than a rotary-wing-type MAV because of the shrouded rotor.

In 2001, the Defense Advanced Research Projects Agency (DARPA) of the United States Department of Defense started the Organic Air Vehicle (OAV) program following the DARPA MAV program (1996–2000) (DARPA 2003). The OAV program is one of the technologies supporting the DARPA/ARMY Future Combat Systems (FCS) program. The smallest category of the FCS is a backpack-sized vertical takeoff and landing (VTOL) MAV for platoon-level operations (FCS class I). One of the contractors of the OAV program is Honeywell, which developed the “T-Hawk” (originally called the “Honeywell MAV”) ducted-fan MAV (Daly 2011). It was selected for the FCS I platform vehicle, and further development included a high performance heavy fuel engine. The U.S. Army and also the U.S. Navy awarded T-Hawk contracts to Honeywell for deployment to Iraq. The U.S. military used the T-Hawk in search missions for roadside bombs in Iraq. The T-Hawk was also used to conduct surveillance of the damaged Fukushima Dai-ichi nuclear power station in Japan in 2011.

Ducted-fan vehicles are unique in many respects: They can hover but are unlike helicopters, and they can dash at high speeds but are unlike airplanes. Much of the design intuition within the aerospace community is no longer applicable when venturing into the realm of VTOL ducted-fan vehicle design (Ohanian et al. 2010). Therefore, a wide variety of research and development has been conducted since the year 2000. Even just focusing on “micro” size, there is considerable research and development of ducted-fan MAVs all over the world (Table 55.1).

Advanced methods for improving the aerodynamic characteristics of ducted fans are being investigated. Barrett (2004) applied piezoceramic actuator technology that enables higher bandwidth control than the conventional servomotor actuator for XQ-138 ducted-fan MAVs. Bilgen et al. (2010) applied a variable camber airfoil via smart materials for the control vanes in wind tunnel tests. Ohanian et al. (2011) applied synthetic jet actuators to the duct lip and the trailing edge to control the force and moment of the duct. Colman et al. (2011) experimentally investigated a cyclic and collective pitch control of a proprotor shrouded with an asymmetric duct.

Table 55.1 Developed ducted-fan MAVs

| MAV name | Duct dia. (in.) | Gross weight (g) |
|--------------------------------|-----------------|------------------|
| XQ-138-6'' (Barrett 2004) | 6 | <378 |
| iMAV (Ohanian et al. 2010) | 6 | 567 |
| SEMi (Kubo et al. 2009) | 6 | 600 |
| RMIT Univ. (Zhao and Bil 2009) | 5.5 | – |
| XQ-138-4'' (Barrett 2004) | 4 | <115 |

Fig. 55.9 MD4-200 by Microdrones (Courtesy of Microdrones GmbH)

55.3.2 Quadro-Rotor UAV

A quadro-rotor-type UAV has been constructed by companies such as Microdrones GmbH(<http://www.microdrones.com>), Ascending Technologies GmbH(<http://www.ascotec.de>), and Dragonfly Innovations Inc. (<http://www.rctoys.com>). The MD4-200 by Microdrones weighs about 900 g with a 37-cm rotor diameter. The X-3D BL by Ascending Technologies weighs about 740 g with a 37-cm rotor diameter. Dragonfly Innovations Inc. developed a UAV with three coaxial rotors, the Dragonfly VI as well as the Dragonfly IV and V, which are quadro-rotor-type UAVs.

Figure 55.9 shows the MD4-200 by Microdrones as one example. This rotorcraft does not have a swashplate and does not need any blade pitch control. The two pairs of rotors (1,3) and (2,4) rotate in opposite directions. The gyroscopic effects and aerodynamic torques tend to cancel in trimmed flight. Increasing or decreasing the four rotors' speed generates vertical motion. Changing the 1 and 3 rotors' speed conversely creates roll motion with lateral motion. Similarly, changing the 2 and 4 rotors' speed conversely causes pitch motion with longitudinal motion. Yaw motion is established by increasing (decreasing) the 2 and 4 rotors' speed and decreasing (increasing) the 1 and 3 rotors' speed while keeping the thrust constant. As the variation of rotational speeds of the rotors is increased, the control moments can be increased. Furthermore, the control moment can be increased by increasing the distance of the motors from the center of the vehicle. The control moment per the

moment of inertia increases with the increase of the distance of motors from the center of the vehicle. This is because the greatest weight is located at the center of a quadro-rotor-type UAV. Therefore, angular accelerations can be increased by increasing the distance of the motors from the center of the vehicle.

55.4 Tail-Sitter MAV

A tail-sitter is an aircraft that takes off and lands on its tail section, with the fuselage pointing upward. In the 1950s, several manned tail-sitter fighter airplanes were developed, and prototypes were constructed in the USA. However, these projects were abandoned because of significant control difficulty during the landing phase for a human pilot. However, tail-sitters have the advantage of eliminating the need for variable mechanisms for making the transition between hovering and cruising modes when compared to tilt-rotor and tilt-wing aircraft; therefore, this configuration is particularly suitable for small UAVs and MAVs that have severe weight constraints because of their small size.

Certain ducted-fan vehicles can be also categorized as “tail-sitter” vehicles because they are designed not only for hovering flight but also for forward high-speed dash performance. The ducted-fan MAV XQ-138 can be considered as a ducted-fan vehicle but is defined as a coleopter in the original paper (Barrett 2004). A coleopter is an aircraft having a fuselage surrounded by an annular wing, which is usually associated with a tail-sitter. Furthermore, several ducted-fan vehicles have small wings to augment cruising efficiency (Zhao and Bil 2009). Considering this, there are no explicit borders between the designs of the ducted-fan and tail-sitter MAV.

For a “fixed-wing” tail-sitter aircraft design, transitional flight – middle air speed flight between zero speed hover to high-speed dash flight – is one of the biggest challenges. Especially for small sized vehicles, the effect of wind during the takeoff and landing phase is critical. For zero wind conditions, tail-sitter vehicles hover with the fuselage pointing in the nearly vertical direction; however, in nonzero wind conditions, the vehicles must compensate the wind drag by tilting the thrust, i.e., the pitch angle of the vehicle. Therefore, the angle of attack will be significantly large under these conditions even when using propeller slipstream effects. Thus, small tail-sitter vehicles must be designed with stall constraint relaxation, such as propeller slipstream effects and high lift devices on the main wing like a leading-edge slat (Kubo and Suzuki 2008).

On the other hand, for the MAV tail-sitter design, the low Reynolds number and aspect ratio wing with propeller slipstream makes the effective stall angle of attack (AoA) significantly larger, which makes transitional flight easier. One of the examples of the fixed-wing VTOL MAVs is the “Hoverfly,” which was developed in the DARPA MAV program by AeroVironment Inc. This is a battery-powered flying wing with coaxial proprotors. Another example is the Mini-Vertigo MAV of the University of Arizona (Chu et al. 2009).

Fig. 55.10 Spherical air vehicle developed by Sato (http://www.mod.go.jp/trdi/research/youshi2010_oral1.pdf)

55.4.1 Sato's Spherical Air Vehicle

Recently, Sato developed an aerial vehicle as shown in Fig. 55.10 (Sato 2010). This vehicle is composed of a tail-sitter airplane and a spherical structure around the tail-sitter airplane. The diameter of the spherical structure is 42 cm, and the total weight is about 350 g. An ordinary tail-sitter airplane is at risk of being toppled by a side wind when it is standing. However, the present vehicle does not have this potential problem. It can roll on the ground, take off vertically, land at any attitude, and make hovering and level flights. Flight speed is between 0 and about 60 km/h, and flight duration at hover is about 8 min.

This airplane has the following characteristics:

1. The center of gravity is aft, and the airplane can stand on the ground stably.
2. The rotational direction of the propeller can be varied, and the direction and magnitude of thrust by the propeller can be controlled.
3. The four control surfaces arranged crosswise are above the center of gravity, and the other four control surfaces arranged crosswise are below the center of gravity. These control surfaces generate moments about the X, Y, and Z axes. These surfaces can generate control moment because the surfaces are in the wake of the propeller. The angle between the two sets of four control surfaces is 45 deg

about the X axis. The aerodynamic interaction between these sets of four control surfaces is reduced.

4. The aerodynamic center of the airplane is below the center of gravity. This provides stability for a level flight. The ducted wing on the spherical structure moves the aerodynamic center more aft.
5. When this airplane takes off and lands, the two control surfaces above the center of gravity act as an elevator. Then, the direction of deflection of the elevator for pitching the airplane up/down remains the same during flight and while rolling on the ground. This provides ease in controlling the vehicle. Note that the airplane rolls on the ground in the direction of the moment about the point where the airplane touches the ground, and the airplane pitches in the direction of the moment about the center of gravity of the airplane.
6. This vehicle can cling to a vertical wall.

55.5 Flow Sensor on the Wing Surface Mimicking Hairs on an Insect's Body

The flight performance of a small airplane can be expected to be improved by using the flow data around the airplane (Tokutake et al. 2011). However, conventional air data systems, such as the pitot tube and the angle of attack sensor, are too heavy to be installed on small airplanes and are not sensitive to their small-flow condition changes. For these reasons, a tiny flow sensor was developed to control the attitude of small airplanes. The flow velocities on the wing surface are measured by the sensor system, which utilizes microelectromechanical systems (MEMS) technology. This sensor system is similar to hairs on an insect. This flight control system was designed to attain stable flight at a high angle of attack with maximum lift coefficient using flow sensor output.

The MEMS flow sensor D6F-W04A1 manufactured by Omron Corporation, which detects the temperature distribution of a heated sensor head, has been improved and adopted. The MEMS flow sensor on the market was disassembled,

Fig. 55.11 Flow sensor on the wing surface

Fig. 55.12 Flow sensor output

Fig. 55.13 Sensor assignments

revealing the sensor head. The sensor head is a 4×4 mm square, and it was used with a half tube cover having a length of 10 mm and a diameter of 5 mm for protection (Fig. 55.11). This MEMS flow sensor can measure the strength of the surface velocity and can detect inverse flow. The weight of the sensor is 1.3 g. Figure 55.12 shows the relationship between the flow velocity and the sensor output. Because the flow conditions at the maximum lift coefficient are of interest in these experiments, the sensor output at the maximum lift coefficient was investigated. Since these sensors are light, they can be mounted on the flight airplane model.

Fig. 55.14 Lift coefficient

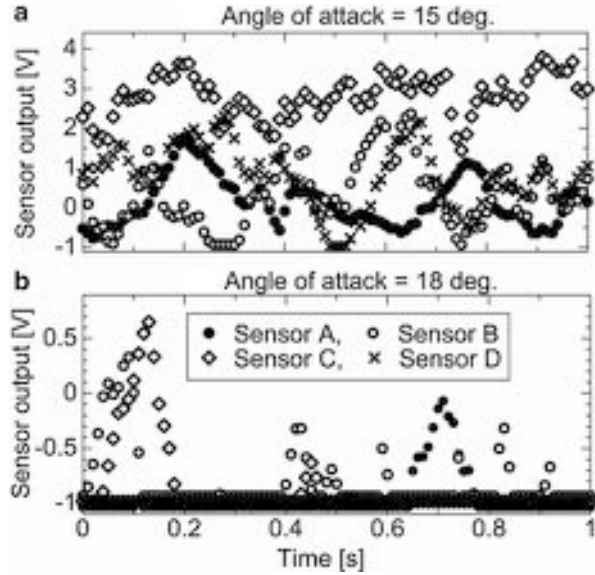

Fig. 55.15 Flow sensor output – angle of attack

A tailless small airplane was studied. MEMS flow sensors were located on the upper wing surface at the quarter span of the right wing while being aligned chordwise with the same distance in-between (Fig. 55.13).

Several static and dynamic wind tunnel tests were performed to investigate the aerodynamic characteristics. Figure 55.14 shows the relations between the angle of attack and the lift coefficients of this small airplane, which reach a maximum value around the angle of attack of 18°, and Fig. 55.15 indicates the flow sensor outputs subject to the angle of attack. Figure 55.16 shows the MEMS flow sensor output for 1 s at a static AOA of 15° and 18°. For these cases, the flow on the entire wing surface at an AOA of 18° is disturbed. At an AOA of 15°, the MEMS flow sensors detect forward flow velocity. The control requirement is then defined as maintaining the output of MEMS flow sensor C as 0. If this requirement is satisfied

Fig. 55.16 Flow sensor output at steady angle of attack

constantly, the flow condition resembles the desired one. As a result, the airplane has a maximum lift coefficient. The purpose of the controller design is to maintain the high lift coefficients. Therefore, the stabilizing controller is designed to maintain the output of flow sensor C at zero under disturbance and model uncertainties.

Flow responses around the wing are determined by airplane attitude. The dynamics between attitude input and flow sensor output are identified via dynamic wind tunnel testing. The pitch angle of the airplane was varied dynamically, and the pitch angle and the sensor outputs were measured. From the experimental results, the relations between the angle of attack and the sensor outputs were identified as a transfer function. The transfer function from the angle of attack to the output of sensor C is as follows:

$$G_a(s) = \frac{-0.02177s^3 - 8.685s^2 - 711.3s - 4.946 \times 10^{-4}}{s^3 + 229.2s^2 + 1.456 \times 10^{-4}s + 1.382 \times 10^{-5}}.$$

From this dynamic model of flow sensor output and longitudinal airplane dynamics, a generalized plant was formulated. The linearized longitudinal dynamics around a trim condition AOA of 18° and forward velocity of 6.2 m/s is as follows:

$$\begin{aligned}\dot{x}_L &= A_L x_L + B_{L1} w_L + B_{L2} \delta \\ x_L &= [u \ \alpha \ q \ \theta]^T\end{aligned}$$

$$A_L = \begin{bmatrix} -2.31 & -5.53 & 0 & -9.8 \\ 0.06 & -5.29 & 0.94 & 0 \\ 6.93 & -28.84 & -0.71 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}$$

$$B_{L1} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad B_{L2} = \begin{bmatrix} -2.69 \\ -2.35 \\ -27.80 \\ 0 \end{bmatrix}.$$

Here, u (m/s) is the forward velocity, α (rad) is the angle of attack, q (rad/s) is the pitch rate, θ (rad) is the pitch angle, and δ (rad) is the elevon deflection angle. These values are perturbed around the trim condition. W_L is an aerodynamic disturbance that accounts for the flow condition change and sensor noise. The values of matrices A_L and B_{L2} are ascertained from the static wind tunnel experiment. The actuator dynamics are formulated as a first-order lag with a time constant of 0.1 s. The airplane dynamics, actuator dynamics, and sensor output dynamics are combined. The H_∞ controller is designed for the developed dynamics so that the pitch rate responses, output of flow sensor C, and elevon deflection angle are restricted under gust input and model uncertainties.

The obtained controller was discretized and installed onto a microcomputer, and flight testing was performed. Figure 55.17 shows the constructed flight model. The flow sensors are installed at the same position as in Fig. 55.13. The airplane was flown at the trimmed condition, and the designed controller was engaged. Figure 55.18 shows the recorded flight data. From these data, the airplane is clearly stabilized, and the output of flow sensor C is maintained around zero. The sensor output near stall of the steady wind tunnel test oscillates (Fig. 55.16). Therefore, it can be said that the output of sensor C in this flight experiment was well stabilized.

Fig. 55.17 Flight model

Fig. 55.18 Flight data

55.6 Effects of Flexibility and Corrugation on Wing Performance

At a low Reynolds number (less than 10^5), a thin wing has a large lift-drag ratio (Kunz and Kroo 2001). Corrugation can make a thin wing more rigid (Rees 1975; Sunada et al. 1998). Thus, a corrugated wing can be thin, and its aerodynamic characteristics can be higher accordingly. Furthermore, Hu and Tamai (2008) pointed out that corrugation prevents large-scale flow separation and improves the flight agility and maneuverability of MAVs at high angles of attack. Figure 55.19 shows the flows around a dragonfly forewing model in a steady flow (Obata and Sinohara 2009) at a Reynolds number of 7,000 and an angle of attack of 5 deg, where the exposure time in Fig. 55.19a and b is 0.02 and 5 s, respectively. In the former picture, unsteady vortices from the airfoil can be observed; in the latter picture, a time-averaged flow pattern around the airfoil can be observed. They also

Fig. 55.19 Flow around a corrugated wing (Obata and Sinohara 2009). (a) Exposure time = 0.02 s. (b) Exposure time = 5 s

pointed out that the flow around the corrugated airfoil with acceleration is similar with that without acceleration. This implies that corrugation can suppress the effect of disturbance for airfoil characteristics, and the corrugated wing is capable to enhance the stability of a small aerial vehicle. Till now, the fixed corrugated wing is the main subject in most studies of aerial vehicles. With respect to a corrugated wing undergoing flapping motion, Meng et al. (2011) studied numerically the aerodynamic effects of corrugation by using several model insect wings, which mimic insect hovering. The results show that the aerodynamic performance of the corrugated wing model is very close to that of the flat-plate wing model. In their computational models, the corrugated wing model performs feathering motion but is rigid without wing deformation during flapping motions. Since the wing corrugation normally shows a strong relationship with wing flexibility as observed in nature, more studies are needed associated with effects of the wing corrugation on aerodynamic performance of flapping wings.

Recently, an important subject about flapping wings is the effect of wing flexibility on the aerodynamic performance of flapping wings. The wing flexibility normally leads to passive wing deformation, which may enhance aerodynamic performance, even in cases with no active control and/or with no extra power consumption. Shyy et al. (2010) gave a review on recent studies associated with the subject about a flapping wing and classified it into three categories: “chordwise-flexible-wing structure,” “spanwise-flexible-wing structure,” and “combined chordwise- and spanwise-flexible-wing structures.” Among these studies, Ho et al. (2003) compared the aerodynamic performance of a cicada wing, which is rigid in spanwise, with a flexible titanium alloy wing but without leading-edge support. They pointed out that stiffness distribution is an important factor for vortex interaction and thrust production. High stiffness is required at the outboard region

of the wing to enhance lift generation, whereas wing flexibility is required at the inward region to enhance thrust.

Heathcote and his colleagues made some experiments about a flexible flapping wing. Heathcote et al. (2004) used a flexible airfoil with plunging motion at 0 freestream velocity. They concluded in two-fold: (1) there is an optimum airfoil stiffness for a given plunge frequency and amplitude, and (2) the thrust/power ratio is greater for the flexible airfoils than for the rigid airfoil. Heathcote and Gursul (2007) used a flexible airfoil with plunging motion at zero and non-zero freestream velocity. They found that stronger trailing-edge vortices and weaker leading-edge vortices correspond to higher thrust coefficients and higher efficiencies, respectively. Furthermore, a degree of flexibility increases both thrust coefficient and propulsive efficiency. Heathcote et al. (2008) further carried out an experiment in a water tunnel to study the effect of spanwise flexibility on aerodynamic performance of a plunging flexible-wing configuration in forward flight.

Yong et al. (2009) analyzed a forward flight of locust by using a computational fluid dynamic solver and by prescribing the three-dimensional wing shape changes based on measurements. They found that the full-fidelity wing model achieved greater power economy than the uncambered model, which performed better than the untwisted model.

A computational FSI (fluid-structure interaction) analysis that is performed by coupling a CFD solver and a computational structural dynamics (CSD) solver is capable of providing detailed information on both flow fields and structural dynamics of flexible wings. Zhu (2007) made a simulation-based FSI analysis. The boundary element method, which is based upon the potential flow framework was used for fluid dynamics, and a two-dimensional nonlinear thin-plate model was used for structural dynamics. He found that (1) chordwise flexibility and fluid-driven deformation can increase efficiency and (2) spanwise flexibility and inertia-driven deformation can increase thrust.

Gopalakrishnan and Tafti (2010) made a computational FSI analysis to analyze the effect of aeroelastic cambering on flapping flight performance using a linear elastic membrane model. The unsteady aerodynamics of the flapping wing was solved using LES (large-eddy simulation) on a deforming body-fitted fluid mesh using a multiblock finite volume methodology. The analysis was carried out for a rigid wing and flexible wings with different prestress values. Flexible wings were found to have a positive and negative camber during the downstroke and upstroke, respectively. The camber was observed to enhance the lift and thrust production and hence propulsive efficiency. Moreover, it was found that the membrane with a low prestress along the chord and a high prestress along the span demonstrates the best aerodynamics and aeroelastic performance.

Nakata and Liu (2011) carried out a simulation-based FSI analysis by coupling a Navier-Stokes equation solver and a finite-element method-based structural dynamics solver, which is further applied to hawkmoth hovering with realistic flexible wings. The wing motion is composed of flapping motion and feathering motion being prescribed at the wing base. The wing is modeled as a flexible flat plate with consideration of realistic properties of material in a hawkmoth wing,

which bends in spanwise and twists in chordwise with some cambers formed as a result of the inertia and aerodynamic forces on the wing. Their results indicate that (1) a dynamic wing bending can delay the breakdown of leading-edge vortices near the wing tip, and hence responsible for augmenting the aerodynamic force prediction, and (2) a combination of the dynamics change of the wing bending and twist can modify the wing kinematics in the distal area in an appropriate way, which can lead to the aerodynamic force enhancement immediately before stroke reversal.

Kang et al. (2011) analyzed the effects of seven nondimensional parameters on the aerodynamic performance of a flapping wing, which includes the Reynolds number, the reduced frequency, the Strouhal number, the aspect ratio, the effective stiffness, the thickness ratio, and the density ratio. With an analytical model, they confirmed that the maximum propulsive force can be obtained when the wing flapping occurs near the resonance, while the optimal propulsive efficiency can be realized when the flapping frequency is about half of the natural frequency.

55.7 Conclusion

Insect-sized MAVs are expected to be capable to perform specific missions in a manner that is superior to other larger air vehicles. At present, the miniaturization of an ornithopter-type MAV such as the NANO hummingbird by AeroVironment, Inc. seems to have more advantages in maneuverability when compared with those of other MAVs. However, an optimal configuration that is most suitable for the insect-sized MAV has not been achieved yet. On one hand, MAVs with potentially high flight performance configurations, such as quad rotor or tail-sitter air vehicles, will also be candidates for insect-sized MAVs. On the other hand, some unusual MAV with a unique configuration such as the Georgia Tech Entomopter (Michelson et al. 2002) or the Embry-Riddle SamarEye (Hockley et al. 2010) may come to fascinate one with remarkable flight performance. Breakthroughs in miniaturization and the achievement of brand-new MAV configurations will only be achieved through a synthesis of various disparate disciplines such as electronics, robotics, aerodynamics, and material science.

Abstract

In this chapter, a brief history of the major discoveries in the scientific exploration of flapping-wing flight is presented. This is followed by a short review of the basic concepts of lift generation on wings in low-speed, steady flight, which leads into a discussion of the generation of thrust due to the flapping of wings. The aerodynamics of single flapping wings in forward and hovering flight, of flapping tandem and biplane wings, and of dual wings using the clap-and-fling effects are discussed. The chapter concludes with an overview of the major characteristics of five representative flapping-wing propelled micro air

vehicles developed to date, including models developed at the AeroVironment Company, the Naval Postgraduate School, Wright State University, and Delft University.

56.1 Introduction

Anyone observing the seemingly effortless flight of birds and insects cannot help but be impressed by their abilities. Indeed, bird flight greatly inspired early aviation pioneers, such as Lilienthal (1992). The bird or insect wing represents what is referred to in modern aeronautical engineering language as a fully integrated lift/propulsion/control system. From today's vantage point, it is understandable that the attempts by Lilienthal and others to imitate bird flight remained unsuccessful for quite some time. There were simply too many phenomena which had to be understood, foremost the aerodynamics of flapping wings. The Wright brothers correctly recognized that the lifting, propulsion, and control elements had to be separated in order to build a successful flying machine. They also recognized that it was sufficient to imitate the shape of a bird wing in order to generate lift but to refrain from flapping it. It took several more years until it was understood that a thick wing with a well-rounded leading edge was to be preferred over a typical birdlike, thin wing.

For many decades, aeronautical scientists had little interest in the study of flapping-wing flight, leaving this field mostly to ornithologists. Nevertheless, Knoller in Vienna and Betz in Göttingen provided a first elementary explanation for thrust generation by wing flapping in independent studies not too long after the Wright brothers' first flight (Knoller 1909; Betz 1912). Inspired by the work of Knoller and using Knoller's wind tunnel, Katzmayer (1922) found that an airfoil mounted in an oscillating airstream experienced a thrust force (Katzmayer 1922). This was the first experimental verification of the Knoller-Betz effect and, although he most likely had not realized it, probably the first experimental study of dynamic soaring, a common flight technique found in the animal kingdom. At about the same time, a more comprehensive explanation of the Knoller-Betz effect was obtained by Birnbaum in his Göttingen dissertation under the guidance of Prandtl (Birnbaum 1924). He applied a concept first proposed by Prandtl in 1922 at a scientific congress in Innsbruck, Austria (Prandtl 1924). Prandtl showed that it was possible to formulate a linearized theory for incompressible, two-dimensional flow past oscillating thin airfoils using the method of singularities. He explained that a vortex must be shed from an airfoil's trailing edge whenever the airfoil's lift changes, in order to satisfy Kelvin's theorem of constancy of the total circulation. Birnbaum applied Prandtl's theory and succeeded in obtaining results for the oscillatory lift in response to a harmonic small amplitude airfoil oscillation. He also showed that a chordwise force is being generated. This force may be a thrust rather than a drag under certain conditions, thus confirming the Knoller-Betz-Katzmayer effect. Another fundamental insight into lift generation was obtained by Wagner in a dissertation submitted at the Technical University in Berlin (Wagner 1925).

It treated the vortex generation and the lift buildup in response to an airfoil's sudden acceleration to a constant speed or to a step change in angle of attack.

This brief history shows that within about 20 years after the first powered flight by the Wright brothers in 1903 and the recognition of the fundamental relationship between lift and circulation found by Kutta (1902) and Joukowski (1907) at about the same time (the Kutta-Joukowski theorem), the mechanism and prediction of lift generation on a finite-span wing in steady flight had been clarified by Prandtl during World War I with his lifting-line theory (Prandtl 1927), and the clarification of the mechanism and prediction of unsteady lift and thrust generation on thin airfoils had been achieved by Knoller, Betz, Katzmayr, Prandtl, Birnbaum, and Wagner. In the following years, the Prandtl-Birnbaum approach became of great importance for the analysis of wing flutter, pioneered by Kuessner in Göttingen (Kuessner 1936) and Theodorsen at NACA-Langley (Theodorsen 1935). Theodorsen's associate Garrick applied the analysis to the prediction of thrust on airfoils executing harmonic pitch or plunge oscillation (Garrick 1936). In the following years, the emphasis remained on flutter and gust response analysis and on the extension of Prandtl's theory to finite-span wings of general plan form in both steady and unsteady flow. As already stated, the use of flapping wings for flight propulsion was considered impractical by most aeronautical engineers for the remainder of the twentieth century. This perception changed only at the end of the century with the recognition that flapping-wing propulsion might have advantages when used on small air vehicles.

In this chapter, an overview of the basic physics of lift generation on wings flying at a constant speed and angle of attack is presented, followed by a discussion of the basics of flapping-wing aerodynamics. Then the major design features and flight characteristics of five of the many successful flapping-wing propelled air vehicles which have been developed during the past 15 years are discussed.

56.2 Lift Generation on Wings Flying at a Steady Angle of Attack

Because of the small flight speeds of flapping-wing propelled air vehicles, the discussion is limited to incompressible flow considerations. Consider the flow over a typical airfoil, shown in Fig. 56.1. The airfoil has a well-rounded leading edge and a sharp trailing edge. The airfoil chord line is inclined relative to the oncoming freestream. The typical explanation for the generation of lift on this airfoil makes use of Bernoulli's equation for incompressible flow:

$$p + \frac{1}{2}\rho u^2 = \text{const} \quad (56.1)$$

where p is the local pressure, ρ is the density, and u is the local flow speed.

The forward stagnation point on this airfoil is seen to be located at a point close to the foremost point near the nose but somewhat below this point on the airfoil lower surface. Consider two neighboring fluid particles, one flowing slightly above

Fig. 56.1 Flow over a stationary airfoil at an angle of attack. Flow is from *left to right*, and the streamline that appears to run into the airfoil is referred to as the *stagnation streamline*

the stagnation streamline and the other one slightly below this line. If they are to arrive at the trailing edge at the same time, it is “readily” seen that the upper fluid particle has to travel a larger distance than the lower particle. Hence it has to flow at a higher speed which, in turn, means according to Bernoulli that the pressure on the upper surface is lower than on the lower surface. This pressure difference between lower and upper surface integrates to a finite lift force.

Although this account is widely used as an explanation of lift generation, the term “readily” is put between quotation marks because it disregards important physical features. The key to a fuller understanding was found by Kutta (1902) and Joukowski (1907). They derived the important equation, now known as the Kutta-Joukowski law:

$$L = \rho U \Gamma \quad (56.2)$$

which relates the airfoil lift, L , to a quantity called *circulation*, given by Γ . Consider the photo shown in Fig. 56.2.

This photo, taken by Prandtl, shows the changes in flow pattern near the airfoil leading and trailing edge as the airfoil is suddenly started from rest while holding it at a small but finite angle of attack. A vortex is observed to form at the trailing edge which, after a while, starts to detach. Kutta and Joukowski recognized the importance of the relationship between the strength of this vortex (its circulation) and the airfoil lift. They recognized that the airfoil can be regarded as a vortex (more precisely as a series of vortices of varying strength extending from the

Fig. 56.2 Vortex generation on an airfoil shortly after an impulsive start. Visible is the counter-clockwise trailing edge vortex

leading to the trailing edge) which induces a circulatory flow. Using ideal inviscid flow assumptions, they could solve the governing equation (the Laplace equation) subject to the proper boundary conditions on the airfoil surface. One condition is the obvious requirement that the airfoil surface is a streamline (i.e., flow cannot pass through the airfoil wall). However, there is a second condition which is crucial for the correct lift prediction. It is the Kutta trailing edge condition requiring that the rearward stagnation point be located at the sharp trailing edge. The use of this condition yields very good agreement with the measurements, as is shown in Fig. 56.3.

The predicted lift is seen to be in excellent agreement with the measurements on a NACA 0012 airfoil up to angles of attack of about 16° but starts to deviate sharply as soon as the flow stalls due to flow separation. Visitors of the National Air and Space Museum will notice that on their airplane the Wright brothers used a much thinner airfoil than the 12 % thick NACA 0012 airfoil. Indeed, all the airplanes used until 1917 had thin airfoils because it was believed that a good airfoil was one that imitated bird wings as closely as possible. However, Prandtl showed that a thicker airfoil with a well-rounded leading edge delayed the onset of stall to a higher angle of attack and therefore had a higher maximum lift coefficient. The famous airplane designer Anthony Fokker adopted this type of airfoil on the Fokker D.VII airplane,

Fig. 56.3 Lift coefficient as a function of angle of attack for a NACA 0012 airfoil. Experimental data due to (Abbott and Von Doenhoff 1959)

Fig. 56.4 Flow over an airfoil at a small angle of attack. Columns of *dots* on the streamlines are released simultaneously far upstream and travel downstream as a wave front. The bound circulation on the airfoil speeds up the particles traveling *above* the wing and slows down the particles traveling *below* the airfoil such that the particles taking the *upper route* actually arrive at the trailing edge before the particles taking the *lower route*

making it possible for the German pilots to outclimb and outmaneuver their French and British opponents. The thicker wings allowed for thicker spars providing much stronger wings, allowing designers to do away with flying wires, and providing a secondary benefit of significant drag reduction.

The vortex formation and detachment from the airfoil trailing edge caused by the sudden start from rest shown in Fig. 56.2 is the key to a full understanding of lift generation. It is this starting vortex that induces a circulatory flow around the airfoil. The two neighboring fluid particles mentioned earlier therefore arrive at different times at the trailing edge, as shown in Fig. 56.4.

Fig. 56.5 Lift as a function of the distance the starting vortex has traveled downstream, due to Wagner

The particle flowing over the upper surface flows at a faster speed, and therefore, applying the Bernoulli equation, the pressure on the upper surface is lower than on the lower surface. It is important to remember the crucial role of a sharp trailing edge. A rounded trailing edge weakens the starting vortex formation. Furthermore, it is important to keep in mind that the formation and detachment of the starting vortex takes a finite amount of time. For this reason, the lift cannot instantaneously jump to its steady-state value in response to an impulsive airfoil start or a sudden change in angle of attack. Instead, as first shown by Wagner (1925) in Fig. 56.5, the airfoil needs to travel some 20 chord lengths before the steady-state lift value is reached.

Having recognized that any change in flow direction (due to flight in gusty air or in an oscillating air stream, as generated by Katzmayr) causes the shedding of starting vortices, it is clear that a flapping wing also causes the shedding of starting vortices due to the continuously changing angle of attack. The K  nner-Betz explanation of thrust generation by wing flapping therefore is incomplete. The complete physics of thrust generation involves the shedding of starting vortices.

The full understanding of lift and thrust generation by a *finite-span wing*, however, requires knowledge of the three-dimensional flow phenomena generated by a finite-span wing. During World War I, Prandtl developed a simplified model for the steady flow past a lifting wing which describes the actual flow amazingly well. It is the famous lifting-line model which became the basis for future more accurate models. Prandtl suggested that the lifting flow over a typical rectangular high-aspect ratio wing can be modeled by replacing the wing by a single vortex line (the bound vortex). Since a vortex line cannot simply end at the wing tips, he postulated that the bound vortex line must be continued at the wing tips by two trailing vortices aligned with the flow direction. In the case of an impulsively starting wing, a closed vortex

Fig. 56.6 Prandtl's lifting-line theory for finite wings

loop is then formed by the bound, trailing, and starting vortices. As in the two-dimensional case, the influence of the starting vortex diminishes with increasing distance between wing and starting vortex. A lifting wing in steady flight therefore can be modeled by the horseshoe model of one bound vortex and two trailing vortices that extend downstream to infinity. However, this model is still incomplete because it implies that the circulation (and therefore the lift) of a single bound vortex is constant along the wing span, requiring the lift to drop to zero abruptly at the wing tips. This being physically impossible, Prandtl refined the single horseshoe model by postulating the shedding of a trailing vortex with every change in lift in the spanwise direction. This lifting-line model is illustrated in Fig. 56.6. The physics of lift generation now becomes clear. The trailing vortex sheet (especially the strong vortices shed near the wing tips) captures a certain amount of oncoming flow and gives it a downward momentum. The reaction to this downward momentum flow is the wing lift. As in the two-dimensional case, lift generation requires the generation of vortices.

Prandtl succeeded in analyzing this flow model mathematically. He showed that the induced downward velocity is related to the wing lift by the formula

$$\frac{w}{U} = \frac{C_L}{\pi AR} \quad (56.3)$$

which can also be written as

$$L = 2\pi s^2 \rho U w \quad (56.4)$$

where w is the induced downward velocity, AR is the finite wing aspect ratio, s is the semispan of the wing, and C_L is the lift coefficient, given by $C_L = 2L/(\rho U^2 S)$, where S is the wing area.

This formula specifies the amount of freestream flow that is captured by the trailing vortex sheet and given a downward velocity. It is the air mass flowing through a circle with a radius equal to the semispan. The downward velocity is twice the downward velocity induced at the wing, another important result of this theory. Most importantly, it is seen that lift generation is brought about by the rate of change of momentum in agreement with Newton's second law. Lift can only be maintained if the wing continues to generate trailing vortices, thus requiring power. Another important result derived by Prandtl was the recognition that the required power becomes a minimum for constant spanwise downwash distribution and elliptic spanwise lift distribution. Equations (56.3) and (56.4) also show that they contain the two-dimensional flow case as the asymptotic limit case. The induced downward velocity becomes zero for infinite aspect ratio, while the captured mass flow becomes infinite so that the product of mass flow and downward velocity yields a finite lift.

56.3 Thrust and Lift Generation on Flapping Wings

In this section, the aerodynamics of single flapping wings and several flapping-wing combinations will be discussed. These configurations are sketched in Fig. 56.7. In each case, the flapping motion can include just a plunge motion or a combination of pitch and plunge with some phase offset, and if the freestream flow drops to zero, the wing is assumed to be hovering.

56.3.1 Flapping Single Wings

For a first understanding of the aerodynamics of flapping wings, it is again advantageous to consider first the two-dimensional flow physics. The visualization

Fig. 56.7 Common flapping-wing configurations. The single flapping wing models the flight of birds and many modern insects. The tandem wing is found in dragonflies and less developed insects. The opposed-plunge model is not found in nature except when a bird is flying near the ground, where the symmetry plane between the two wings is replaced by the ground

of the vortical wake shed from the trailing edge of an airfoil (visible on the left-hand side) is shown in Fig. 56.8 for increasing flapping frequency. In Fig. 56.8a, the airfoil is held steady. Two vortex rows are seen to be shed from the airfoil trailing edge such that the upper row consists of clockwise-turning vortices and the lower row of counterclockwise vortices.

This type of vortex street is known as a Kármán vortex street, and it typically forms in the flow over cylinders and airfoils at low Reynolds numbers. Interesting changes in vortex street behavior occur when the airfoil is being oscillated in a pure plunge (up and down) motion. As the frequency and amplitude of oscillation are increased, the mushroomlike vortices of Fig. 56.8b are generated which switch to the vortical wake shown in Fig. 56.8c and finally to the vortex street of Fig. 56.8d. This vortex street is usually denoted as the reverse Kármán vortex street because the upper row of vortices now turns counterclockwise and the lower row turns clockwise.

It is apparent from the fact that the upper vortices turn counterclockwise and the lower vortices turn clockwise that a relatively high velocity is being induced between the two rows. Thus, the time-averaged flow at a given station downstream from the airfoil trailing edge resembles that of a jet flow, as shown in Fig. 56.9. This jet flow could be predicted with an inviscid flow analysis (panel code). Although it is not generally realized, birds employ the same jet propulsion principle used for the propulsion of airplanes and missiles. Wing flapping provides the energy needed to obtain a momentum increase. A flapping wing therefore can be regarded as a “rectangular” propeller which draws air into the propeller and gives it a momentum increase, which must result in a thrust force according to Newton’s second law.

In Figs. 56.8 and 56.9, the airfoil was oscillated in a pure plunge mode. A similar but weaker propulsion effect is obtained by pitching the airfoil about, say, the quarter chord point. It turns out that a thrust is generated only above a certain threshold reduced frequency (reduced frequency is the product of chord length times flapping frequency divided by the freestream speed). However, a combined pitch-plunge oscillation is advantageous because the propulsive efficiency is a maximum when the pitch leads the plunge oscillation by roughly 90° . It also turns out that at the small Reynolds numbers, typical for micro air vehicles, viscous effects can be quite strong, especially at small reduced frequencies. For a more detailed discussion and computational analysis of these effects, refer to Platzer et al. (2008), Young and Lai (2004, 2007), and Shyy et al. (2008).

As in the steady lifting case, discussed above, the oscillating finite-span wing sheds additional vortices, especially near the wing tips. In the case of a single-step change in angle of attack, a single vortex ring is generated consisting of the bound vortex on the wing, two trailing vortices that reach from the wing tips back to the starting vortex that was generated at the moment of the step change. As seen in Fig. 56.10, the oscillating finite-span wing generates alternating vortex rings. The flow shown in Fig. 56.10 was obtained using an inviscid three-dimensional panel code. Viscosity effects change this picture considerably, especially at increased distance from the trailing edge. The flow in the mid-span vertical plane is seen to resemble the two-dimensional reverse Kármán vortex shedding shown in Fig. 56.8d.

Fig. 56.8 Transition from normal to reverse Kármán vortex street with increasing frequency and amplitude of airfoil oscillation. (a) Stationary airfoil shedding a Kármán vortex street, indicative of drag. (b) Flapping with a low frequency and amplitude such that net thrust is still negative. (c) Flapping with a frequency and amplitude where the net thrust is essentially zero. (d) Flapping with a frequency and amplitude where thrust exceeds drag, producing a reverse Kármán vortex street

Fig. 56.9 Time-averaged streamwise velocity profile in the wake of a flapping wing measured experimentally and predicted numerically

Fig. 56.10 Alternating vortex rings in the wake of a finite-span flapping wing

56.3.2 Flapping Tandem Wings

Consider the two-foil tandem arrangement shown in Fig. 56.7b. If the second airfoil is stationary, an oscillation of the leading airfoil will expose the non-oscillating trailing airfoil to an oscillatory flow. This is the flow situation first studied by Katzmayr (1922), where he measured a thrust on an airfoil mounted in an oscillatory air stream. Schmidt appears to have been the first one during and after World War II

to use this arrangement for the development of his *wave propeller* (Schmidt 1965). It is now well recognized that birds can minimize their wing flapping and, therefore, energy expenditure by seeking to fly in wavy air, a form of dynamic soaring. Similarly, fish can remain stationary with minimum tail flapping in wavy water flow, such as the Kármán vortex street behind a rock in a river. A more complicated interaction effect occurs when both foils are oscillated. Depending on the phase angle and amplitude of oscillation of the two airfoils, rapid thrust and lift changes can be achieved, giving insects such as the dragonfly astounding maneuverability. For more details, refer to Isogai et al. (2004) and Yamamoto and Isogai (2005).

56.3.3 Flapping Biplane Wings

It is well known that a wing flying very close to the ground experiences a substantial increase in lift. This favorable ground effect occurs also on flapping wings. Both the thrust and the propulsive efficiency are significantly increased on wings flapping close to the ground, as shown in Fig. 56.11. Birds make use of this effect when flying close to a water surface, for example, as shown in Fig. 56.12. The same effect can be achieved in flight out-of-ground effect when two wings are used that flap in counterphase, as shown in Fig. 56.7c. According to Wootton and Kukalova-Peck (2005), large insects existed a long time ago that had forewings and hind wings which overlapped extensively, thus making use of this favorable biplane effect. However, no present-day insects are known to use it. Hence micro air vehicles, such as the one developed by the present authors (Jones et al. 2005), must be classified as biomorphic vehicles, where the characteristics of natural flyers are modified considerably, in contrast to biomimetic vehicles which try to simulate natural flyers as closely as possible. Further details about computational and experimental data on flapping biplane wings can be found in Platzer et al. (2008) and Jones et al. (2000, 2005).

56.3.4 Two Wings Flapping in the Clap-and-Fling Mode

There exists another thrust and lift generation mechanism used by natural flyers. Consider the typical hovering insect configuration depicted in Fig. 56.13. As the two wings close up as shown in Fig. 56.13b, c, e, the wings force air out of the wing trailing edges, thus creating a jet flow and hence lift. Then, as the wings begin to open up at the top, as shown in Fig. 56.13f, h, i, a low pressure is induced between the wings, causing the formation of strong leading edge vortices, thus again generating a substantial amount of lift. Parts a, d, and g correspond to parts f, h, and i, illustrating what the insect is doing in three dimensions. This effect was first observed and described by Weis-Fogh in 1973 and is often referred to as the Weis-Fogh effect (Weis-Fogh 1973). Lehmann et al. report a recent experimental investigation of this effect (Lehmann et al. 2005). Figure 56.13 is a composite image using sketches by

Fig. 56.11 Predicted thrust and efficiency for flapping wings in ground effect

Fig. 56.12 A brown pelican and a great egret demonstrating the use of ground effect to minimize operator workload

Weis-Fogh (1973) and Sane (2003), available online at the Journal of Experimental Biology (Sane 2011).

56.3.5 Hovering Single Wings

Hummingbirds and many insects are able to hover by moving their wings in an approximately horizontal plane. Although the actual wing motion more closely follows a figure eight trajectory, the basic effect can be understood by studying the vortex shedding caused by the motion in a horizontal plane. As shown in Fig. 56.14,

Fig. 56.13 Clap-and-fling or Weis-Fogh effect to enhance lift/thrust (Reproduced/adapted with permission from the Journal of Experimental Biology Weis-Fogh 1973; Sane 2003, 2011)

the airfoil moves to the left at constant positive angle of attack, then rotates at the end of the stroke so that the leading edge points in the opposite direction, proceeds to the right with positive angle of attack and then rotates back at the right end of the stroke. Strong vortices are shed during the airfoil rotation, thus generating substantial amounts of lift. Other hovering modes are possible, as discussed for example in Shyy et al. (2008).

56.4 Flapping-Wing Micro Air Vehicles

56.4.1 Microbat (AeroVironment Inc.)

While model airplane enthusiasts had been building rubber band-powered ornithopters for many decades, the AeroVironment Microbat, shown in Fig. 56.15, was the first known remotely controlled MAV ornithopter design. The design philosophy applied by the AeroVironment Company was to take a functional rubber band-powered vehicle and substitute an electric motor drivetrain for the rubber band and add a radio for control. The Microbat model uses a 2-cell lithium polymer (Li-poly) battery and a three-channel radio. It has a span of 23 cm and a total weight of 14 g. Its endurance is approximately 25 min. In trying to mimic bird flight, the Microbat is an example of a biomimetic design.

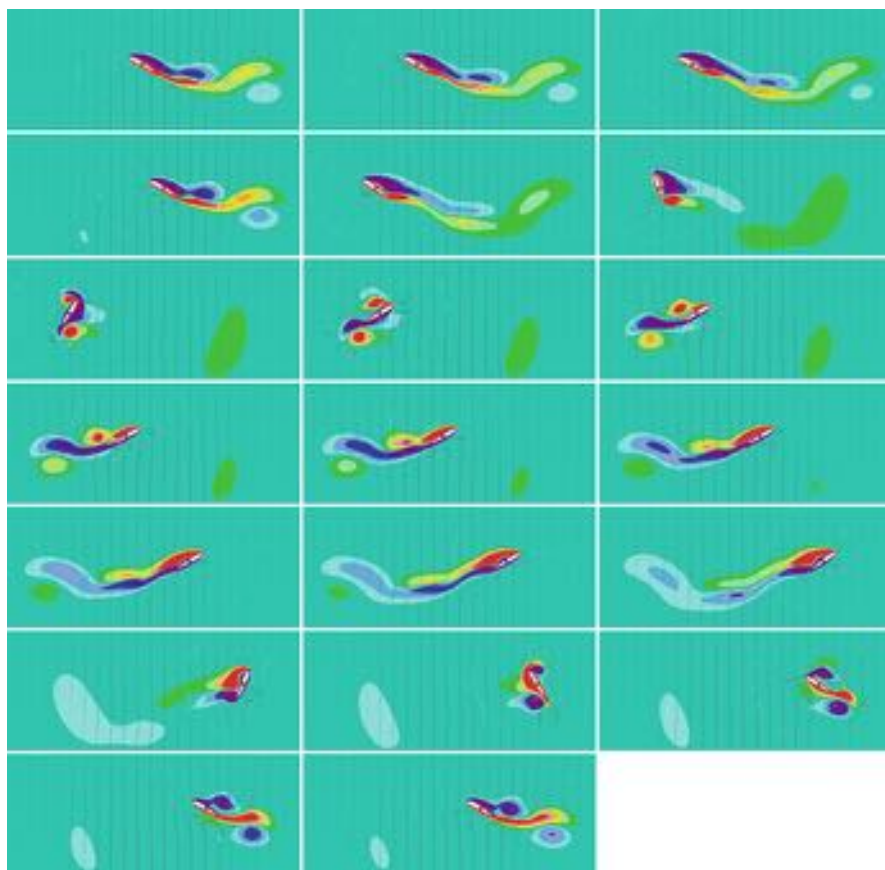

Fig. 56.14 Numerical prediction of a single wing flapping in a figure eight hovering mode (Kurtulus et al. 2005)

56.4.2 “NPS Flyer” (Naval Postgraduate School)

In contrast, the present authors decided to use flapping wings primarily for propulsion while generating most of the lift by a stationary (non-flapping) wing, hence to pursue the concept of a biomorphic design. Having chosen to separate thrust and lift generation, it remained to choose the type of flapping-wing propeller and its location. These decisions were greatly facilitated by knowledge about the superiority of flapping biplane wings and by the possibility of flow separation control through a closely coupled wing-propeller arrangement. Since it is well known that propellers mounted close to the wing trailing edge entrain the flow and therefore delay wing stall, the flapping-wing propeller was positioned downstream of the fixed wing. Another key decision was the choice of flapping mechanism which would make it possible to build a sufficiently lightweight biplane flapper.

Fig. 56.15 Microbat flapping-wing vehicle (AeroVironment Inc.) (Keennon and Grasmeyer 2003)

Fig. 56.16 MAV-sized biplane propulsion test model

The configuration shown in Fig. 56.16 consists of two swing arms which flap about a point several chord lengths ahead of the biplane wings, driven by a crankshaft that is connected to a tiny geared electric motor. The wings are elastically coupled to the swing arms such that aerodynamic loads create a passive coupled pitching motion.

As already mentioned, conventional propellers located close to but downstream of a wing's trailing edge have a favorable effect on the flow over the wing's upper surface. This consideration is particularly important for low Reynolds number air vehicles due to their increased tendency toward flow separation. High-aspect ratio flapping-wing propellers have the advantage over conventional propellers that the flow along the whole wing span can be entrained. The effectiveness of this type

Fig. 56.17 Visualization of separation control on the fixed/flapping-wing test model. In the *left photo*, the trailing flapping wings are at rest, and a massive, turbulent separated region above the main wing is visible. In the *right photo*, the biplane flapping wings are active, and the separated region above the main wing is gone. The reattachment process is very fast, requiring about four flapping strokes to complete

Fig. 56.18 The first flyable flapping-wing MAV at NPS

of flow control can be clearly seen in Fig. 56.17. The upper image shows the flow over the wing for the case where the two small biplane wings are stationary. Flow separation over the wing upper surface is clearly visible. The lower figure shows the case where the biplane wings are flapping. The flow separation over the upper wing surface is seen to be greatly reduced due to the entrainment effect of the flapping-wing propeller.

Fig. 56.19 An improved NPS flapping-wing model

The first complete, flyable micro air vehicle is shown in Fig. 56.18. It first flew in December 2002. It had a main wing with a 30 cm span and 14.5 cm chord and flapping wings with a 25 cm span and 4 cm chord. The weight was 14.4 g. Subsequent development made it possible to reduce the span to 23 cm and the weight to 11 g, as shown in Fig. 56.19. Minor trim changes allowed for flight speeds between 2 and 5 m/s. The endurance on the single rechargeable lithium polymer battery was about 12 min. Further details can be found in Jones et al. (2005).

56.4.3 Delft University DelFly

As previously mentioned, the rubber-powered model airplane community had been experimenting with flapping-wing aircraft for the better part of a century. Most successful aircraft looked pretty much like birds, but in 1985 Frank Kieser came up with the design shown in Fig. 56.20. It used four wings that flapped in counterphase, providing the same mechanical and aerodynamic symmetry as the NPS flyer, but with wings that were hinged at the root, more like birds and insects. His design was very successful and held endurance records for many years.

The DelFly, developed at the Technical University of Delft, is a variation on the Frank Kieser's design, moving the flapping wings to the front and adding the empennage at the rear (Lentink et al. 2009; de Croon et al. 2009). The DelFly I, shown in Fig. 56.21, had a 50-cm span and 21 g mass and was only capable of cruise flight. The DelFly II, shown in Fig. 56.22, had a 28-cm span and 16 g mass, carried a wireless video camera, and was able to hover and take off and land vertically using

Fig. 56.20 Frank Kieser's record-breaking rubber-powered x-wing flapper

Fig. 56.21 DelFly I – 50-cm span, 21 g mass

its tailfins as landing gear. On the DelFly II, the upper set of wings was designed to come together at the top to make use of the Weis-Fogh effect.

The latest addition to the fleet was the DelFly Micro, shown in Fig. 56.23, with a 10-cm span and 3.07 g total mass including video. It is the smallest known flapping-wing MAV.

56.4.4 Wright State University Micro Air Vehicle

At the Wright State University, a flapping-wing micro air vehicle was developed that makes use of the Weis-Fogh clap-and-fling effect (Hsu et al. 2010;

Fig. 56.22 DelFly II in hovering flight – 28-cm span, 16 g mass, with video camera

Dawson et al. 2011). The design is based on a three-way clap-and-fling mechanism. Two wings on either side are flapping in such a way that they come together on both ends of the stroke as the wings are in the horizontal and vertical positions, as shown in Fig. 56.24. The wings are covered with a thin polyester film with a thickness of $25\ \mu$. The maximum flapping frequency is 20 Hz, and the wing span is 20 cm. The total weight including a 0.67 g camera is 12.56 g. The vehicle was demonstrated to be capable of hovering and of performing simple aerobatic maneuvers.

56.4.5 “Nano Hummingbird” (AeroVironment Inc.)

The design requirement, specified by the Defense Advanced Research Projects Agency (DARPA), was to develop a biomimetic vehicle that would simulate a hummingbird as closely as possible. Therefore, it had to be capable of hovering for a minimum of 8 min as well as to transition into forward flight. As shown in Fig. 56.25, both body and wings closely resemble a hummingbird. To achieve

Fig. 56.23 DelFly Micro – 10 cm span 3.07 g mass

Fig. 56.24 Clap-and-fling micro air vehicle developed at Wright State University

this biomimetic design, very lightweight flexible wings had to be developed which allowed the camber and twist to reverse symmetrically from forestroke to backstroke to modulate lift and drag for control purposes while looking in shape and color like its natural counterpart. A major challenge was the development of the wing

Fig. 56.25 Nano Hummingbird (AeroVironment Inc.) sitting in the palm of a hand and in hovering flight (Photos courtesy of the AeroVironment Corporation)

flapping mechanism. A string mechanism was selected. Two strings, attached to a continuously rotating crankshaft driven by an electric motor, are each connected to two pulleys which are mounted on the wing hinge flapping axes. As the crankshaft turns, the pulleys oscillate. Two additional strings connecting the pulleys keep the two pulleys (and wings) matched in phase. This mechanism made it possible to generate control moments in the roll, pitch, and yaw axes using only the flapping wings. This was accomplished by modulating the wing rotation and the wing twist. The complete vehicle weighs 19 g and has a wing span of 16.5 cm. It can hover for several minutes and fly forward up to 6.7 m/s. Further details are described in the recent paper by Keennon et al. (2012). The Nano Hummingbird is the only known model that hovers with just two wings and provides all stability and control through the same wings with no tail surfaces at all.

56.5 Concluding Remarks

Twenty years ago, flapping-wing-propelled *micro air vehicles* were of primary interest only to children and enthusiasts who wanted to fly rubber band-powered airplanes. This situation changed rapidly after the Defense Advanced Research Projects Agency's call for micro air vehicle proposals in 1996. As described in the preceding pages, the basic physics of flapping-wing aerodynamics, acquired in the early twentieth century, was sufficiently well understood to demonstrate several flapping-wing-propelled air vehicles for hovering and forward flight. The amazing progress in battery power density and electric motor miniaturization made it possible to switch from rubber band power to electric power.

The above-described five micro air vehicles were largely developed by an iterative cut-and-try approach. However, great progress has been made over the past 20 years in acquiring experimental data and developing computational methods to improve knowledge of the complex unsteady three-dimensional low Reynolds number aerodynamic phenomena occurring on various flapping-wing propelled vehicles. This progress is evidenced by the large number of papers published in recent years on various facets of flapping-wing vehicles. It will undoubtedly lead to further innovative designs of such vehicles in the near future.

Abstract

In recent years, research efforts have focused on the design, development, and deployment of unmanned systems for a variety of applications ranging from intelligence and surveillance to border patrol, rescue operations, etc. Micro aerial vehicles are viewed as potential targets that can provide agility and accurate small area coverage while being costeffective and can be easily launched by a single operator. The small size of MAVs allows such flight operations within confined space but the control effectors must provide sufficient maneuverability, while maintaining stability, with only limited sensing capability onboard the platform. To meet these challenges, researchers have long been attracted by the amazing attributes of biological systems, such as those exhibited by birds and insects. Birds can fly in dense flocks, executing rapid maneuvers with g-loads far in excess of modern fighter aircrafts, and yet never collide with each other, despite the absence of air traffic controllers. This chapter introduces a novel framework for the design and control of a micro air vehicle. The vehicle's conceptual design is based on biologically inspired principles and emulates a dragonfly (Odonata-Anisoptera). A sophisticated multilayered hybrid and linear/non-linear controller to achieve extended flight times and improved agility compared to other rotary and flapping wing MAV designs. The chapter addresses the design and control features of the proposed QV design and gives an overview on the developmental efforts towards the prototyping of the flyer. The potential applications for such a high-endurance vehicle are numerous, including airdeployable mass surveillance in cluster and swarm formations. The disposability of the vehicle would help in battlefield deployment as well, where such a, MAV would be made available to soldiers for proximity sensing and threat level assessment. Other applications would include search and rescue operations and civilian law enforcement.

57.1 Introduction

In recent years, many military and civilian missions in an urban setting require improved surveillance and reconnaissance. To address the need for real-time

intelligence, unmanned aerial vehicles (UAVs) have been used to provide video surveillance. Of particular interest in urban operations are MAVs that require minimum operator workload, are user-friendly, and can be deployed in closed quarters or in dense and cluttered urban areas with their primary mission to detect and report target positions.

Of particular interest in urban operations are MAVs that require minimum operator workload, are user-friendly, and can be deployed in closed quarters or in dense and cluttered urban areas with their primary mission to detect and report target positions. The successful deployment and application of such micro flyers warrants that the MAVs be able to sustain flight for appreciably long durations. The prospect of such an MAV flight has so far eluded researchers. The MAV platforms inspired from flapping wing, biological counterparts have shown very limited flight endurance (Cox et al. 2002; Grasmeyer and Keenon 2001; Kornbluh 2002; Samuel et al. 2000; Pornsin sirirak et al. 2000). The majority of flight-capable flapping-wing MAVs have very limited VTOL/hovering capabilities. Their primary functionality is to mimic fixed-wing flight with the primary difference of producing forward thrust by the aid of flapping air backwards. The requirement is to have MAVs be able to hover and sustain long-flight endurance at the same time. The simultaneous inclusion of these two primary requirements in an MAV calls for a paradigm shift in the development of enabling actuation mechanisms and control techniques.

Missions envisioned for MAVs, such as intelligence, surveillance, and reconnaissance (ISR) in urban environments, require exceptional long flight times and significant sensor payloads. These missions typically involve flight through or in close proximity to buildings, tunnels, and trees and require the MAVs to maneuver using sharp dives and climbs along with small-radius turns. The small size of MAVs allows such dynamic flight operations within confined space but the control effectors must provide sufficient power for both dynamic maneuvers and long flight times. Also MAVs operate in a very sensitive Reynolds number regime, wherein aerodynamic flow physics exhibits strong variance from conventional steady aerodynamic effects seen over the wings of fixed and rotary wing MAVs. Hence, designing vehicles that can efficiently fly in this regime represents an entirely new challenge to design engineers (Table 57.1).

57.2 State of the Art

Table 57.2 (<http://www.ornithopter.org>) showcases some of the state-of-the-art MAVs that have been developed over the years (Cox et al. 2002; Grasmeyer and Keenon 2001; Kornbluh 2002; Samuel et al. 2000; Pornsin sirirak et al. 2000). At present, a uniformity among most of the MAV designs can be seen from their propulsion/actuation, a variation of a simple reciprocating crankshaft mechanism, symmetric flapping through mechanical coupling to a single rotary actuator, restricted control schemes, and low energy efficiency attributed to the use of frequency modulated flapping, as opposed to amplitude modulation, as used in insect and bird flight (Cox et al. 2002; Pines and Bohorquez 2006; Ratti and

Table 57.1 DARPA: MAV definition/design requirements

| Specifications | Requirements | Details |
|----------------|-------------------|------------------------|

Vachtsevanos 2010; Rayner 1979). Elastic storage and reuse of pectoral muscle energy is not facilitated. Complete 6 DoF dynamics is attained by addition of an airplane-like tail rudder or a tail elevator.

57.3 Quad-Wing MAV Design: Background

Limitations of fixed, rotary wing technologies heighten with size, following the Reynolds number decrease with smaller wing surfaces. (Aerodynamic effects in the low Reynolds number region are still a subject of much research (Prosser et al. 2011).) However, insects and birds are adept flyers at low Reynolds numbers. A lot of research in the unsteady Reynolds number region has also supported the fact (Pines and Bohorquez 2006). Flight comparison of the flying mechanisms between

a bird, hummingbird, butterfly, and dragonfly (Ratti and Vachtsevanos 2010) was made to choose the most suitable MAV design (Fig. 57.2).

57.3.1 MAV Design Conception: QV Design

Flight mechanism comparison between a bird, hummingbird, butterfly, and a dragonfly was made to choose the optimal MAV design; a dragonfly-like design (Ratti et al. 2010; Ratti and Vachtsevanos 2010) chosen as the inspiration for the QV (QV stands for quad-winged MAV. The name has been chosen to abbreviate the most basic appearance of the proposed quad winged MAV design) design was born. Figure 57.3 illustrates the in-flight control of primitive maneuvers by the coordinated control of power distribution to the individual wings.

57.3.2 QV Developmental Plan

The MAV program has been centered around the parallel research and development scheme of various software/hardware elements illustrated in Fig. 57.4 (Prosser et al. 2011; Ratti et al. 2010, 2011a; Ratti and Vachtsevanos 2010, 2011).

An actuation mechanism converting a rotary motion to reciprocating motion by the use of a crank mechanism exhibits this problem. The system amplitude is always constant, and thus the system can accelerate or decelerate based on how fast the wings are flapping. For generating higher thrusts, the wings are simply made to move faster at the fixed amplitude of motion. But for a fixed frequency flight system like in the case of insects and birds, changing flapping frequency disturbs the spring-mass system dynamics, resulting in more energy consumption and poor performance. Hence most of the flyers do away with the spring altogether, thereby losing a lot of flight performance exhibited by birds and insects.

The idea of using a system which maintains constant frequency but varying amplitude better approximates the flight dynamics of insects and birds. Such a system has been attempted but never implemented in a flying prototype (Michelson et al. 1997; Michelson 1988; Keshavan et al. 2007; Raney and Slominski 2004). The mathematical model of the actuation mechanism has been developed by Ratti and Vachtsevanos (2010).

The system model is based on two coupled mechanisms in series, a four-bar linkage mechanism, and an inverse crankshaft mechanism.

As seen in Fig. 57.5, the linear actuator drives the wing up and down by pushing or pulling the wing. However to obtain an appreciable amplitude, the placement of the solenoid needs to be very close to the wing pivot, as shown in the Fig. 57.5. This raises linkage and structural deformation concerns. The four-bar linkage was utilized to overcome the linkage difficulties. The solenoids are attached much further from the wing pivots now, as shown in Figs. 57.5 and 57.6. The wing with the actuator, spring, and four-bar linkages has been shown in Fig. 57.5.

57.4 Prototype Design and Construction

57.4.1 Hardware-in-Loop-Simulation (HILS)

The HILS setup is shown in Fig. 57.7. The flight dynamics have been modeled on a computer and the flight visualization has been linked to the dynamics. The model continuously sends out states of the system to the autopilot. The autopilot

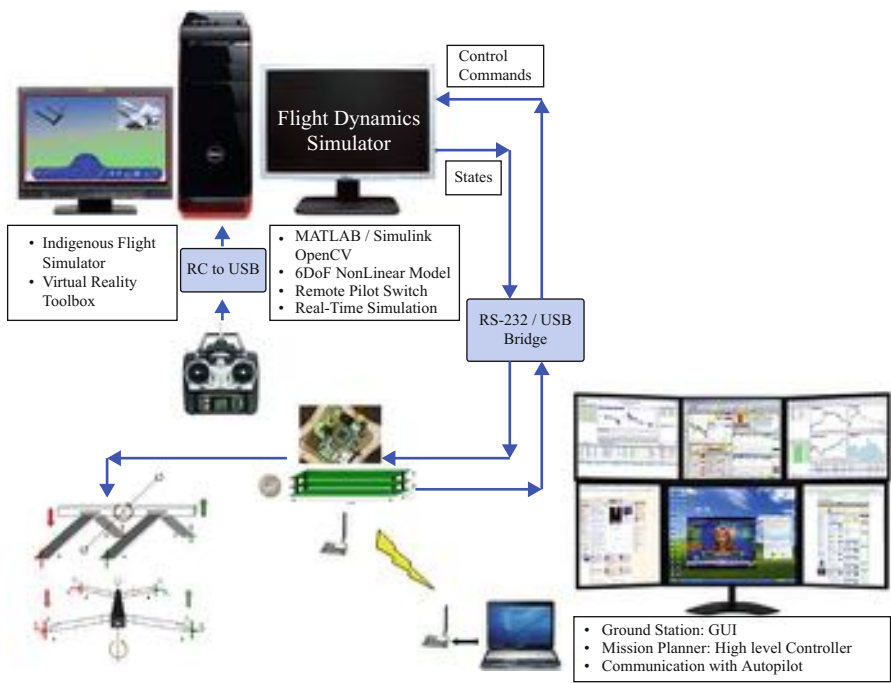

Fig. 57.7 Hardware in the loop simulation setup

Fig. 57.8 2, 4, N-wing MAVs: repeating the basic unit

processes the control routines and sends back control commands to the computer (simulator/modeler). The ground station constantly keeps a communication lock with the autopilot and receives and sends mission status from time to time. The RC controller is connected to the modeler.

57.5 Conclusion

A new micro unmanned aerial vehicle design was developed and presented. This chapter focused on the review of the MAV conceptual design and the development of the constituent sensing and control algorithms. Simulation results demonstrated the efficacy of the design. The research seeks to achieve stable flying conditions by combining the unique design features of the MAV with novel sensing and control strategies. The objective is to integrate the MAV hardware and software modules into a device that will exhibit attributes of stable and robust flying conditions. The inspiration for the design stems from the study of various flying insects and other entomophthora developed in the past. The design was mathematically modeled and verified in simulation. A hierarchical control paradigm was pursued to capture various control requirements from actuation to trajectory following. A brief overview of the hardware mechanisms, embedded autopilot designs, and hardware-in-the-loop simulation architecture was presented. A laboratory prototype is currently under development (Fig. 57.25).

57.6 Energy Reserve Enhancement

The QV design's inherent advantage lies in providing the MAV with a manyfold increase in lift, thus the ability to carry higher payloads in the form of avionics and battery packs.

57.6.1 Energy Enhancement: Multi-wing MAV

From Fig. 57.9 (Ratti and Vachtsevanos 2011), the energy saving per actuator is demonstrated for multi-wing vehicles with changing avionics power consumption, showing energy savings of the order of 100 % and more in cases. Energy efficiency on the QV design goes beyond that provided by the four-wing configuration over a two-wing configuration alone; the inclusion of elastic/restorative wing flapping further improves the energy efficiency of the MAV. It has been proved (Ratti and Vachtsevanos 2011) that by adding a passive spring at the wing joints of the MAV, considerable torque (and in turn energy) savings is observed, which is greater for lower air-damping on the wings.

57.7 Fixed Frequency, Variable Amplitude

Definition 1 *Fixed Frequency, Variable Amplitude (FiFVA) Control Problem:* An actuation mechanism converting a rotary motion to reciprocating motion by the use of a crank mechanism exhibits a low efficiency state. The system amplitude

Fig. 57.9 Energy saving/flight time increase curves

is always constant, and thus the system can accelerate or decelerate based on how fast the wings are flapping (frequency modulation). But for a fixed frequency flight system (insects/birds), changing flapping frequency disturbs the spring-mass system dynamics, resulting in more energy consumption and poor performance.

57.7.1 Non-linear State Space Model for Each Wing

The idea of using on the QV, a system which maintains constant frequency but controls lift and maneuvering by amplitude modulation, better exhibits the flight dynamics of insects and birds. Such a system has been attempted but met with limited success (Keshavan et al. 2007; Raney and Slominski 2004). The mathematical model of the actuation mechanism has been defined in Ratti et al. (2010) and Ratti and Vachtsevanos (2010). The model is based on two coupled mechanisms in series, a four-bar linkage mechanism, and an inverse crankshaft mechanism (Fig. 57.10). Our two FiFVA actuators are as follows:

The wing state vector X bundles the dynamic relationships between the four-bar mechanism, the inverse crankshaft mechanism, the solenoidal linear motion, and current intake at an input u . The state space model representation is as shown:

$$\dot{X} = f(X, u), Y = g(X, u) \quad (57.1)$$

Fig. 57.10 Kinematic illustration of the basic wing mechanism

$$X = \begin{bmatrix} x \\ \dot{x} \\ \theta_1 \\ \theta_2 \\ \theta_k \\ \theta_3 \\ \dot{\theta}_3 \\ i \end{bmatrix} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \\ x_7 \\ x_8 \end{bmatrix}, \dot{X} = \begin{bmatrix} \text{Solenoid Linear Velocity} \\ \text{Solenoid Linear Acceleration} \\ \text{[Joint Angular Velocities]} \\ \text{Joint 3 Angular Acceleration} \\ \text{Solenoid Current Gradient} \end{bmatrix} \tag{57.2}$$

The dynamics of the wing motion depend on various configuration-specific elements and constants of the wing coupling which have been captured using X in Eq. 57.2.

The outputs for the system are the lifting forces produced by the wings of the MAV. The output model is shown below with its dependence on wing configuration parameters like shape and size and also on air drag and density coefficients (Fig. 57.11).

A full nonlinear model and state space derivation has been given in Ratti and Vachtsevanos (2010):

$$Y = K_{\text{constant}} \cdot x_7 |x_7| \begin{bmatrix} -\sin x_6 \\ \cos x_6 \end{bmatrix} \tag{57.3}$$

Fig. 57.11 Micro solenoidal actuator: CAD (*left*); working prototype (*right*)

1. *Solenoidal – One-spring configurations:* The solenoidal/magnetic actuation methodology was designed to produce FiFVA actuation and control using just one actuator with only one control/power input. The actuator was also miniaturized to weigh 5 g and produced an output torque of 75 g-cm. At 3.6 V, the coil drew 500 mA and reached a resonant frequency of 20 Hz (Ratti et al. 2011a).
2. *Hypocycloidal Gear Train:* A hypocycloidal gear train was examined since by the use of an additional worm gear arrangement, amplitude modulation is possible, providing FiFVA control over wing flapping (Fig. 57.12) (Ratti et al. 2011a).

57.8 Aerodynamics

57.8.1 Grid and Wing Mesh

The unsteady flapping + feathering motion of the cambered elliptical wing was simulated in Ansys Fluent V12.1. (Through a commercially available CFD software package.) Figure 57.13 shows the unstructured tetrahedral grid generated using *Gambit*. (A commercially available software for grid generation.) The overall grid was divided into two parts: an inner smaller spherical domain bounding the wing motion with a fine mesh to ensure good resolution of the flow around the wing and an outer spherical domain with a coarser mesh.

57.8.2 Vortex Formation

Figure 57.14 represents the formation of leading edge vortex which plays an important role in production of lift for unsteady flapping wings at low Reynolds number. At time $t = 0$, the wing is horizontal. Due to the increased acceleration of the wing from its initial position, a leading edge vortex grows from the base towards

Fig. 57.12 Inter-meshing of the internal gears (*left*); working prototype (*right*)

Fig. 57.13 Wing mesh (*left*); mesh grain/boundary (*right*)

the tip. The growth of the vortex is maximum at a point about $3/4$ of wing span. The formation of this vortex is believed to be related to the dynamic stall phenomenon due to which a wing produces high lift even at high angles of attack.

57.9 Flapping Hardware and Prototyping

57.9.1 Load Cell and Wind Tunnel Rig Designs

Figure 57.15 is a scale model of the wing actuation mechanism, connected to a 6-axis load cell.

Fig. 57.14 Leading edge vortex dynamics on wing surface (from left): at 0 s, $T/8$ s, $T/4$ s, $T/2$ s, $7T/8$ s

57.9.2 Feathering Mechanism

Addition of an extra actuator proves bulky and difficult to install. The feathering mechanisms we have implemented constitute spring-loaded passive feathering of the wings to conform to fixed frequency, variable amplitude flapping as exhibited by birds and insects.

1. *Passive Feathering* – Designs: Some of the modular passive feathering wing designs tested on the flapping setup shown in Fig. 57.15 are presented in Fig. 57.16.

57.10 Micro Architecture and Control (MARC) Avionics Platform

The conventional mini- and large-scale UAV systems span anywhere from approximately 12 in. to 12 ft, endowing them with larger propulsion systems, batteries/fuel tanks, which in turn provide ample footprint and power reserves for onboard avionics and wireless telemetry. The conventional MAV (Table 57.1) can have a maximum dimension of 6 in. and weighs no more than 100 g. Under these tight constraints, the footprint, weight, and power reserves available to onboard avionics are drastically reduced. The chapter presents the advent of a new line of micro architecture and control (MARC) avionics systems with very lowpower, multisensor, multiprocessor avionics, interconnect architecture designed specifically with the power and payload constraints of MAVs in mind towards matching performance to their larger-scale UAV cousins.

Fig. 57.15 Flapping mechanism

Passive-feathering designs

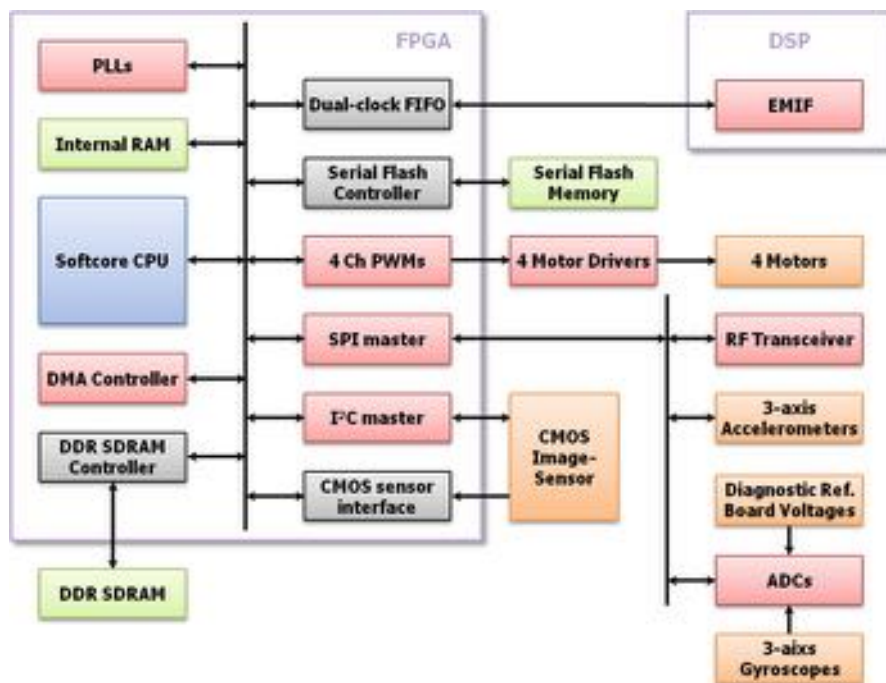

Fig. 57.17 Embedded hardware architecture

57.10.1 Avionics Design

Figure 57.17 shows the outline of the embedded hardware onboard the MAV. The selection of the processors for this embedded device involved many important considerations such as power consumption, size/weight, and performance.

1. *Embedded Vision and Wireless Telemetry*: The ground station tele-operations the MAV and/or uploads waypoints for semiautonomous flight navigation. The MARC collects internal state information and environmental data including aerial video/images during flight and transmits this data via a block data packet to the ground station also through the RF transceiver; Fig. 57.18 briefly illustrates the link.

57.11 Real-Time Flight Control

The MAV control architecture is illustrated through the flow diagram (Jung et al. 2009; Vachtsevanos 1998; Vachtsevanos and Ludington 2006) shown in Fig. 57.21. The *mission* module describes the global mission parameters to be met by the

Fig. 57.18 Wireless link between the MAV and the ground station

Fig. 57.19 MARC-1 (dsPIC33F) single core

MAV, such as flying from point A to point B to point C and avoiding point D. The *path/trajectory planning* module incorporates the above mission goals and assigns a trajectory to be followed to meet the mission goals. The *target positioning* layer produces reference Euler angles and rates for the MAV to successfully follow the waypoints produced in the previous higher layer. The *flight control* layer is a linear controller, which matches the vehicles dynamic Euler angles and rates to conform to the reference values generated by the immediately upper layer. The *hybrid energy controller* is responsible for sustaining oscillations about the wing-beat frequency. The energy controller controls the thrust produced by each wing by modulating the power output of each wing. There are four actuators in the system, which together control pitch (and forward/backward translation), yaw, roll (and left/right translation) (Figs. 57.19 and 57.20).

The MAV plant has been expanded for better understanding of the internals of the system. The plant can be seen to comprise the following as shown in Fig. 57.21. The system energy is calculated from output – sensor feedback and internal sensor feedback for the system – by taking into account the length and mass, angular position, spring extension, and angular velocity of the wing. The interface of the nonlinear controller can be seen from Fig. 57.21. The energy controller controls the power delivered to the actuators, in effect controlling the three body angular rates of the system. Details on the hybrid energy controller can be found under Ratti et al. (2010) and Ratti and Vachtsevanos (2010) (Fig. 57.21).

Fig. 57.20 MARC-2 (Cyclone III, TI 55xx DSP) dual core

57.11.1 Real-Time Operating System Architecture

The architecture of the hardware-in-the-loop (HILS) setup utilizing the RTOS (Jung et al. 2009) has been shown in Fig. 57.23. The architecture has been designed to keep the code flexible enough to allow adding higher level tasks to mission directives sent by the ground station. All this can be achieved without engrossing into the system-level intricacies of handling and programming a microcontroller/microprocessor. The flexibility of the architecture also makes it extremely efficient to debug faults in low-level, mid-level, or high-level tasks, without having to recode/interfere with the other tasks.

57.11.2 Results: Power Drain and Weight

The goal of the MARC-2 board was to keep all the avionics within a total weight of 15 g and the onboard avionics power requirement within 0.75 W. Towards that end the different processors and peripherals were selected. The total weight of the MARC-2 avionics suite was 15.75 g and the total power consumption was 0.65 W.

57.12 MAV Designs Based on Different Actuation Schemes

57.12.1 Modular MAV Configurations

At present there are four different MAV prototypes being constructed in our laboratory conforming to the QV design specifications; each has four wings to produce lift and 6 DoF control. Some of the 3D prototypes are shown in Fig. 57.24.

57.12.2 6 DoF Testing of the First MAV Prototype

A test-bench simulator has been designed to perform 3 DoF motions and maneuvers. The goal is to test different control algorithms and their performance on a bench-top

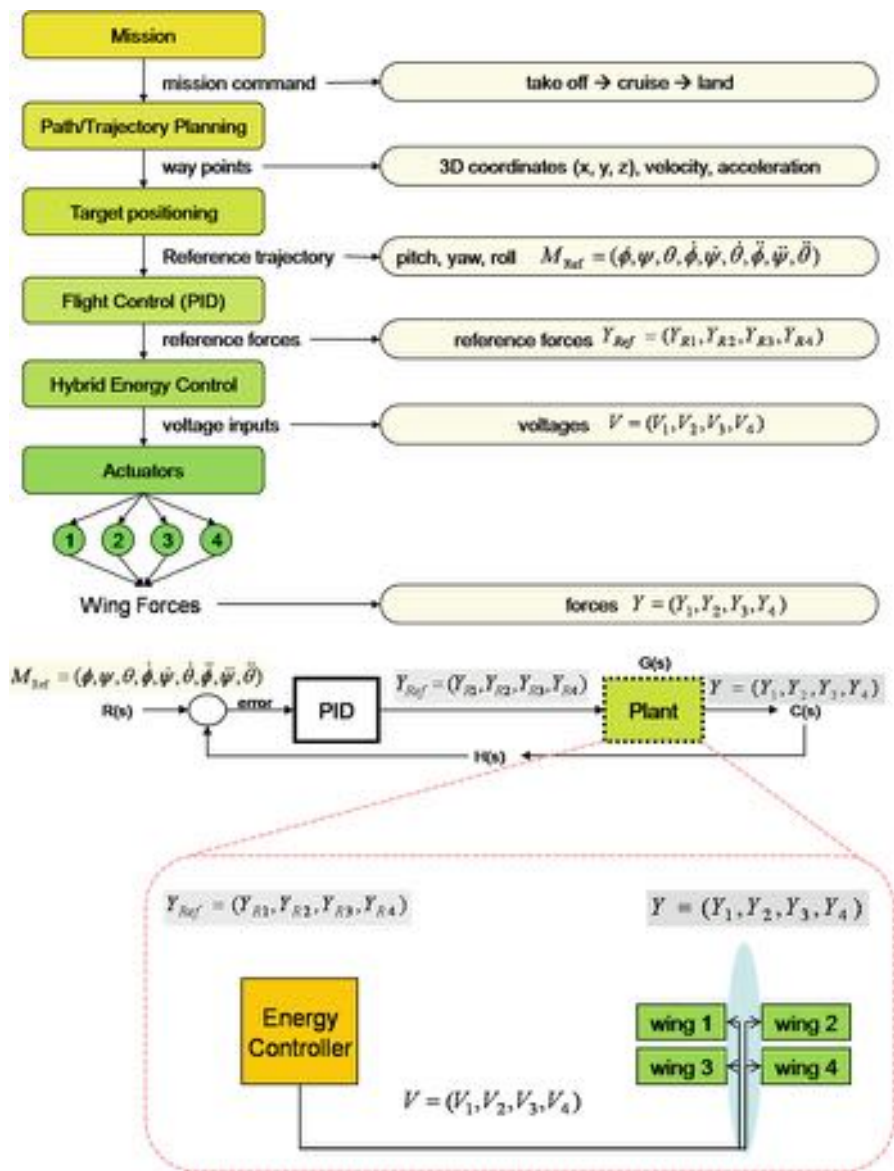

Fig. 57.21 MAV hierarchical control structure

setup without the need to initially subject the prototype to unnecessary wear and tear, crashes, and in-flight failures. The vehicle has to be made 6 DoF capable by the installation of an indigenous, low-weight autopilot (Ratti et al. 2011b) (Fig. 57.19 and 57.20).

Fig. 57.22 Linear control visualization

57.13 Simulation Results

The system step response for a given initial condition of $\phi_{\text{Ref}} = -12^\circ$, $\theta_{\text{Ref}} = 11^\circ$, $\psi_{\text{Ref}} = 11.5^\circ$ is shown in Fig. 57.26. The MAV has also been commanded to maintain a level altitude of 20 cm above its launch position (Fig. 57.27).

57.13.1 Constant Gain: Manually Selected

The PID gains for the mid-level controller have been kept constant at reasonably agreeable values in the first controller and the system response for the above reference parameters is shown in Fig. 57.26. The five graphs show pitch, roll, yaw, altitude, and actuator thrust response versus time.

57.13.2 GA-Based Gain Tuning and Performance Improvement

Typically, the gains in the PI controller are adjusted by observing characteristic factors such as rising time, settling time, and overshoot under a step response until the desired performance metrics are achieved. However, the QV system is highly nonlinear and the driving mechanism is underactuated as well; thus the choice of gains is highly experimental and cannot guarantee satisfactory performance. In order

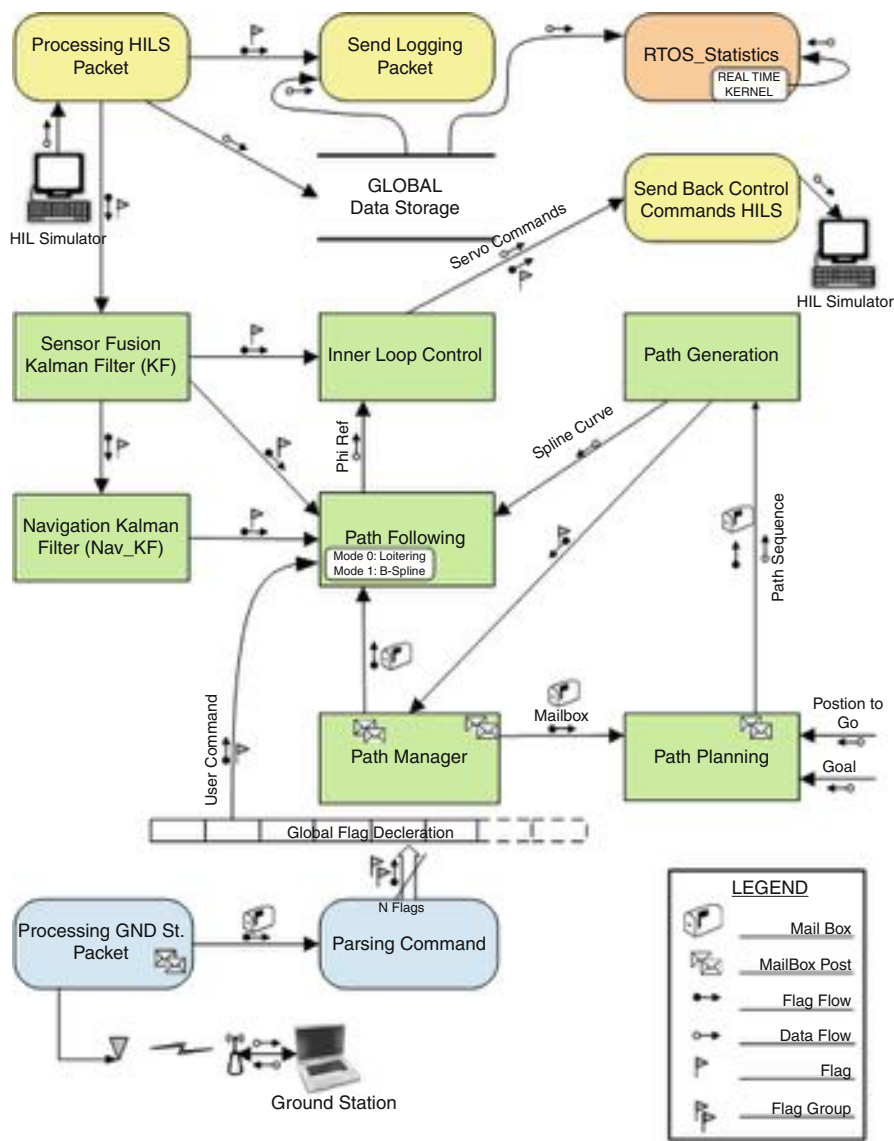

Fig. 57.23 RTOS architecture for flight-control and path planning

to optimize the step response performance of the MAV, a good set of PI controller gains are necessary; the genetic algorithm (GA) is applied towards that goal. The performance of the proposed system can be measured by the system response times to a step input.

Fig. 57.24 MAV designs based on coil actuators, micro linear actuators, cam-follower drive trains

Fig. 57.25 3 DoF benchtop prototype

Cost Metric: The cost function for the GA is defined as the cumulative area under the step response graph until the system settles down. The smaller the area, the faster the response time.

Generally, in order to apply the GA to a selection problem, the gene structure and evaluation method should be prepared; in this research, the set of PI gains is defined as a gene and the fitness function is defined as the cost metric. The crossover rates and the mutation rates are set as 100 and 10 %, respectively. Figure 57.28 highlights the results of gain tuning using the devised GA after six generations.

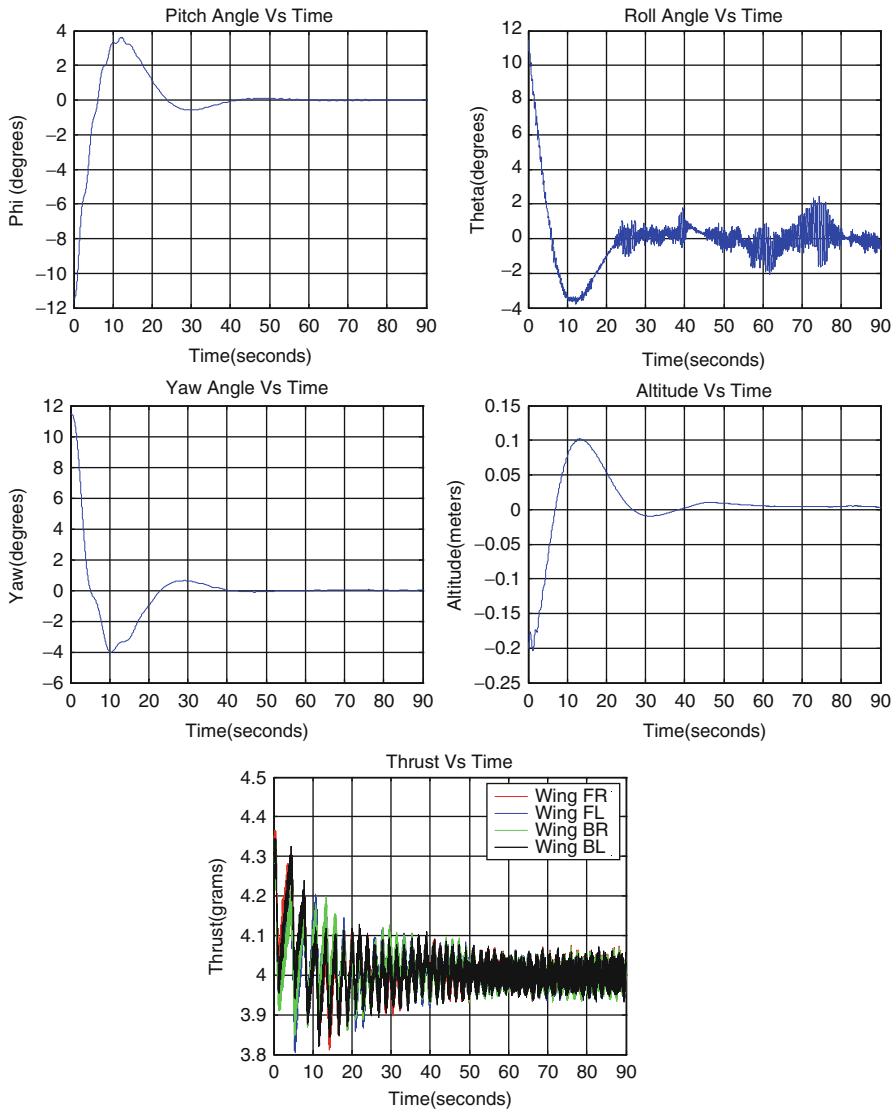

Fig. 57.26 Linear/hybrid energy control step response: manual PID gain selection

There has been a marked performance improvement over manual gain selection. Settling time for manual selection was about 50–60 s to start with, with an overshoot of approximately 4°. The GA-based gain tuning had 0° overshoot and the settling time has been reduced to approximately 5 s. The step response after GA tuning conforms to a critically damped system and has shown very promising results (Table 57.3).

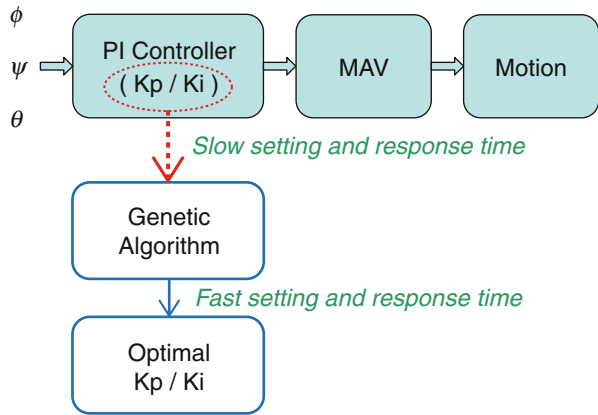

Fig. 57.27 GA tuning block diagram

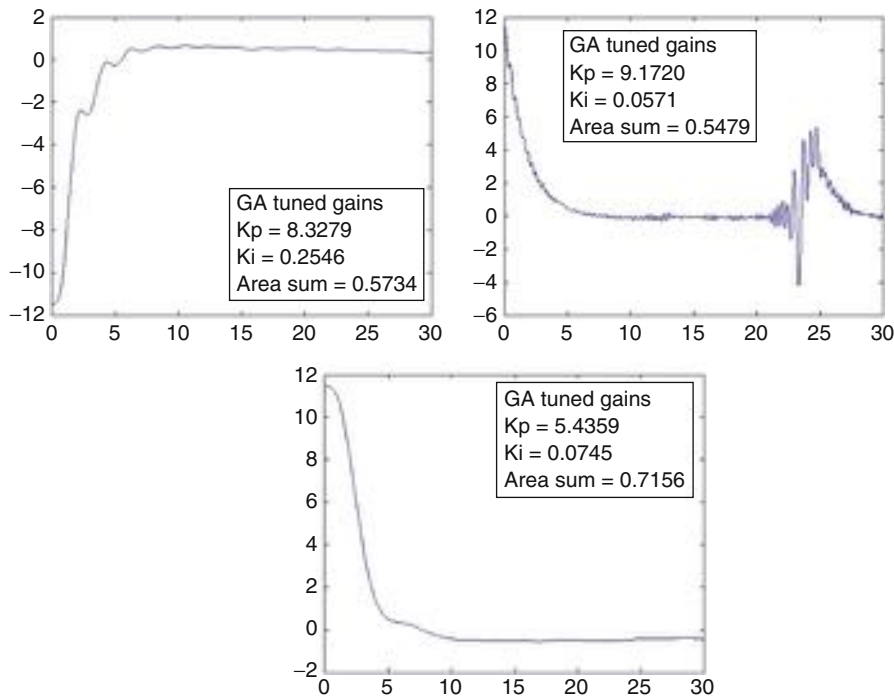

Fig. 57.28 Linear control/hybrid energy control: step response: GA-based PID gain selection

57.13.3 Visualization Environment and Simulation

The indigenous flight simulator/Visualization environment has been shown here:

57.14 Conclusions

The chapter presented the novel designs and developmental progress made towards the engineering of a high-endurance, micro aerial robot for ISR operations. The advent of a novel flight control and MAV configuration was illustrated in the form of a quad-wing MAV (QV). The discussion was led onto the design and successful development of a new actuation methodology for MAVs based on the dynamics of insect flight. The fixed frequency, variable amplitude (FiFVA) actuation was engineered and used to successfully demonstrate the possibility and effectiveness of replicating insect wing-flapping mechanisms. High-performance, onboard processing capability is essential for any surveillance robot, and thus

the stringent size, weight, and power consumption limitations of micro flyers addressed in the form of the MARC avionics control board. The aerodynamics of the MAV were researched towards the design and development of efficient wings and flapping/feathering schemes. The research aims to improve energy efficiency of MAVs, resulting in higher endurance micro robotic aerial vehicles, with the capacity for both military and civilian applications (Fig. 57.1).

Acknowledgments We thank the Air Force Office of Scientific Research for sponsoring the research and development of the project. We also acknowledge the support of our industrial partner Impact Technologies, LLC. Abstract

Micro air vehicles (MAVs) face a unique set of challenges due to their size. Limited payload capacity leads to considerable constraints on power sources, sensors, and communication systems. Power sources are by far the most weight-inefficient components on an MAV. MAV designers are forced to look elsewhere to optimize their designs. The best way to do so in lieu of focusing on improving battery technology is to optimize the systems that draw power, thereby increasing endurance. Motors, onboard processing, and communications transceivers are the largest three power consumers on MAVs today. While motors and embedded processing are important to optimize, the sheer number of available communications options may leave MAV designers unsure how to proceed. By building an MAV around its onboard communications system, designers can increase reliability, endurance, and capability with little or no added cost. Making the right data link and antenna choices at the beginning of the MAV design process greatly eases the constraints later in the project. Specific MAV missions can and should inform the choice of the best communication architecture. Care must be taken to ensure that the end result meets the power, aerodynamic, and electromagnetic requirements for the particular MAV and its particular mission. This chapter seeks to answer many of the communications link questions that MAV designers may have and give a high-level overview of the factors that affect MAV data and control links.

58.1 Introduction

Micro air vehicles (MAVs) face a unique set of challenges due to their size. Limited payload capacity leads to considerable constraints on power sources, sensors, and communication systems. Communications is perhaps one of the largest problems since it has repercussions on so many other onboard systems. If an MAV cannot communicate, then it is of little use as it cannot be teleoperated and it cannot report back data. Many of today's roles for MAVs are indoors where loss due to walls, steel framing, and electromagnetic interference are commonplace. This chapter seeks to explore the various obstacles to MAV communications as well as present several possible solutions to overcoming those obstacles. The majority of this chapter is presented in layman's terms so MAV designers without a heavy RF background can gain the foundational conceptual knowledge to make informed design decisions.

58.2 The Major Considerations

The DARPA definition of an MAV requires that the vehicle be smaller than 15 cm in any dimension (McMichael and Francis 1997). A flying platform with dimensions of merely 15 cm drastically constrains the payload available for designers to use (Zhu et al. 2007). In an average communications system, provisions must be made

for batteries, receivers, transmitters, modulators, digital circuitry, antennas, and interconnecting cabling. Luckily, many of these parts of the transceiver chain are now available in single chip solutions.

58.2.1 Power Considerations

The first major constraint is power. Batteries are typically the heaviest single component (and the least weight efficient) on an MAV. They require a large amount of supporting structure that does not directly provide power. The energy densities available in batteries are an order of magnitude lower than the gasoline used to power the propulsion systems on larger vehicles. For example, the energy densities of common lithium-ion polymer batteries are around 0.5 MJ/kg, whereas gasoline has an energy density of 44.4 MJ/kg (Voelcker 2009). For comparison, a 1-ton car traveling at 100 miles per hour has approximately 1 MJ of kinetic energy (Beidel 2012). A 9-V 1,200 mA-h battery weighs on the order of 35 g. The well-known Black Widow MAV weighs a total of 80 g (National Research Council 2002). This means that the battery accounts for the vast majority of the payload.

Recently, MAVs have started to utilize other power sources such as hydrogen fuel cells. While not technically an MAV, the Hornet, a 6-oz, 15-in. vehicle, successfully demonstrated in 2003 that fuel cells can provide for powered flights of up to 15 min (AeroVironment, Inc. (AV) 2012). Hydrogen and solid-oxide fuel cells provide energy densities much higher than traditional batteries. These technologies will become very viable power sources once miniaturization technology has matured. Many of the recent developments in this field have been driven by cellular phone technology since cellular phones face many of the same constraints that are present in MAVs.

This chapter does not focus heavily on battery or power source technology. Instead, it seeks to present power saving and optimization recommendations for MAV communications subsystems. By optimizing the communications link, designers can increase flight endurance by reducing wasteful power consumption.

58.2.2 Data and Command Link Considerations

Modulation, or the means by which data is encoded on an RF signal, should be tailored to specific MAV roles. Some modulation schemes are designed for spectral efficiency (bandwidth efficiency), some for power efficiency, and others for throughput robustness (Green 2000). There are numerous modulation types, each having unique advantages and disadvantages. The following section describes common analog and digital modulation schemes, amplifier types, and their associated advantages and disadvantages for use in MAVs. Since everything is a trade-off in systems engineering, it is important to know what can and should be sacrificed to meet particular communications requirements. This section should help MAV designers determine which communications trade-offs are worth making.

From a systems engineering perspective, maximizing the efficiency of the MAV's communication links can save power and increase reliability. Higher-efficiency communications can ease the impact of the inherent power constraints since it is comparatively far easier to optimize communication systems than to optimize their power source. Before delving into the particulars of modulation, a primer on amplifier classes is needed in order to appreciate the modulation trade-offs.

58.2.3 Amplifier Classes

Amplifiers are one of the most important components in a transceiver. Radio waves are generally very weak and must be amplified many hundreds or thousands of times to be useful. Amplifiers come in several varieties known as classes. The trade-off between the classes is between output linearity and power consumption. Linearity is a term that describes how accurately an amplifier increases the power level of a signal without distorting the signal. Some might refer to linearity from a qualitative perspective as fidelity (Weisman 2002). This chapter will cover A, B, AB, and C class amplifiers.

For the most accurate and linear amplification of an input signal, a class-A amplifier is desired. Class-A amplifiers are active (or conducting) all of the time. Class-A amplifiers can be thought of as pushing and pulling the signals to reproduce them most accurately. While this is good from a linearity perspective, Class-A amplifiers are very inefficient at converting source power to RF power (Quilter 1993). The power that is not converted to RF is converted to heat. Battery power converted to heat is waste. Class-A amplifiers are required in certain systems where high data rates are required. As a general rule of thumb, class-A amplifiers should be avoided for MAV applications since efficiencies are generally around 25 %.

Class-B amplifiers are conducting approximately half of the time. They can be thought of as only pushing the signals and letting them return to zero on their own. This means that the power required is roughly one-half of a class A, but since the signal is not being pulled to the exact input signal, the output can vary somewhat from the input. This leads to non-linearity and distortion (Quilter 1993). To demodulate signals with high accuracy, linearity is required. If a digital sequence in a signal was supposed to contain 10110 but the values of 1 and 0 were weak, a nonlinear amplifier might skew some of those values to the point that they might get interpreted as 10111. In a digital system, this would be problematic. Such nonlinearity is typically unacceptable in high-bandwidth systems since the error rates would climb to unacceptable levels (Green 2000). Class-B amplifiers have efficiencies on the order of 75 %.

Class-AB amplifiers are a compromise between A and B amplifiers. They operate more than 50 % of the time but less than 100 % of the time. This results in acceptable linearity with lower power requirements than a pure class-A amplifier. These amplifiers can be biased toward class-A operation or class-B operation, thereby allowing the designer to tune where they want the power to linearity trade-off to fall.

These amplifiers are popular because they afford designers a degree of flexibility. Class-AB amplifiers can achieve efficiencies between 50 and 70 % (Quilter 1993).

Class-C amplifiers are much more efficient than A or B since they operate less than 50 % of the time. This results in efficiencies exceeding 80 % (Quilter 1993). Class-C amplifiers are typically not used for advanced modulation since they have low-output linearity (Chi and Das 2008). They can however be used for certain low-bandwidth applications where linearity is not required. This type of amplifier can be used for continuous wave (CW) (such as Morse code transmission) and frequency-shifted modulation schemes where amplitude is not terribly important. These modulation schemes will be discussed later in this chapter.

The input and output waveforms for each of these amplifier classes are shown below for comparison (Fig. 58.1).

When viewed graphically, the effects of only conducting part of the time become apparent. Every section of the input signal that is not reproduced accurately results in distortion of the signal and an increased occurrence of demodulation errors.

For most MAV applications, the bandwidth requirements will be low to medium since the power requirements of high-data-rate sensors are typically too great for MAV platforms. Telemetry, sensor data, and command and control are common MAV data links. Class-AB amplifiers are typically acceptable for use on MAVs with such data links since the data rates are comparatively low. If telemetry and low-speed sensor traffic are the only things sent across the data link, then a class-B amplifier may even suffice. MAV designers must determine the sensor data rates and ascertain how much error is acceptable. Switching from a class-AB to a class-B amplifier could provide several minutes of increased mission endurance. A high-level summary of the amplifier classes is shown in Table 58.1.

Modulation schemes are the next key element that must be understood in order to make the best decision for an MAV communications architecture. In order to understand the underlying theory behind the most popular digital modulation schemes, a primer on three common analog modulations is required. The waveforms for the three basic types of modulation are shown below (Fig. 58.2).

58.2.4 Amplitude Modulation (AM)

Amplitude modulation (AM) is an analog modulation scheme that has been used for a long time. AM modulation increases and decreases the envelope of the RF carrier to convey information. The term envelope refers to the waveform's shape that is formed by the changing amplitude of the faster moving carrier. Figure 58.2 shows an AM-modulated waveform.

The "value" of the modulated data is determined by the height of the envelope at any point in time. The faster moving waveform inside is the carrier. The modulated data rides on top of the carrier. An AM receiver simply extracts the envelope, so the value of the signal can be determined. The advantage to this modulation scheme is that it is very simple to demodulate. An AM demodulator can be implemented

Fig. 58.1 Comparison of amplifier waveforms

with very little hardware and requires very little power (Carr 1997). The downside to this modulation scheme for use in MAVs is that it is relatively bandwidth limited. Bandwidth is a term that describes how much data can be sent per unit time. If the MAV is required to send back data at a medium or high rate, AM is definitely not the best candidate.

Table 58.1 Pros and cons of various amplifier classes

| Amplifier class | Pros | Cons |
|-----------------|-----------------------------|--------------------------|
| A | Highly linear | Highly power inefficient |
| AB | Reasonable linearity | Low to medium efficiency |
| B | Reasonable power efficiency | Low to medium linearity |
| C | Very power efficient | Low linearity |

Fig. 58.2 Comparison of modulation waveforms

The other primary disadvantage is that the only means of overcoming noise in an AM system is to increase the transmit power. Increasing transmit power drains the batteries at a faster rate. Noise is present in all communications systems. Noise comes from numerous natural and man-made sources. Anything that contains rapidly changing electrical currents generates RF noise. The sun, auroras, car starters, and everything with a temperature above absolute zero all create a degree of RF noise that can make receiving signals difficult. Using filtering or placing receiver electronics in a Faraday cage can reduce noise levels. Faraday cages act as an RF shield, so spurious and unwanted signals stay out of the receiver. There are other modulation schemes that are significantly less sensitive to noise than AM.

One of the main problems with AM modulation is that AM transmitters require high linearity since the value of the data is directly proportional to the instantaneous power level. If the amplifiers were nonlinear, then the true value of the data would have to be scaled by some correction factor to be interpreted correctly. Linear amplifiers are more complex and require more power than nonlinear amplifiers as was previously discussed.

The last, and perhaps most problematic, issue is spectral efficiency. AM wastes a large percentage of the transmitted energy with redundant and unused power. AM modulation creates a carrier and two main sidebands. Each sideband contains a duplicate version of the data, so only one of the sidebands is actually used by most AM receivers. The extra sideband conveys no extra information yet the power in this redundant sideband must be sourced by the battery (Carr 1997). For these reasons, AM is not the most efficient modulation scheme for MAVs to use.

58.2.5 Frequency Modulation (FM)

Frequency modulation (FM) offers many advantages over AM. FM encodes information in frequency offsets from the main carrier frequency (Carr 1997). In an FM system, the shift off of the main carrier frequency (positive or negative) represents a value. Notice in the FM waveform that the output power envelope is constant over time and only the frequency changes (Weisman 2002).

The main advantages of FM are noise resilience, signal strength resilience, linearity invariance, and higher efficiency. FM is relatively impervious to noise because noise superimposes itself on top of the desired signal, thereby randomly affecting the amplitude. Since FM receivers are not demodulating based on amplitude but on frequency, the noise has little effect on the demodulated signal. This extends itself to allow FM signals to be somewhat signal strength invariant as well. Within reason, a frequency shift in a signal with a small amplitude can be demodulated just as easily as a signal with a large amplitude. By comparison, a weak AM signal will become increasingly inundated by noise and may not be discernible.

Linearity does not affect FM signals like it does AM since linearity directly influences amplitude and not frequency. This means that class-B or class-C amplifiers could be used without a significant impact on the reliability of an FM link (Weisman 2002).

FM signals have a much larger bandwidth than AM signals. This allows them to carry more data per unit time. Spectrally, FM signals are much more efficient than AM as well since the data in all of the sidebands is used. This means that there is little wasted energy. An FM signal's sidebands increase in amplitude and number as the modulated signal increases in frequency deviation from the carrier (this is known as a modulation index).

There are two main downsides to FM modulation. The first is that it requires a significantly more complex modulator and demodulator than AM. This not only increases cost but typically results in a larger demodulation circuit. Another negative aspect of FM is that the sidebands extend out infinitely far in frequency (theoretically), so a wide unused RF range must be allocated to keep FM signals from interfering with neighboring signals. To constrain the transmitted frequencies to a particular range, additional filters must be added. This filtering can distort the signal, but this is typically not a large problem. FM modulation is perfectly conducive to use in MAV applications. It is appropriate to use FM for control and telemetry links. Until the advent of 2.4 GHz radios, hobbyist radio control transmitters typically used FM. The only reason that it is not recommended for MAV data links is that there are multiple digital modulation techniques that have much higher efficiency.

58.2.6 Phase Modulation (PM)

Phase modulation sends information via the instantaneous phase of the carrier signal (Carr 1997). This modulation scheme is not terribly common for analog data links because it has some inherent weaknesses. The first weakness is that there is not

Fig. 58.3 4-QAM and 16-QAM constellations

a good way to determine whether a signal is at -180° or $+180^\circ$ since they look identical. The modulation hardware is also more complex than FM. Spectrally, PM is not terribly efficient either as it doubles the required baseband bandwidth. PM is used far more often in its digital form. An example of a digital PM signal is shown below (Fig. 58.3). Notice the phase transitions. In its digital form, PM is known as PSK or phase-shift keying (which will be explained later).

This modulation scheme is used as a component of many advanced digital modulation schemes. Its usefulness as a stand-alone modulation scheme is questionable for MAV applications.

58.2.7 Quadrature Amplitude Modulation (QAM)

QAM is the one of the most common modulation schemes used for high-bandwidth digital wireless data links. IEEE 802.11 (Wi-Fi), IEEE 802.16 (WiMAX), and numerous cellular standards (HSPA+) are based on QAM. QAM attempts to pack more data per unit time into the signal. This is accomplished by adding additional carriers. By amplitude modulating these two out of phase carriers (one carrier called I and the other “quadrature” carrier 90° out of phase called Q), two independent values can be sent at once. In order to determine what value the combination has, one carrier is assigned to an I value and one is assigned to a Q value on a Cartesian coordinate grid called a constellation (Weisman 2002). Each unique I, Q coordinate can be associated with a “symbol” value on the plane. The symbol mapping is agreed upon ahead of time by the transmitter and receiver, so proper decoding can take place.

Constellations can be implemented with varying degrees of granularity. If only positive and negative values are sent for I and Q, then there are four possible combinations. This would mean that one of only four possible values could be sent

at once. In order to increase the data rate, additional possible values can be added by breaking those quadrants up into smaller quadrants. The constellations for 4-QAM (4 regions or a 2×2 constellation) and 16-QAM (16 regions or a 4×4 constellation) are shown below (Fig. 58.3).

Note that 16-QAM can send 4 bits in each symbol whereas 4-QAM can only send 2 per symbol. That means that the theoretical maximum data rate of 16-QAM is twice that of 4-QAM. In reality, 16-QAM, 64-QAM, and 256-QAM are the most used for wireless data links. As the density of the constellation increases, the required demodulation accuracy increases and the amount of acceptable error decreases. If a value is not demodulated correctly due to noise, then the wrong constellation value will be read resulting in data corruption. Notice how much error is allowed in 4-QAM before a boundary is crossed compared to 16-QAM. For this reason, QAM density cannot be extended indefinitely. Only in high-precision optical links can extremely high-density constellations such as 4096-QAM be used (64×64 constellation) (Weisman 2002).

The complexity of QAM transceivers is much higher as well. The additional out-of-phase demodulator requires additional mixers, filters, and amplifiers, which increase cost and device footprint size. The most significant problem, however, is that QAM is an advanced form of AM modulation. As such, it requires that the amplifiers be linear. This means that QAM transceivers are power inefficient.

Noise susceptibility is a large problem. Noise causes improper constellation decoding, so if the MAV is expected to communicate in an urban environment with a high noise floor, range will be limited. The large number of noise sources present indoors may also be a problem for MAVs with indoor missions. QAM is therefore not recommended for command and control data links where high reliability is required. Nonessential, error-tolerant high-data-rate sensor traffic such as video are more suited to QAM modulation.

58.2.8 Phase-Shift Keying (PSK)

PSK uses the same constellation principle as QAM. The difference is that instead of modulating the main and quadrature carriers' amplitudes, it instead modulates their phase. Each unique phase combination is mapped to a set of symbols (Weisman 2002). Instead of implementing the constellation in rectangular I and Q terms as in QAM, PSK instead implements the constellation on a circle. Constellation density increases as points are added to the circle. A standard quadrature PSK (QPSK) and a higher-density 8-PSK constellation are shown below for comparison (Fig. 58.4). Although viewed from a different perspective, a QPSK constellation is technically equivalent to the 4-QAM constellation, and the signals are indistinguishable.

PSK is less susceptible to noise than QAM since noise directly affects amplitude and not phase. For this reason, PSK is more suited to noisy urban environments. PSK is also bandwidth efficient. The negative aspect to PSK is that phase is relative,

Fig. 58.4 QPSK and 8-PSK constellations

so the receiver must be phase and frequency locked with the transmitter in order to determine the phase offsets.

Binary phase-shift keying (BPSK) is a variant of PSK that can only encode a 1 or 0. The constellation contains only two points. A sine wave is interpreted as a 0, and an inverted sine wave is interpreted as a 1. This is not spectrally efficient but is very robust as a large amount of error can be tolerated before data is corrupted. For long range high-reliability data links with relatively low data rates (such as control links), BPSK is optimal.

58.2.9 Frequency-Shift Keying (FSK)

Frequency-shift-keying is the digital form of FM modulation where the frequency shift is discretized. The simplest form is called binary FSK (BFSK) where frequencies lower than the carrier are interpreted as zeroes and frequencies higher than the carrier are interpreted as ones (Weisman 2002). This concept can be extended by assigning different symbol values to the various frequency offsets. This can be thought of as a linear constellation in one dimension.

FSK, like FM, requires a greater bandwidth since the carrier can move up and down in frequency. FSK has two major advantages over PSK. First, there is no need in FSK to phase and frequency lock with the transmitter. Second, since FSK is a form of FM, it does not require highly linear amplifiers. For this reason, if an MAV design does not have much overhead left on the power budget, FSK would be better than PSK or QAM. The downside to FSK is that at a given power level, the error rate is higher than PSK.

Table 58.2 Summary of modulation schemes

| Modulation | Environment | Power required | Data rate | Link reliability | Bandwidth |
|------------|---|----------------|-------------|------------------|-------------|
| AM | Low noise, rural, long distance | High | Low | Low | Low |
| FM | High noise, urban or rural | Low | Medium | High | Medium |
| PM | High noise, urban or rural | Low | Medium | Medium | Medium |
| QAM | Low noise, outdoor, rural | High | Very high | Low | Medium-high |
| PSK | High noise, urban or rural, indoor or outdoor | Medium | Medium-high | Medium-high | High |
| FSK | High noise, urban or rural, indoor or outdoor | Low | High | Medium-high | High |

58.2.10 Modulation Summary

MAV designers must prioritize their needs based on MAV roles. Power, robustness, and data rates are all constraints at odds with one another. For maximum range and minimum power consumption, FSK is likely the best choice. A high-power amplifier is required for long-distance data links, so it is best to design for FSK modulation that can use amplifiers that are efficient at the expense of linearity. For high-reliability operation in noisy environments, BPSK is best suited since it can tolerate a large degree of noise and nonlinearity. For the highest data rates, a high-order QAM modulation is best. Multiple data links may be used concurrently for the various onboard systems so long as care is taken to avoid self-interference. If multiple data links are used, designers should ensure that the transceivers support a sleep mode to reduce the power requirements. There are other modulation types, but many of them are variations or combinations of the six mentioned here. Table 58.2 sums up the features of the six modulation schemes discussed in this chapter.

58.2.11 Multiple Access

Modulation alone does not solve all MAV communication issues since there is no provision for communicating with multiple MAVs concurrently. Swarm operations are a very real possibility in the future, so having a multiple access architecture in place is advisable. Communicating with multiple receivers concurrently is known as multiplexing or “multiple access.” Of course, the trade-off here is that this capability requires yet more transceiver complexity and reduces the error tolerance of the data link.

There are three primary methods for communicating with multiple recipients: time division multiple access (TDMA), frequency division multiple access (FDMA), and code division multiple access (CDMA). Do not get confused; these are not modulation schemes. These operate in a layer above modulation that requires additional processing and therefore additional power consumption. These multiple access schemes are required if multiple MAVs must communicate in the same frequency space at the same time.

58.2.12 Frequency Division Multiple Access (FDMA)

The first multiple access scheme breaks up the users into frequency slots. This is called frequency division multiple access (FDMA). Each user is assigned a particular frequency (called a channel) by a controller. Each user then can use that one frequency as long as is needed. This would be like people talking at the same time but in different pitches, so the individual speakers could be distinguished concurrently.

The controller knows the frequency allocations and can quickly switch to the various frequencies to communicate with multiple MAVs. Each user can transmit and receive constantly since each has a dedicated channel. This allows for data rates that are equivalent to non-multiple access scenarios. FDMA requires a much larger available bandwidth since whole channels must be allocated to each user. The downside to this is that users that are not actively utilizing their channel are still assigned a channel. This leads to wasted time and bandwidth. If a limited bandwidth is available (as is almost always the case), only so many channels can be carved out before transmitters start leaking over into adjacent channels. For this reason, FDMA cannot support large numbers of users. If a large MAV swarm must communicate, pure FDMA is not the best choice. FDMA is not a good choice for mesh communications either. If each MAV must communicate with other MAVs, FDMA requires that each MAV either switch frequencies or send information via a controller acting as an intermediate relay (Green 2000).

58.2.13 Time Division Multiple Access (TDMA)

The second method is similar to a group of people talking in a round-robin fashion where one person talks and then the next person talks and so on until all of the people have talked. At this point, the first person can again talk. This is known as time division multiple access (TDMA). The difference between people talking and TDMA is that the times during which each person is allowed to talk are assigned. Time slots are assigned to and reserved for each transmitter, so two are never transmitting at the same time. This allows a scheduled rotation to take place, so multiple MAVs can share the same frequency. Each complete rotation is called a frame. Each frame is broken into time slots assigned to each user. A diagram of a TDMA rotation for four users is shown below (Fig. 58.5).

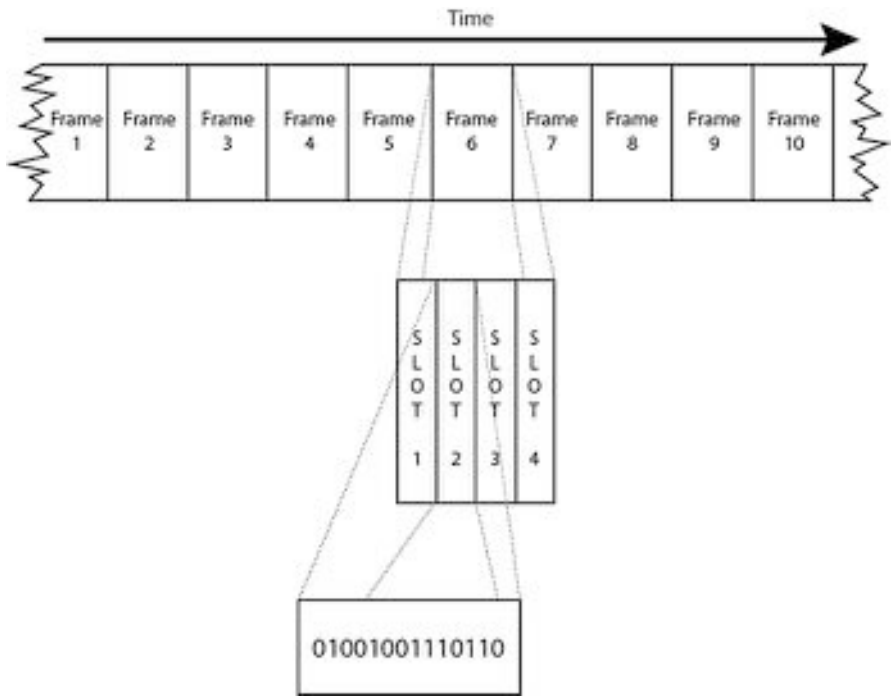

Fig. 58.5 Visualization of time-domain multiple access

This access scheme requires there to be a controller that is in charge of coordinating and assigning the time slots. As additional transceivers are added, the controller must re-allocate the frames and inform all of the transceivers of the new rotation parameters. The downside to this scheme is that the data throughput for any one user drops as more users are added. Furthermore, all users must be time synchronized, so every user knows when their frame slot starts and ends. This requires a more complex controller. For large MAV swarms where high data rates are required, TDMA may not be the best choice. For small swarms (10–20 MAVs), TDMA is a reasonable choice. An advantage TDMA has over FDMA is that MAVs can communicate with one another since each MAV is listening and transmitting on the same frequency.

FDMA and TDMA can coexist to gain the best of both worlds and increase the number of supported users by using TDMA on several FDMA channels. This primarily serves to increase the maximum possible number of concurrent users.

58.2.14 Code Division Multiple Access (CDMA)

The latest multiple access scheme to see widespread use is called code division multiple access (CDMA). CDMA is equivalent to a group of people speaking in multiple languages. Anyone speaking a different language is ignored just like all

of the other environmental noise. CDMA assigns each user a unique code that can be used to modulate that user's data. The receiver then tries to correlate all of the received signals with the unique code to interpret the data. A CDMA receiver can pull the coded data out of noise since noise is random and the individual signals are not random. The nonrandom nature of the desired signal allows it to be pulled out of the noise by a digital receiver that knows the characteristics of the desired signal.

CDMA is a spread-spectrum multiple access scheme where each user's bandwidth is spread evenly across the entirety of the used bandwidth. This scheme requires a more complex and power-hungry transceiver than FDMA or TDMA since relatively complex mathematical processing must be done in real time to correlate the various codes with the signals.

If MAVs must operate with a very limited bandwidth, CDMA is not a good choice since it requires much more bandwidth than FDMA or TDMA. This, however, can be good and bad. Since the signal is spread over a large frequency range, it is more resistant to interference from narrowband noise sources. CDMA is much better in noisy urban environments than FDMA or TDMA. If a noise source is present at or near the frequency used for FDMA or TDMA, the signal can quickly become difficult to demodulate whereas a CDMA data link would still be able to operate (Weisman 2002).

Another advantage of CDMA is that it can support a large number of users at the same time on the same frequency. Since a unique code is used for each receiver, neighboring transmitters can transmit at the same time and still be received without difficulty. For this reason, CDMA is an excellent choice for swarm MAV applications.

If the MAV application requires a solid jam-resistant data link, then CDMA is the best multiple access scheme. While TDMA signals could be confusing to interpret, jamming them is trivial since all of the signals are at one frequency. FDMA is slightly more difficult to jam since multiple frequencies are involved; however, the frequencies are all relatively close to one another. A high-power jammer would have enough bleed over into adjacent channels that an FDMA system could be jammed quite easily (Chi and Das 2008).

CDMA is hard to jam because the energy is spread across a large frequency range. Jammers typically operate at a fixed frequency at any given time. A traditional jammer would only affect a small portion of the CDMA bandwidth since there is only so much power available with which to jam. To a CDMA receiver, a jammer would merely raise the noise floor several dB. This is not terribly problematic for CDMA since CDMA can operate below the noise floor anyway (Kashyap et al. 2004).

58.3 Aerodynamic Issues

The second large constraint is not based on power but on aerodynamics. The lifting capability of a 15 cm airfoil is relatively low. The addition of communications systems is not only heavy but may adversely affect the aerodynamic properties

of the platform. To overcome this, designers must integrate the communications systems into the airframe as much as possible while utilizing the lightest available materials.

58.3.1 Antenna Integration and Frequency Issues

Data link frequency is a major concern. The tradeoff with respect to frequencies is threefold. Low-frequency signals are much more able to penetrate walls and travel large distances than are high-frequency signals at the same power. On the other hand, low-frequency signals inherently have less available bandwidth (Green 2000). If high-data-rate digital traffic must be relayed, then low frequencies will not be able to support the necessary bandwidth. This is a key constraint, but MAVs are more constrained by size than by bandwidth.

Low-frequency signals are received and transmitted much better by antennas that are on the same order of magnitude as the wavelength of the signal (Green 2000). Wavelength is the physical distance required for a signal to go through one cycle. Low frequencies have high wavelengths, and high frequencies have low wavelengths. With the limited space available on an MAV, designers are forced to move toward higher-frequency communications simply to accommodate the antennas. Large antennas weigh more and have more aerodynamic drag.

There are three antenna classes that are particularly conducive to use on MAV platforms. The first is the patch antenna, the second is the whip monopole style antenna, and the third is the dragged wire-style antenna.

This section will describe the advantages of each antenna type and will demonstrate how best to integrate them with MAV platforms from an aerodynamic and RF standpoint.

58.3.2 Patch Antennas

Patch antennas use thin microstrips laid down on a flat surface that is separated from a “patch” of metal that acts as a ground plane. Ground planes effectively act as an RF mirror to extend a short antenna to twice its electrical length (Weisman 2002). A well-designed ground plane can greatly increase the efficiency of an antenna. The microstrips are designed to be $\frac{1}{2}$ wavelength (or $\frac{1}{4}$ in some cases). An example of a simple dual patch antenna is shown below (Fig. 58.6).

Gain is a term referring to the degree that an antenna concentrates its energy in a particular direction. Do not think of gain as energy that an antenna creates. Antennas cannot create additional power since they are passive devices. Gain is a measure of how much more power a receiver in the direction of the gain lobe would see compared to an antenna that radiated perfectly evenly in all directions (the so-called “isotropic radiator”). This quantity is measured in the logarithmic unit of decibels relative to an isotropic radiator, or dBi. The term “lobe” refers to the direction of the

Fig. 58.6 Example of a patch antenna

Fig. 58.7 Example of a patch antenna radiation pattern

gain (Carr 1997; Schwarz 1990; Green 2000). A diagram of an example radiation pattern for a patch antenna with a large gain (main lobe) in the 90° direction is shown above (Fig. 58.7).

Gain is good and bad depending on the design application. If the design application requires that there be omnidirectional (e.g., all horizontal directions) coverage, then a low-gain antenna is desired. If the data link is fixed in a particular direction, then it is good to have very high gain in that direction. The higher the gain, the more narrow the main lobe. The smaller secondary lobes are always present and result from nonideal characteristics that cannot be totally overcome in physical antennas (Durney and Johnson 1969).

The gain of a patch antenna can be tuned by an RF designer to meet the particular design specifications of MAV designers. Patch antennas are small and easy to integrate into the airfoils of wings or vertical stabilizers. For this reason, they are particularly conducive to use on an MAV from an aerodynamic perspective. Patch antennas can easily be integrated into wing surfaces or vertical stabilizers.

Fig. 58.8 Example of a whip monopole antenna

58.3.3 Whip Monopole (Rubber Ducky) Antennas

Whip antennas are common in consumer electronics. The external antennas on wireless routers are examples of whip antennas. Older cell phones often used whip antennas. An examples of a removable whip monopole antenna is shown below (Fig. 58.8).

This antenna style has a relatively low gain, so it is useful for omnidirectional applications. The main reason that this antenna type is covered in this chapter is that they are what many people think about when they start to research antennas. As such, MAV designers may flock to them as an easy solution. This is not advisable for MAV designs. The main reason is that whip monopoles are aerodynamically troublesome. Dragging a vertical pole through the air creates turbulence in the form of shed vortices that detrimentally affect a MAV's drag characteristics. Unless the antenna can be integrated into the vertical stabilizers in such a way that laminar flow is maintained on the downwind side of the antenna, avoid their use.

58.3.4 Dragged Wire Antennas

Dragged wire antennas have been used for a long time for both MAVs and larger platforms. This type of antenna has the advantage that it can be cut to any length to match the wavelength of the desired frequency (Schwarz 1990). Adding or removing wire length has little effect on the aerodynamic drag of the MAV (Fig. 58.9).

Fig. 58.9 Example of a dragged wire antenna

Low-frequency patch and monopole antennas become too large to integrate into the vehicle. If the MAV application requires operation at significant distance, then the dragged antenna is the best choice. As was stated before, low frequencies are better for long-range communications. Aerodynamically, the dragged wire antenna is not as favorable as an integrated patch antenna and also introduces additional risks to the platform such as snagging on objects or becoming tangled in propulsion systems (especially on rotary wing platforms). Another consideration is that these antennas will be roughly horizontally polarized when in forward flight, yet they will be vertically polarized when hovering. Polarization refers to the spatial orientation of the electromagnetic fields emitted by and best received by an antenna. Having matching polarization on both the transmitting and receiving antenna is desirable, so designers need to take this into consideration when designing the MAV as well as the ground station antennas (Weisman 2002). Vertical antennas will tend to stay mostly vertical in flight, whereas horizontal antennas change their relative orientation as the platform turns.

58.4 MAV Data Link Power Saving Tricks and Advanced Communications

In lieu of developing lighter and more efficient batteries, reducing the power consumption of onboard systems is the logical path forward. One of the two power-hungry systems onboard is the data link transceiver (the other being the electric motor). Lower power consumption results in increased endurance and range.

The implementation of this trade-off seems initially paradoxical. If transmitter power is reduced, one might conclude that the data link's range will be reduced. This is not necessarily the case. By employing some interesting technologies, MAVs can reduce transmitter power while increasing range.

58.4.1 The Case for Antenna Arrays

Omnidirectional antennas emit energy in all horizontal directions relatively equally. Omnidirectional antennas are easy to mount since they do not require aiming, but they have very low gain. The energy radiated from an omnidirectional antenna is not utilized very efficiently (Weisman 2002). Consider an antenna radiating in a 360° horizontal pattern. The receiving antenna is only in one direction so all of the energy radiated in other directions is wasted. This seems like a waste of precious limited battery power. The obvious initial solution is to use directional antennas with high gains. Unfortunately, it is not that simple to implement a traditional directional antenna on an MAV. Yagi and dish antennas are far too large and would require a servo-driven steering apparatus, which is not feasible on an MAV. Regular high-gain patch antennas are lighter and smaller and can achieve gains of 8–12 dBi, but they still would require servo-driven steering. One possible solution is employing antenna arrays which are a number of antennas working together (Carr 1997).

58.4.2 Beamforming

Phased array transmission was discovered in 1905 by Nobel Laureate Karl Ferdinand Braun. He was able to electronically steer radio waves using phase-shifted signals and multiple antennas. This concept grew into the large phased array radars that are used today. On a smaller scale, phased arrays have made their way into consumer devices such as 802.11n wireless routers and in some 4G cell phones.

The corollary that better fits application to MAVs is the wireless router. Modern 802.11n routers utilize a technology called Multiple-In, Multiple-Out, or MIMO. MIMO uses multiple receive and transmit antennas to provide some unique and useful characteristics that could be of particular use to MAVs.

Beamforming generally refers to the adjustment of the power and phase of the signals at each transmitting antenna (or element). The resulting constructive and destructive interference can null the signal in certain directions and increase the signal in others (effectively creating gain lobes and nulls). The lobes created by a beamforming technique effectively increase the signal gain in a direction, thereby increasing the received signal strength at the receiver (Schwarz 1990). This is good for MAVs since it allows for very fast beam steering without any moving parts. Lower power transmitters at higher frequencies can achieve beamforming gains that overcome the otherwise troublesome problems associated with transmitting a signal in free space (Sung 2004; Gollakota et al. 2009).

One of the most important things MIMO can do is to counteract free-space path loss by using MIMO precoding to “steer” a beam toward a receiver by using onboard intelligence instead of raw power (Biglieri et al. 2007). This is done using digital signal processing, the details of which will not be discussed here. Beamforming and precoding together can direct a data link directly at an MAV without interfering with the neighboring MAVs, thereby effectively giving a dedicated RF channel to each MAV (Bakr 2010).

There are a few caveats to this however. Beam steering requires some knowledge about the direction of the receiver (Sung 2004). If the MAV is launched from a known location, periodic location updates would be required to keep the beam aimed at the MAV. This is not an insurmountable problem due to their relatively slow speed. If the initial location is not known, the MAV will have to report its position back using a beaconing technique. An antenna array can be temporarily omnidirectional if properly driven, thereby allowing for occasional beaconing signals. Once the beam is aimed at the MAV, periodic updates can keep it aimed for the remainder of the flight. This same idea works in reverse and allows the MAV to aim its beam at the ground station.

This concept can be expanded to allow for communication with multiple MAVs using one ground station. By utilizing TDMA on top of precoding, time slots are assigned to each MAV for data transfer. During each time slot, the beam is steered toward a particular MAV. This does however reduce the data rate to any one MAV. If location information is shared in an MAV swarm, MAVs can even send communications between one another by aiming their beams at each other during specific TDMA slots. The key factors that must be maintained by each MAV and the ground station are relative location and time.

When beamforming is utilized, the antenna pattern is always symmetrical. This means that at best 50 % of the emitted energy is headed toward the intended receiver. While not optimal, this is much better than the fraction of a percent of the energy heading toward the receiver as was the case with the omnidirectional antennas.

As an example, consider a system using the 5.8-GHz band. If small $1/2$ wavelength patch antenna arrays were used, each would only need to be 1" long. Theoretically, MIMO antennas should be spaced $1/2$ wavelength apart for optimal gain. When $1/2$ wavelength spacing is used, the antennas are said to be critically spaced, resulting in only one pair of main lobes being emitted. At other spacings, additional wasteful side lobes form in other directions. A 4-antenna array (4×4 MIMO, meaning 4 receiving and 4 transmitting antennas) would only need 4 in. in any dimension to mount a 5.8-GHz antenna array (Jiang 2004). Many MAVs can accommodate this as the definition of an MAV is less than 6 in. in any dimension. Black Widow, for example, could accommodate a 4-antenna patch array with very little weight or aerodynamic drag. If an airframe cannot accommodate a 4-antenna array, a 2-antenna array could be used (with the obvious caveat that your beamforming gain will drop significantly). The larger the array of antennas, the narrower the beam that can be achieved (Gollakota et al. 2009).

4×4 MIMO systems have been commercially shown to have +12 to +25dB beamforming gains (<http://www.quantenna.com/beamforming.html>). These types of gains are just not possible using conventional steerable small antennas that would fit on a MAV. Extending the previous 5.8 GHz example, assume a standard 250-mW (24-dBm) data link using a single $1/4$ wave antenna with 2 dBi of gain is used. The effective output power relative to an isotropic radiator (EIRP) is now 26 dBm (24 dBm + 2 dBi). Assume the MAV and the ground station are 1 km apart. The logarithmic link budget equation is the standard method for determining signal strength at a receiver given a particular transmitter and antenna gain (Fig. 58.10) (Laskar et al. 2009; Green 2000).

Fig. 58.10 Graphical representation of the logarithmic link budget equation

$$\begin{aligned}
 \text{ReceivedPower(dBm)} &= 24\text{dBm} + 2\text{dBi} + 2\text{dBi} - (32.45\text{dB} \\
 &\quad + 20 * \log[5, 800\text{Hz}] + 20 * \log[1\text{km}]) \\
 &= 28 - 107.7\text{dB} = -79.7\text{dBm}
 \end{aligned}$$

With a 4-element MIMO array having 18 dBi of gain at the MAV and ground station, received power = $60 - 107.7\text{ dB} = -47.7\text{ dBm}$.

This means that if you used MIMO array antenna arrays on both ends that you could lower your MAV transmitter power by 32 dB and achieve similar performance. That allows your 250 mW radio to become 200 μW . The effect on battery life is tremendous.

There is a slight penalty that must be paid when using array antennas and MIMO. MIMO processing is intensive, and therefore the precoding processor will consume some additional power. However, this power consumption (using current technology and system on a chip solutions) will not outweigh the savings gained by using beamforming and MIMO.

58.4.3 Diversity Matters

TDMA, as mentioned before, is a form of time diversity that allows multiple data streams to occupy the same channel. There is a second form of diversity called spatial diversity or antenna diversity (Laskar et al. 2009). Spatial diversity is achieved by utilizing antennas that are placed sufficiently far apart that the channel fading between the antennas vary and are therefore independent. Fading is the amount of loss along a given path between the transmitter and receiver. This antenna independence effectively creates multiple signal paths that can be used (Green 2000).

In most cases, multipath and scattering are considered to be negative in the world of communications. Multipath is the receiving of the same signal along multiple paths. For example, if a signal was received directly and a short time later a version of that same signal that bounced off a mountain and then to the receiver was received, then there would be an RF echo called multipath (Laskar et al. 2009).

Scattering is the deviation in the trajectory of a reflected signal due to variations in the medium that they are traversing (Paris and Hurd 1969). Both of these phenomena create problems when demodulating the signal.

However, in MIMO, multipath is actually helpful. This is a good thing since much of the MAV's role is in urban and indoor environments where signals are scattered and bounce off multiple surfaces readily. The scattering separates the signals in both space and time. This phenomenon is known as Rayleigh fading and has the effect of decorrelating the signals or making multiple independent versions of the signal with slightly different characteristics (Jiang 2004). The slight variation in characteristics can be detected and separated by a digital processor. Diversity gain takes advantage of the spatial diversity of the receive and transmit antennas to receive a higher-quality signal that would otherwise be possible (Gollakota et al. 2009).

This Rayleigh diversity, if properly exploited, can be used to achieve a diversity gain. With multiple transmit and receive antennas, signals can be differentiated despite the fact that they are close together. By using averaging of the signals received at each antenna, Gaussian white noise can also be cancelled, thereby increasing the signal-to-noise ratio (SNR). Linear matrix algebra can be used to correlate all of the channels and sum them to reconstruct the original data stream.

Between spatial diversity, temporal diversity, and beamforming gain, signals can be sufficiently strong to support communications even at reasonably long distances and inside buildings. For these reasons, MIMO is particularly useful for MAVs.

58.4.4 Additional Beamforming Advantages

Another advantage of beamforming is communications covertness. A beam is much harder for an eavesdropper to detect. Omnidirectional antennas make eavesdropping easy since the signal is being sent in all directions. With MIMO beamforming, an eavesdropper would have to be in the beam's path to detect the signal. For covert operations, having a minimal signature both acoustically and electromagnetically is preferred. With a plethora of low-cost frequency scanners on the market, it is important to have direct narrow-beam communications to avoid detection.

58.5 Conclusion

When considering the best communications architecture for MAVs, designers must remember that everything is a trade-off. As such, designers should use a three-step process to arrive at the optimal solution. First, determine the characteristics of the operating environment. This should consider urban vs. rural, indoors vs. outdoors, and short vs. long distance. This determination will dictate which frequencies, modulation schemes, and multiple access schemes are appropriate. Second, designers should determine the data rates involved. High data rates require the sacrifice of other desirable aspects. The proper balance must be determined, and consideration of data rates will help pair down the options resulting from the first

consideration. Finally, the designer should decide what level of data link reliability is required. This again is in direct conflict with the other two considerations. Once the link parameters have been considered in light of these three steps, iterate once more through them to arrive at the optimal solution for the particular MAV application. Talking with an RF engineer early in the design process is advisable since many of the optimal solutions require integration with the air vehicle in a way that is not conducive to implementation late in the project.

As technology continues to miniaturize and advance, many of the weight and power constraints will ease. Unfortunately, RF characteristics are largely bounded by the universal constraints of nature and are therefore not controllable by the designer. RF links and power will continue to be problematic for MAVs for many years to come, particularly as MAVs become smaller. The best that designers can hope for is an optimal communications solution given the current state of technology. Everything else must then be built around that solution.

Kimón P. Valavanis and George J. Vachtsevanos

UAV Mission and Path Planning moves beyond fundamental UAV technologies to higher level functionalities such as mission and path planning for single and multiple UAVs, as UAVs are deployed to execute a variety of “missions” in both military and civilian environments. Planning and executing a mission in terms of prescribing the path or trajectory generation and other related topics are challenging problems that require careful consideration. The chapters in this section present a plethora of methods and techniques, along with specific examples from the utility of mission and path planning technologies, suitable to assist the planner to complete an assigned mission.

► *Cooperative Mission Planning for Multi-UAV Teams* by Ponda, Johnson, Geramifard, and How provides an overview of three of the most common planning frameworks: integer programming, Markov decision processes, and game theory. It also considers various architectural decisions that must be addressed when implementing online planning systems for multi-agent teams, providing insights on when centralized, distributed, and decentralized architectures might be good choices for a given application and how to organize the communication and computation to achieve desired mission performance. Algorithms that can be utilized within the various architectures are identified and discussed, and future directions for research are suggested.

► *Multi-team Consensus Bundle Algorithm* by Argyle, Beard, and Casbeer focuses on how the consensus-based bundle algorithm (CBBA) is incorporated into

a hierarchical concept of operation, where agents are divided into teams and each team plans for its agents to service a set of tasks. This team planning is carried out in a distributed manner using the traditional CBBA. An “outer-loop” team CBBA strategy coordinates teams’ plans. The hierarchical structure of the team CBBA facilitates a manageable architecture for large numbers of unmanned agents through human-centered operations. This is because each team is managed by a human operator with the team CBBA aiding coordination between teams.

► *Cooperative Mission and Path Planning for a Team of UAVs* by Oh, Shin, Kim, Tsourdos, and White addresses the cooperative mission and path planning problem of multiple UAVs in the context of the vehicle routing problem. Since the conventional vehicle routing algorithms approximate their path to straight lines to reduce computational load, the physical constraints imposed on the vehicle are not to be taken into account. In order to mitigate this issue, a framework is described allowing integrated mission and path planning for coordinating UAVs using the Dubins theory based on the differential geometry concepts which can consider non-straight path segments. The main advantage of this approach is that the number of design parameters can be significantly reduced while providing the shortest, safe, and feasible path, which leads to a fast design process and more lightweight algorithms. In order to validate the integrated framework, cooperative mission and path planning algorithms for two missions are developed: (1) road-network search route planning patrolling every road segment of interest efficiently based on the optimization and approximation algorithm using nearest insertion and auction negotiation and (2) communication relay route planning between a ground control station and the friendly fleet satisfying the constraints on the UAV speed and the avoidance of nonflying zones.

► *Cooperative Task Assignment and Path Planning for Multiple UAVs* by Moon, Shim, and Oh presents a hierarchical framework for path planning and task assignment for multiple UAVs in a dynamic environment. The discussed path planning algorithm is based on the visibility and shortest path principles in Euclidean space, with the A* algorithm adopted to find an admissible path in a “best-first” approach during the search process. The path planner is augmented with a potential field-based trajectory planner, which solves for a detouring trajectory around other agents or pop-up obstacles. Task assignment is achieved by a negotiation-based algorithm, which assigns a task with the lowest cost to each agent after comparing all task costs of all participating agents. These algorithms are implemented on MATLAB/Simulink, which can run with simulated vehicle models or actual UAVs through a communication network. In the simulations, the algorithms are validated to perform task assignment and path planning flawlessly. In actual flight tests, the proposed algorithms were tested with a number of fixed-wing UAVs in a fully realistic situation under various reality factors such as communication loss or tracking errors. The flight test shows, even in the presence of such uncertainties and logistic factors, the algorithms were able to perform all of the given tasks without any collision with other agents or obstacles.

► *On the Decentralized Cooperative Control of Multiple Autonomous Vehicles* by Hirsch and Schroeder is concerned with dynamically determining appropriate

flight patterns for a set of autonomous UAVs in an urban environment, with multiple mission goals. The UAVs are tasked with searching the urban region for targets of interest and tracking those targets that have been detected. It is assumed that there are limited communication capabilities between the UAVs and that there exists possible line of sight constraints between the UAVs and the targets. Each UAV operates its own dynamic feedback loop, in a receding-horizon framework, incorporating local information as well as remote information to determine the task to perform and the optimal flight path of UAV over the planning horizon. This results in a decentralized and more realistic model of the real-world situation. As the coupled task assignment and flight route optimization formulation is NP-hard, a hybrid heuristic for continuous global optimization is developed to solve for the flight plan and tasking over the planning horizon. Experiments are considered as communication range between UAVs varies.

► *Innovative Collaborative Task Allocation for UAVs* by Karaman, Koyuncu, and Inalhan is devoted to a large-scale distributed task/target assignment problem for a fleet of autonomous UAVs, deriving an algorithm that uses the delayed column generation approach on a non-convex supply-demand formulation for the problem. The algorithm exploits a computationally tractable distributed coordination structure, i.e., a market for tasks and targets created by the UAV fleet. The resulting structure is solved via a fleet-optimal dual simplex ascent in which each UAV updates its respective flight plan costs with a linear update of waypoint task values as evaluated by the market. Synchronized and asynchronous distributed implementations of this approximation algorithm are demonstrated in a thorough experimental study involving dynamically changing scenarios with random pop-up targets.

► *Control of Communication Networks for Teams of UAVs* by Kopeikin, Ponda, and How studies the communication network that is a fundamental component of a multi-UAV system, as it enables exchanges in command and control messages and allows for remotely sensed mission data to be sent to processing centers. Network control is critical for the system to function properly. Challenges in network communication control are presented, followed by a background discussion in wireless networking including system architecture, wireless channel performance, topology models, and information routing, as well as bounds and limitations in cooperative control and decision making because of network limitations. Several network control strategies for multi-UAV systems are discussed, including motion planning methods to control the topology and relay deployment techniques to extend the performance of the network.

► *Information-Theoretic Exploration of Unmanned Aerial Vehicle in Unknown Cluttered Environment* by Yang, Gan, and Sukkarieh proposes an information-theoretic path planning method for exploration mission in unknown environments. Instead of using traditional grid-based occupancy maps, the Gaussian process (GP) is used to build an environmental map. The GP map performs inference directly on the collected sensor datasets, which allows it to infer the probability of collision for any query point in continuous 3-D space, removing the need for maintaining a full discrete map. This GP map is fused with the rapidly exploring random tree (RRT) path planner to plan a safe path and acquire information about the

unknown environments. Using mutual information as an information measure, the most informative path is chosen as the path for exploration. Simulation results show that GP map combined with RRT planner achieves exploration task successfully in unknown complex environment and present their potential implementation in UAV missions.

► *Implementing Dubins Airplane Paths on Fixed-Wing UAVs* by Beard and McLain presents a 3-D Dubins airplane model, deriving a complete architecture for implementing Dubins airplane paths on small fixed-wing UAVs. A vector field method is then used to design a guidance law that causes the Dubins airplane model to follow straight-line and helical paths. Dubins airplane paths are more complicated than Dubins car paths because of the altitude component. Based on the difference between the altitude of the start and end configurations, Dubins airplane paths are classified as low-, medium-, or high-altitude gain. While for medium- and high-altitude gains, there are many different Dubins airplane paths, it is proposed to select the path that maximizes the average altitude throughout the maneuver. The proposed architecture is implemented on a six-degrees-of-freedom MATLAB/Simulink simulation of an Aerosonde UAV, and results from this simulation demonstrate the effectiveness of the technique.

► *Health Monitoring of a Drone Formation Affected by a Corrupted Control System* by Lechevin, Rabbath, and Maupin proposes a dynamic feature that is instrumental in achieving vulnerability assessment of a network of UAVs, whose control system is possibly affected by the diffusion of malware. The feature consists of the characterization of the transition from stability to instability with probability one. The stability of the networked UAVs can be indirectly affected by malicious attacks targeting the communication units or the control systems. The network is modeled as a discrete-time, jump, linear system whose state space variables represent the probabilities that each node receives a malware and is infected by it. The stability analysis is obtained by means of a stochastic Lyapunov function argument and yields a sufficient condition expressed as a linear matrix inequality (LMI). This LMI involves the networked asset state space matrices and the probability that each UAV's control system is infected. An approximation to the sufficient condition is proposed so that convergence of the system trajectories could be monitored online.

efficient mission execution. However, as the number of agents, system components, and mission tasks increase, planning for such teams becomes increasingly complex, motivating the development of algorithms that can operate in real-time dynamic environments.

Given the complexity of the cooperative missions considered, there have been numerous solution approaches developed in recent years. This chapter provides an overview of three of the most common planning frameworks: integer programming, Markov decision processes, and game theory. The chapter also considers various architectural decisions that must be addressed when implementing online planning systems for multi-agent teams, providing insights on when centralized, distributed, and decentralized architectures might be good choices for a given application, and how to organize the communication and computation to achieve desired mission performance. Algorithms that can be utilized within the various architectures are identified and discussed, and future directions for research are suggested.

60.1 Introduction

The use of robotic agents, such as unmanned aerial vehicles (UAVs) or unmanned ground vehicles (UGVs), has motivated the development of numerous autonomous cooperative task allocation and planning methods. Applications of these planning algorithms include utilizing teams of heterogeneous networked agents to accomplish autonomous missions (e.g., intelligence, surveillance, and reconnaissance (ISR) operations (U.S. Army UAS Center of Excellence 2010; U.S. Air Force Chief Scientist AF/ST; Office of the Secretary of Defense 2007)), as shown in Fig. 60.1. Other promising applications of autonomous vehicles include environmental disaster relief (Maza et al. 2011); chemical, biological, radiological, and nuclear (CBRN) search and rescue in the aftermath of an attack in an urban area (Welch and Edmonds 2003); precision agriculture (Schmale et al. 2008); fighting forest fires (Sujit et al. 2007); and weather forecasting (Frew and Argrow 2010). Typically agents within the team have different roles and responsibilities, and ensuring proper coordination between them is critical for efficient mission execution. This process requires ensuring spatial and temporal synchronization of the team, while considering mission costs, available resources, and network constraints.

Given the complexity of the cooperative missions considered, there have been numerous solution approaches developed in recent years. The following sections briefly describe three common formulations of the problem: integer programming, Markov decision processes, and game theory. The chapter also considers various architectural decisions that must be addressed when implementing online planning systems, providing insights on when centralized, distributed, and decentralized architectures might be good choices for a given application, and how to organize the communication and computation to achieve desired mission performance.

Fig. 60.1 Illustration of an example intelligence, surveillance, and reconnaissance (ISR) mission scenario involving numerous UGV and UAV assets that must perform a variety of search, track, and escort tasks

Algorithms that can be used within each of these architectures are identified, technical challenges and limitations are discussed, and directions for future research are suggested.

60.2 Approaches

This section introduces three of the most common planning frameworks for cooperative multi-agent decision-making problems: integer programming, Markov decision processes, and game theory.

60.2.1 Integer Programming

60.2.1.1 Problem Statement

Given a set of N_t tasks and a set of N_a agents, the goal of a task allocation algorithm is to find an allocation that maximizes a global reward function while enforcing all of the problem- and domain-specific constraints. This generalized task assignment problem can be written as

$$\begin{aligned} \underset{\mathbf{s}, \mathbf{x}, \boldsymbol{\tau}}{\operatorname{argmax}} \quad & \sum_{j=1}^{N_t} R_j(\mathbf{s}, \mathbf{x}, \boldsymbol{\tau}) \\ \text{subject to:} \quad & \mathbf{s} \in \mathcal{S}(\mathbf{x}, \boldsymbol{\tau}), \quad \mathbf{x} \in \mathcal{X}, \quad \boldsymbol{\tau} \in \mathcal{T}. \end{aligned} \quad (60.1)$$

In Eq. 60.1, $R_j(\mathbf{s}, \mathbf{x}, \boldsymbol{\tau})$ represents the score achieved by the team for task j . This score is a function of \mathbf{s} , representing the state trajectories for all agents; of \mathbf{x} ,

a matrix of decision variables (specifically where x_{ij} is a binary decision variable equal to 1 if task j is assigned to agent i and 0 otherwise); and τ_{ij} is a variable representing the time at which agent i services task j if $x_{ij} = 1$ and is undefined otherwise. The index set that iterates over agents i is defined as $\mathcal{I} \triangleq \{1, \dots, N_a\}$, and the index set that iterates over tasks j is defined as $\mathcal{J} \triangleq \{1, \dots, N_t\}$. $\mathcal{S}(\mathbf{x}, \boldsymbol{\tau})$ defines the set of possible trajectories that satisfy both vehicle and environmental constraints as a function of \mathbf{x} and $\boldsymbol{\tau}$; \mathcal{X} defines the set of all feasible task allocations taking into account agent capability constraints and constraints between tasks; and \mathcal{T} defines the set of all feasible task servicing times, taking into account possibly complicated temporal constraints between these tasks. In general, the full constraint space of the task allocation environment is defined by the triple of $(\mathcal{S} \times \mathcal{X} \times \mathcal{T})$. This state space can be used to specify most task allocation and motion planning problems. Because of this extreme generality, the cardinality of the state space is uncountably infinite and thus is a very difficult space to search, even approximately. The following sections will outline some simplifying assumptions that are typically added to the above formulation to make solution approaches tractable.

Task Servicing Uniqueness

A standard assumption made in the task allocation literature is that every task may be assigned to at most one agent. Roughly speaking, this means that two agents are not allowed to service the same task. While often true for most missions, this assumption also has the effect of dramatically reducing the cardinality of \mathcal{X} . This task servicing uniqueness constraint is formalized as

$$\sum_{i=1}^{N_a} x_{ij} \leq 1, \quad \forall j \in \mathcal{J},$$

$$x_{ij} \in \{0, 1\}, \quad \forall (i, j) \in \mathcal{I} \times \mathcal{J}.$$

Even though this constraint explicitly prohibits multiple agents from performing the same task, it still allows for cooperation given some creative task construction. For example, some approaches like posting multiple tasks at the same location and time (implying cooperation will take place) are a brute force way to establish cooperation at a task location. Other approaches may encode this cooperation explicitly as a more complicated constraint, rather than requiring uniqueness of assignment.

Task Independence

Another simplifying assumption is that the score achieved for each task is independent of the completion of all other tasks and locations of all other agents. This enables the reward function to be decoupled so that the only two things that affect the score of the task are the capabilities of the agent servicing the task (including the availability of the agent due to commitments of servicing other tasks) and what time the task is actually serviced. The form of the reward function in Eq. 60.1 then simplifies to

$$\sum_{j=1}^{N_t} R_j(\mathbf{s}, \mathbf{x}, \boldsymbol{\tau}) \rightarrow \sum_{j=1}^{N_t} R_j(\mathbf{x}_j, \boldsymbol{\tau}_j), \quad (60.2)$$

where $\mathbf{x}_j \triangleq \{x_{1j}, \dots, x_{N_a j}\}$ is a vector indicating which agent i (if any) will be servicing task j and $\boldsymbol{\tau}_j \triangleq \{\tau_{1j}, \dots, \tau_{N_a j}\}$ is the corresponding vector that indicates the service time of task j (this vector will have at most 1 defined component corresponding to the assigned agent). It is worth noting that Whitten (Whitten et al. 2011) also addressed the problem of introducing more complicated task dependencies consistent with Eq. 60.2 above. The solution he proposed was to add constraints that make the task selection infeasible if certain constraints were not met. This introduces coupling in the task constraints instead of in the score function. Explicit coupling in the score function between tasks can often violate a property called *submodularity*. Submodularity is an important property in greedy algorithms because it allows assignments to perform provably well with respect to optimal. Because of this, introducing the coupling as a constraint is often a more tractable approach to searching the assignment space.

Decoupling of Path Planning Solution

Another standard approximation of the original problem formulation is to avoid explicitly solving for \mathbf{s} , the actual dynamic paths that every agent must follow to service its assigned tasks (Richards et al. 2002; Bellingham et al. 2002). Instead, the approach is to guarantee that, given a feasible task allocation \mathbf{x} and a set of service times $\boldsymbol{\tau}$, there *exists* some $\mathbf{s} \in \mathcal{S}(\mathbf{x}, \boldsymbol{\tau})$. The problem of actually optimizing \mathbf{s} is deferred to path planning optimization. Typically conservative estimates of the maneuvering capabilities of the agent are used, leading to straight-line (or possibly Dubin's car) path estimates of the route and timing (Rathinam et al. 2007; Savla et al. 2005; Bellingham et al. 2002). While this decoupling greatly reduces the complexity of the full task allocation optimization, the accuracy of the timing and cost estimates used in the planner can be a concern, possibly leading to poor performance if the optimized paths vary greatly from those assumed in the task allocation process.

60.2.1.2 Full Problem Description

With these standard assumptions, the full problem of interest can be written as

$$\underset{\mathbf{x}, \boldsymbol{\tau}}{\operatorname{argmax}} \quad \sum_{j=1}^{N_t} R_j(\mathbf{x}_j, \boldsymbol{\tau}_j), \quad (60.3)$$

$$\text{subject to: } \sum_{i=1}^{N_a} x_{ij} \leq 1, \quad \forall j \in \mathcal{J},$$

$$\mathbf{s} \in \mathcal{S}(\mathbf{x}, \boldsymbol{\tau}), \quad \mathbf{x} \in \mathcal{X}, \quad \boldsymbol{\tau} \in \mathcal{T},$$

$$x_{ij} \in \{0, 1\}, \quad \forall (i, j) \in \mathcal{I} \times \mathcal{J}.$$

This formulation, although mathematically complete, is not structured in a convenient form to explain the algorithmic tools used to solve it. The following sections introduce further notation to highlight where the problem can be decoupled and what pieces can be solved separately and introduce some of the data structures used to keep track of the relevant information:

1. For each agent, an ordered data structure called a *path* is defined, $\mathbf{p}_i \triangleq \{p_{i1}, \dots, p_{i|\mathbf{p}_i|}\}$, whose elements are defined by $p_{in} \in \mathcal{J}$ for $n = \{1, \dots, |\mathbf{p}_i|\}$. The path contains the information representing what tasks are assigned to agent i . The order of the tasks in the path represents the relative order in which they will be serviced.
2. A score function matrix $\mathbf{c}(t)$ is defined, which is composed of elements c_{ij} that represent the score that agent i would receive by servicing task j at time t .
3. For each agent i , a maximum path length L_i is defined, representing the maximum number of tasks that the agent may be assigned. This is an artificial constraint placed on the problem to help with computation and communication efficiency. This constraint is often paired with an implicit receding time horizon to guarantee that an agent does not commit to tasks too far in the future and exhaust its path length.

Using these new data structures, the problem definition can be augmented as follows:

$$\begin{aligned} \underset{\mathbf{x}, \boldsymbol{\tau}}{\operatorname{argmax}} \quad & \sum_{i=1}^{N_a} \left(\sum_{j=1}^{N_t} c_{ij}(\tau_{ij}(\mathbf{p}_i(\mathbf{x}_i))) x_{ij} \right), \quad (60.4) \\ \text{subject to:} \quad & \sum_{j=1}^{N_t} x_{ij} \leq L_i, \quad \forall i \in \mathcal{I}, \\ & \sum_{i=1}^{N_a} x_{ij} \leq 1, \quad \forall j \in \mathcal{J}, \\ & \mathbf{s} \in \mathcal{S}(\mathbf{x}, \boldsymbol{\tau}), \quad \mathbf{x} \in \mathcal{X}, \quad \boldsymbol{\tau} \in \mathcal{T}, \\ & x_{ij} \in \{0, 1\}, \quad \forall (i, j) \in \mathcal{I} \times \mathcal{J}. \end{aligned}$$

Given the formulation specified in Eq. 60.4, it may become apparent that the computation can be distributed across multiple agents. At this point, given \mathbf{x} , the matrix $\boldsymbol{\tau}$ can be determined by each agent independently. Furthermore, with \mathbf{x} , each individual agent can find its own contribution to the full matrix $\boldsymbol{\tau}$ by solving

$$\underset{\boldsymbol{\tau}}{\operatorname{argmax}} \quad \sum_{j=1}^{N_t} c_{ij}(\tau_{ij}(\mathbf{p}_i(\mathbf{x}_i))) x_{ij}. \quad (60.5)$$

Using Eq. 60.5, each agent i will first have to optimize its own path \mathbf{p}_i , given a list of tasks it has a responsibility to service, \mathbf{x}_i , and subject to the path planning feasibility constraint $\mathbf{s} \in \mathcal{S}(\mathbf{x}, \boldsymbol{\tau})$ and the feasibility of arrival times constraint $\boldsymbol{\tau} \in \mathcal{T}$. During the path optimization, optimal values for $\boldsymbol{\tau}$ will also be determined. Furthermore, from this optimization, the agent's individual scores for each assigned task will be fully determined. The main result of Eq. 60.5 is that the primary source of distributed coupling in the path assignment problem is restricted to the choice of the assignment vector \mathbf{x} . Given this, once all agents agree on a value for \mathbf{x} , the distributed task assignment problem has been solved.

60.2.1.3 Planning in Uncertain Domains

An important issue associated with cooperative planning for networked teams is that planning algorithms rely on underlying system models, which are usually approximations of the real systems involving many limiting assumptions and complex dynamics. Discrepancies between these planner models and the actual system dynamics cause degradations in mission performance. Furthermore, the impact of these discrepancies on the overall quality of the plan is typically hard to quantify in advance due to nonlinear effects, coupling between tasks and agents, and interdependencies between system constraints (e.g., longer-than-expected service times impact the arrival times of subsequent tasks). However, if uncertainty models of planning parameters are available, they can be leveraged to create robust plans that explicitly hedge against the inherent uncertainty given allowable risk thresholds.

For example, for the problem definition introduced in Eq. 60.4, if the score function matrix $\mathbf{c}(t)$ depends on uncertain planning parameters with associated probability distributions, stochastic planning algorithms can be used to create plans that explicitly account for the *variability* in $\mathbf{c}(t)$. There are several metrics that can be used to account for uncertainty in the planning formulation. Perhaps the most common approach is to maximize the expected mission performance (Bertsekas 2007), where the objective function from Eq. 60.4 becomes

$$\operatorname{argmax}_{\mathbf{x}, \boldsymbol{\tau}} \quad \mathbb{E} \left\{ \sum_{i=1}^{N_a} \left(\sum_{j=1}^{N_t} c_{ij}(\tau_{ij}(\mathbf{p}_i(\mathbf{x}_i))) x_{ij} \right) \right\}. \quad (60.6)$$

Note that optimizing Eq. 60.6 is *not* the same as planning using the mean values of uncertain planning parameters, which can often lead to poor planning performance since the problem formulation fails to capture the nontrivial coupling of uncertainty in scores, dynamics, and constraints. This is especially problematic when scores are coupled and can lead to biased predictions that drastically misrepresent the actual expected performance.

While optimizing Eq. 60.6 provides a plan that maximizes the expected performance of the system, an actual single run execution of this best expected plan is still subject to the uncertainty in the environment and may result in a relatively poor plan (worse than expected) with some nonzero probability. If the current

mission tolerance to failure is very low, a more *robust* planning objective involves maximizing the worst-case scenario:

$$\operatorname{argmax}_{\mathbf{x}, \tau} \min \left\{ \sum_{i=1}^{N_a} \left(\sum_{j=1}^{N_t} c_{ij} (\tau_{ij} (\mathbf{p}_i (\mathbf{x}_i))) x_{ij} \right) \right\}. \quad (60.7)$$

Optimizing Eq. 60.7 guarantees that the plan execution will result in a score *no worse* than that predicted by the algorithm; however, sometimes this is too conservative (especially for parameter distributions with infinite support).

Several robust optimization and stochastic optimization methods, that find the best solution within some predefined risk threshold, have been developed to mitigate this issue of conservatism (Nemirovski and Shapiro 2007; Bertsimas et al. 2011). One such approach involves optimizing a risk-adjusted expected performance, where a risk function $R(c_{ij})$ biases the original cost function c_{ij} towards more conservative solutions to account for the acceptable level of risk. Another approach is to bound the domain of the uncertainty set to be within certain ranges (e.g., ellipsoids for specified confidence intervals (Ben-Tal and Nemirovski 1998)) or to take on a set of discrete representative values (Chen et al. 2010; Bertsimas and Brown 2009), thus limiting the support of the uncertain parameters. Classical robust convex optimization techniques can then be used to solve the resulting approximate problem. Although these methods allow control over the planner risk, there are a few issues which make their practical implementation difficult. Firstly, it is not usually obvious how to design the risk functions $R(c_{ij})$ or the bounded uncertainty sets, and the selection of these is typically problem specific, time consuming, and ad hoc. A more serious issue, however, is that when a global risk threshold is available, the metric of interest is the *cumulative* risk of the total solution, not the individual parameter or task risks, and it is difficult to quantify how these individual parameter bounds will affect the global risk. Nonlinearities in the cost functions, complex variable coupling and interdependencies, and discrete optimization effects often affect the solution in unpredictable ways, and it is therefore hard to ensure that the total mission outcome is within the desired risk threshold.

An alternative approach that guarantees that the global mission performance will be within a certain risk threshold is the chance-constrained formulation (Delage and Mannor 2010; Nemirovski and Shapiro 2007; Blackmore and Ono 2009),

$$\begin{aligned} & \operatorname{argmax}_{\mathbf{x}, \tau} y \\ & \text{s.t. } \mathbb{P} \left\{ \sum_{i=1}^{N_a} \left(\sum_{j=1}^{N_t} c_{ij} (\tau_{ij} (\mathbf{p}_i (\mathbf{x}_i))) x_{ij} \right) > y \right\} \geq 1 - \epsilon. \end{aligned} \quad (60.8)$$

The goal of Eq. 60.8 is to maximize the worst case score within the allowable risk threshold specified by ϵ (can be interpreted as guaranteeing that the solution will be at least as good as y with probability greater than or equal to $1 - \epsilon$). When $\epsilon = 0$,

the score is guaranteed to be at least y with probability 1 (absolute worst-case), and the chance-constrained formulation reduces to the robust formulation of Eq. 60.7. The main drawback of the chance-constrained formulation is that it is difficult to solve, especially given the extensive coupling between agents and tasks (double sum over distributions). Previous work has mainly considered linear or quadratic optimization with continuous variables (Delage and Mannor 2010; Nemirovski and Shapiro 2007; Blackmore and Ono 2009), where, under special circumstances, optimal solutions and bounds can be found analytically. However, task allocation is a mixed-integer program, and these techniques cannot be easily extended to discrete optimization, especially given nonlinear and heterogeneous score functions with coupled distributions. Furthermore, these solution strategies are centralized and cannot be trivially extended to distributed environments. Recent work has considered implementing distributed approximations for chance-constrained multi-agent programs (Ponda et al. 2012); however, this remains an open area of research.

60.2.1.4 Solution Algorithms

Numerous researchers have examined many aspects of the UAV assignment problem (Chandler et al. 2002; Schumacher et al. 2002; Bellingham et al. 2002; Castanon and Wohletz 2009; McLain and Beard 2005; Beard et al. 2002; Passino et al. 2002; Saber et al. 2003; Ren et al. 2007; Shima and Rasmussen 2009; Leary et al. 2011; Kim et al. 2007). This includes traditional methods for vehicle routing problems (VRPs) from the operations research (OR) and artificial intelligence (AI) communities (Toth and Vigo 2001; Cormen 2001). Exact optimization methods such as branch and bound, branch and cut, constraint satisfaction problems (CSPs), and dynamic programming (DP) have been used to solve the problem to optimality, using standard software solvers (ILOG 2006). While guaranteed to yield optimal results, these methods are computationally intensive, and this complexity becomes an important issue when the problem has *hard* side constraints (Floudas 1995). These complexity issues typically make optimal solution techniques intractable for many problems of interest, and, as a result, numerous approximation methods have been proposed. Classical heuristic methods, such as constructive and two phase methods, have been used to solve large VRP problems relatively quickly (Laporte and Semet 2002), but these methods can generate solutions that are far from optimal. Different heuristic methods such as tabu search (Glover and Marti 2006), cross-entropy (De Boer et al. 2005; Undurti and How 2010; Manh et al. 2010), particle swarm optimization (Salman et al. 2002; Cruz Jr et al. 2004), genetic algorithms (Chockalingam and Arunkumar 1992; Shima et al. 2006; Eun and Bang 2010), and evolutionary algorithms (Nikolos et al. 2007; Pongpunwattana et al. 2003) have also been proposed in recent years to solve these complex optimization problems. These approximations help to reduce the computation time as compared to exact methods, but most of these algorithms are still computationally intractable for real-time replanning environments with complex constraints.

Several strategies have been considered in the literature to further reduce the computation time required to solve these problems. One approach is to reduce the

problem size by limiting the duration (in time or plan length) using a receding horizon formulation (King et al. 2004; Alighanbari and How 2008a; Castanon and Wohletz 2009). A key challenge here, however, is to develop an effective and computationally efficient approximation of the “cost-to-go” from the terminal point of the plan, to avoid having an overly short-sighted planner. Other authors have identified several efficient mixed-integer linear programming formulations that dramatically reduce the number of variables and constraints required. Although problem specific and applicable only in certain environments, these formulations cover a variety of UAV task assignment problems of practical interest (Alidaee et al. 2009, 2011). These reductions significantly alleviate the computational effort required and should always be considered if the particular problem of interest fits into the appropriate formulation. Other approaches have considered fast constant-factor approximate algorithms for multi-UAV assignment problems, which involve making mild assumptions to approximate the vehicle dynamics (e.g., constraints on turning radius) (Rathinam et al. 2007). Finally, recent work has considered employing *learning* techniques to guide the MILP solution process (Banerjee et al. 2011). The approach involves using machine learning to efficiently estimate the objective function values of the LP relaxations to within an error bound and to use that information to perform fast inference at run time for new but similar relaxation problems that occur when the system dynamics and/or the environment changes slightly.

The algorithms presented in this section are all centralized solution strategies, meaning that all of the planning relevant computation occurs in a single location. Section 60.4 breaks this assumption and describes how certain algorithms are able to handle this.

60.2.2 Markov Decision Processes

Another well-studied framework to enable cooperative planning strategies for multi-agent teams is the Markov decision process (MDP), which constitute a formal architecture for representing stochastic sequential decision-making problems (Sutton and Barto 1998; Buşoniu et al. 2010). Cooperative planners based on MDPs have shown tremendous versatility in modeling multi-agent systems (Guestrin et al. 2001; Stone et al. 2005; Valenti et al. 2007; Bethke et al. 2008), and the associated solution algorithms, such as dynamic programming, have enabled near-optimal solutions in many application domains. A well-known issue however, as described in the previous section, is that MDPs and related dynamic programming techniques suffer from bad scalability (Bellman 2003) and quickly become intractable as the number of participating agents increases. As a result, many approximation algorithms have been developed to mitigate this computational challenge (Sutton 1996; Bertsekas 2007; Mahadevan et al. 2006; Buşoniu et al. 2010; Geramifard et al. 2011). While many of these approaches have been successfully used to solve large multi-agent problems which would otherwise remain intractable (Stone et al. 2005; Bethke 2010), most have fundamental limitations such as difficulty in

selecting appropriate approximation architectures or absence of proper guidance in tuning algorithm parameters. This section describes the MDP architecture and its variants and discusses popular solution approaches, challenges, and limitations. Section 60.4.2 extends the frameworks presented in this section to address the additional requirements associated with decentralized planning.

60.2.2.1 Problem Statement

A finite horizon Markov decision process can be described by the following tuple $\langle \mathcal{S}, \mathcal{A}, P, R, T \rangle$, where the elements are described as follows:

- \mathcal{S} : Defines the state space which is composed of a discrete set of states $s \in \mathcal{S}$
- \mathcal{A} : Defines the action space with a discrete set of actions $a \in \mathcal{A}$
- P : Defines a transition function of the form $P(s, a, s') : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0, 1]$ specifying the probability of transitioning to state $s' \in \mathcal{S}$ from state $s \in \mathcal{S}$ having taken action $a \in \mathcal{A}$
- R : Defines a reward function $R(s, a, s') : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$ specifying the rewards and costs associated with applying action $a \in \mathcal{A}$ in state $s \in \mathcal{S}$ and transitioning to state $s' \in \mathcal{S}$
- T : Represents the discrete finite horizon (number of time steps)

A *trajectory* is a sequence $\{s_0, a_0, r_0, s_1, a_1, r_1, s_2, \dots\}$, where the action a_t is chosen given a *policy* $\pi : \mathcal{S} \rightarrow \mathcal{A}$ mapping states to actions. Given a policy π , a value $Q_k^\pi(s, a)$ can be defined for each state-action pair with k remaining time steps, which represents the expected sum of discounted rewards for an agent following π for k steps, starting at s with action a :

$$Q_k^\pi(s, a) = E_\pi \left[\sum_{t=0}^k r_t \mid s_0 = s, a_0 = a \right]. \quad (60.9)$$

Accordingly, the value of each state for the fixed policy π with k remaining steps is

$$V_k^\pi(s) = \max_a Q_k^\pi(s, a). \quad (60.10)$$

The objective of the MDP problem is to obtain an optimal policy π^* that maximizes the expected cumulative reward for each state and time step:

$$\pi_k^*(s) = \operatorname{argmax}_{\pi} Q_k^\pi(s, \pi_k(s)). \quad (60.11)$$

For some domains, specifying the exact planning horizon is not feasible. Such problems are modeled using MDPs with infinite horizons represented by the tuple $\langle \mathcal{S}, \mathcal{A}, P, R, \gamma \rangle$. The definitions of all terms except γ remain the same as for finite horizon MDPs. $\gamma \in [0, 1)$ represents the discount factor associated with obtaining rewards in the future instead of now. The Q function corresponding to policy π for infinite horizon MDPs is

$$Q^\pi(s, a) = E_\pi \left[\sum_{t=0}^{\infty} \gamma^t r_t | s_0 = s, a_0 = a \right]. \quad (60.12)$$

Notice that the subscript k was dropped from the definition as compared to Eq. 60.9. Similarly, the V function and the optimal policy π^* are changed to

$$V^\pi(s) = \max_a Q^\pi(s, a), \quad (60.13)$$

$$\pi^*(s) = \operatorname{argmax}_\pi Q^\pi(s, \pi(s)). \quad (60.14)$$

Although the distinction between finite and infinite horizon MDPs seems minor, the choice of problem formulation impacts the potential solution algorithms that can be used (e.g., policy trees cannot be expanded forever in the infinite horizon case, thus requiring an alternate representation). Further discussion of solution algorithms is provided later in Sect. 60.2.2.2.

In the presence of uncertainty, it is often useful to consider partially observable domains, where the state is not directly observable yet it can be inferred from observations of the environment. The partially observable MDP (POMDP) extends the previously described MDP framework to such domains where the global state cannot be necessarily uniquely determined given the information provided by the observations. The POMDP is defined by the tuple $\langle \mathcal{S}, \mathcal{A}, P, R, \Omega, \mathcal{O}, T \rangle$ or $\langle \mathcal{S}, \mathcal{A}, P, R, \Omega, \mathcal{O}, \gamma \rangle$ for the finite and infinite horizon cases, respectively, where the additional elements are:

- Ω : Defines a finite set of observations $o \in \Omega$, where o_t represents the observation at time t
- \mathcal{O} : Defines an observation function of the form $O(a, s', o) : \mathcal{A} \times \mathcal{S} \times \Omega \rightarrow [0, 1]$ specifying the probability of receiving observation o after executing action a and transitioning to state s'

In a POMDP, at step t , a *belief* vector $b_t \in \mathbf{R}^{|\mathcal{S}|}$ is maintained using inference which defines a probability distribution over the whole state space. Solving POMDPs is much more challenging as compared to their MDP counterparts because the optimal policy is now a mapping from the belief space to the action space (i.e., $\mathbf{R}^{|\mathcal{S}|} \rightarrow \mathcal{A}$) as opposed to $\mathcal{S} \rightarrow \mathcal{A}$. This increases the dimensionality of the problem leading to higher algorithm complexity for POMDP solvers.

Direct applications of the MDP and POMDP frameworks to cooperative multi-agent scenarios are referred to as multi-agent Markov decision processes (MMDP and MPOMDP). MMDPs are represented by essentially the same tuples as described above but with the addition of n to indicate the number of participating agents. As \mathcal{S} now represents the *joint* state space of all agents, \mathcal{A} the *joint* action space, and Ω the *joint* observation space, it follows that $s \in \mathcal{S}$, $a \in \mathcal{A}$, and $o \in \Omega$ now denote *joint* states, actions, and observations which collectively represent the team's decisions. Formally, the actions and observations can be decomposed as:

- $\mathcal{A} = \mathcal{A}_1 \times \cdots \times \mathcal{A}_n$, where \mathcal{A}_i is the action space for agent i and each $a \in \mathcal{A}$ is a vector describing the joint action, $a = (a_1, \dots, a_n)$.

- $\Omega = \Omega_1 \times \dots \times \Omega_n$, where Ω_i is the observation space for agent i and $o \in \Omega$ describes a joint observation of the form $o = (o_1, \dots, o_n)$.

The joint state can involve complex coupling depending on the specific application, but, in some instances, it can be factored into individual agent components (see Sect. 60.4.2). Solving the MMDP involves computing an optimal joint policy $\pi^* = (\pi_1^*, \dots, \pi_n^*)$ where each π_i^* describes the individual policy for agent i . It is well known that the computational complexity of MMDPs scales exponentially in the number of agents making this a difficult problem to solve for large teams (Redding et al. 2012). Furthermore, a very limiting assumption of both MMDPs and MPOMDPs is that all agents must have identical knowledge of the global state. In the MMDP case, this is referred to as *individual full observability*, where each agent can observe the full joint state, and, similarly in multi-agent POMDPs, each agent is required to have identical partial knowledge of the joint state. This is usually an unrealistic assumption when distributed teams of cooperating agents are involved, where each agent is likely to have different local information, motivating decentralized frameworks which can handle varying situational awareness among agents. The next section describes solution algorithms for the centralized MDP and its variants, and more details on decentralized techniques are provided in Sect. 60.4.2.

60.2.2.2 Solution Algorithms

The primary goal for solving an MDP involves finding an optimal policy π^* as defined in Eqs. 60.11 and 60.14. In the finite horizon case, the most common approach is to use dynamic programming, which involves solving a backward recursion using a recursive form of the expected reward function, given by

$$\begin{aligned} Q_k^*(s, a) &= \sum_{s' \in \mathcal{S}} P(s, a, s') (R(s, a, s') + V_{k-1}^*(s')), \\ V_k^*(s) &= \max_a Q_k^*(s, a), \\ \pi_k^*(s) &= \operatorname{argmax}_a Q_k^*(s, a), \end{aligned}$$

where the terminal condition for the final time step is given by $V_0^*(s) = 0$. As a reminder, $V_k^*(s)$ specifies the value of the state given k remaining time steps; therefore, at time step $t = 0$, there are T remaining steps to go and the state values are given by $V_T^*(s)$. Likewise at the T th time step, there are 0 steps to go which is why the terminal condition is given by $V_0^*(s)$. Thus, k can be thought of as a backwards index in the recursion. The key insight here is that, at every step k , the expected cumulative return for step $k - 1$ can be lumped into one quantity; thus, by solving backward, one obtains the optimal policy for the desired time step. Notice that the optimal policy in the case of finite horizon MDPs is time dependent; thus, different time horizons result in different policies. This fact should be taken into consideration when selecting an appropriate time horizon for planning. The main benefit of dynamic programming versus forward search is that suboptimal branches

Algorithm 1: Policy Iteration**Input:** R, P, γ **Output:** π $\pi(s) \leftarrow \text{Random}(\mathcal{A})$ for $s \in \mathcal{S}$ changed $\leftarrow \text{True}$ **while** changed **do** $V^\pi \leftarrow (I - \gamma P^\pi)^{-1} P^\pi R^\pi$ **for** $s \in \mathcal{S}$ **do** $\pi^+(s) \leftarrow \operatorname{argmax}_{a \in \mathcal{A}} \sum_{s' \in \mathcal{S}} P(s, a, s') [R(s, a, s') + \gamma V^\pi(s')]$ changed $\leftarrow (\pi^+ \neq \pi)$ $\pi \leftarrow \pi^+$ **return** π

of the policy tree are pruned early on, and thus less computation is required to find the optimal solution. For the infinite horizon case, an alternate formulation is required since there is no final step. In this case, the optimal policy can be found by iterating over two steps: (1) *policy evaluation* and (2) *policy improvement*. The policy evaluation step finds the value function for a given fixed policy. In particular, Eq. 60.13 can be written as

$$V^\pi(s) = \sum_{s' \in \mathcal{S}} P(s, \pi(s), s') (R(s, \pi(s), s') + \gamma V^\pi(s')), \quad (60.15)$$

$$\triangleq T^\pi(V^\pi(s)),$$

where T^π is the Bellman operator. Writing the above equation for all states in matrix form results in $V^\pi = T^\pi V^\pi = P^\pi R^\pi + \gamma P^\pi V^\pi$, where $P^\pi(i, j) = P(s_i, \pi(s_i), s_j)$ and $R^\pi(i, j) = R(s_i, \pi(s_i), s_j)$. The above equation can be solved in closed form as

$$V^\pi = (I - \gamma P^\pi)^{-1} P^\pi R^\pi, \quad (60.16)$$

where I is the identity matrix. Given the value function, the policy can be improved by a one-step lookahead update:

$$\pi(s) = \operatorname{argmax}_{a \in \mathcal{A}} \sum_{s' \in \mathcal{S}} P(s, a, s') [R(s, a, s') + \gamma V^\pi(s')]. \quad (60.17)$$

Putting these two phases together (i.e., Eqs. 60.16 and 60.17 gives the policy iteration method shown in Algorithm 1. The output of the algorithm is guaranteed to be the optimal policy for the given MDP (Sutton and Barto 1998). Note that the algorithm requires $\Theta(|\mathcal{S}|^3)$ calculations per iteration to evaluate the policy (line 4) and $\Theta(|\mathcal{A}||\mathcal{S}|^2)$ to calculate the new policy (lines 5, 6). However, as long as the value function is getting closer to the exact solution, the policy evaluation/improvement loop still converges to the optimal solution (Sutton and Barto 1998). This idea

leads to a process that saves substantial computation for finding a good policy because, as long as the ranking of actions in each state is correct, the result of policy improvement yields optimal action selections. To accommodate this idea, line 4 can be changed to the following update rule, known as the Bellman update:

$$V^\pi(s) = \max_{a \in \mathcal{A}} \sum_{s' \in \mathcal{S}} P(s, a, s') [R(s, a, s') + \gamma V^\pi(s')], \quad \forall s \in \mathcal{S}, \quad (60.18)$$

where the value of each state is improved by a one-step lookahead. This change produces the value iteration method shown in Algorithm 2. The resulting policy for this algorithm is also guaranteed to be optimal. Coping with computer precision limitations, practitioners often replace line 8 of Algorithm 2 with a checkpoint verifying that the maximum change applied to the value function is less than a small positive number (Sutton and Barto 1998). The value iteration algorithm eliminates the matrix inversion step that required $\Theta(|\mathcal{A}||\mathcal{S}|^2)$ computations per iteration. Note that the inner loop requires a loop over all states. Both policy iteration and value iteration are instances of dynamic programming methods.

For large state spaces, representing the value function using a lookup table is not feasible due to memory and computation restrictions. The next sections describe approximate DP methods applied to such domains by trading off solution quality for lower memory and computation requirements.

60.2.2.3 Linear Function Approximation

Holding a tabular representation of the Q function (i.e., storing a unique value for each state-action pair) is impractical for large state spaces. A common approach to coping with large state spaces is to use a linear approximation of the form $Q^\pi(s, a) = \theta^T \phi(s, a)$. The feature function $\phi : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}^n$ maps each state-action pair to a size n vector of scalar values. Each element of the feature function $\phi(s, a)$ is called a *feature*; $\phi_f(s, a) = c \in \mathbb{R}$ denotes that feature f has scalar value c for state-action pair (s, a) , where $f \in \mathcal{X} = \{1, \dots, n\}$. \mathcal{X} represents the

set of features (e.g., being close to a wall and having low fuel or other properties of interest); the vector $\theta \in \mathbb{R}^n$ holds weights representing how important each feature is considered to be.

60.2.2.4 Approximate Dynamic Programming

Thus far, for the policy evaluation phase, V represented the value function for a fixed policy as a point in an $|\mathcal{S}|$ -dimensional space using $|\mathcal{S}|$ parameters (elements of the V vector). The idea of approximate DP (ADP) methods is to approximate the value function by representing it using a lower-dimensional space with $n \ll |\mathcal{S}|$ parameters. In particular, for the linear family of approximators explained in Sect. 60.2.2.3, the value function can be represented as $V \approx \tilde{V} \triangleq \Phi_{|\mathcal{S}| \times n} \theta_{n \times 1}$. When the value function is approximated using linear function approximation, the true value function might not lie in the space spanned by the feature function (i.e., column space of Φ). Hence, a metric is required to define the best approximate value function in the span of Φ . There are two major metrics used in the literature to define the best approximated value function (Bradtke and Barto 1996; Lagoudakis and Parr 2003; Farahmand et al. 2008; Sutton et al. 2009; Scherrer 2010), namely, (1) Bellman residual minimization (BRM) and (2) projected Bellman residual minimization, also known as least-squares temporal difference (LSTD). When the value of each state is being approximated, a weight vector is also required to highlight concerns with respect to the resulting error in each state. Intuitively, states that are visited more often should have higher weights, penalizing the error correspondingly. This intuition is captured through the *steady-state probability distribution* for a fixed policy, defined as a vector $\mathbf{d}_{1 \times n}$, where

$$\begin{aligned} \mathbf{d}P &= \mathbf{d}, \\ \text{s.t. } \|\mathbf{d}\|_{\ell_1} &= 1, \\ \forall i \in \{1, \dots, |\mathcal{S}|\}, \quad \mathbf{d}_i &\geq 0, \end{aligned} \tag{60.19}$$

where \mathbf{d}_i is the i th element of \mathbf{d} . Essentially, the steady-state probability distribution is the eigenvector of P^\top , representing a probability distribution over states that is invariant to the transition model (notice that the transition model P already includes the fixed policy π). For mathematical purposes, $\mathbf{D}_{|\mathcal{S}| \times |\mathcal{S}|}$ is defined as a matrix, with \mathbf{d} on its diagonal ($\mathbf{D} = \text{diag}(\mathbf{d})$).

Figure 60.2 depicts a geometric view of the optimal value function V and its projection into the span of Φ , using the orthogonal projection operator Π . Unfortunately, V is not known, but the value function which has zero Bellman error for all states (i.e., $\mathbf{T}(\tilde{V}) - \tilde{V} = \mathbf{0}$) is guaranteed to be optimal. Hence, both the BRM and LSTD approaches minimize a term defined with respect to the Bellman error with the desired goal that the resulting solution be close to ΠV . In particular, BRM minimizes the norm of the Bellman error shown as the solid green vector, while LSTD minimizes the projected Bellman error shown as the dashed blue line. The closed-form solution for BRM is

Fig. 60.2 A geometric interpretation of what Bellman residual minimization (*solid green*) and projected Bellman residual minimization (*dashed blue*) minimize, as described in Lagoudakis and Parr (2003). Π is the projection operator, mapping every point to its orthogonal projection on the span of Φ , shown as the 2-D plane. T is the Bellman operator

$$\begin{aligned} \theta &= \left[\underbrace{(\Phi - \gamma P \Phi)^\top D (\Phi - \gamma P \Phi)}_{A_{\text{BRM}}} \right]^{-1} \underbrace{(\Phi - \gamma P \Phi)^\top D R}_{b_{\text{BRM}}} \quad (60.20) \\ &= A_{\text{BRM}}^{-1} b_{\text{BRM}}. \end{aligned}$$

Note that the inverse of A_{BRM} always exists (Scherrer 2010). The closed-form solution for LSTD is given by

$$\begin{aligned} \theta &= \left[\underbrace{\Phi^\top D (\Phi - \gamma P \Phi)}_{A_{\text{LSTD}}} \right]^{-1} \underbrace{\Phi^\top D R}_{b_{\text{LSTD}}} \quad (60.21) \\ &= A_{\text{LSTD}}^{-1} b_{\text{LSTD}}. \end{aligned}$$

The LSTD solutions can be approximated using L_1 sampled transitions in the form of (s_i, a_i, r_i, s'_i) , where $s'_i = s_{i+1}$:

$$\tilde{\Phi} = \begin{bmatrix} \text{---} \phi^\top(s_1) \text{---} \\ \text{---} \phi^\top(s_2) \text{---} \\ \vdots \\ \text{---} \phi^\top(s_{L_1}) \text{---} \end{bmatrix}, \tilde{P}\tilde{\Phi} = \begin{bmatrix} \text{---} \phi^\top(s'_1) \text{---} \\ \text{---} \phi^\top(s'_2) \text{---} \\ \vdots \\ \text{---} \phi^\top(s'_{L_1}) \text{---} \end{bmatrix}, \tilde{R} = \begin{bmatrix} r_1 \\ r_2 \\ \vdots \\ r_{L_1} \end{bmatrix}, \quad (60.22)$$

$$\tilde{A}_{\text{LSTD}} = \frac{1}{L_1} \tilde{\Phi}^\top (\tilde{\Phi} - \gamma \tilde{P}\tilde{\Phi}), \quad (60.23)$$

$$\tilde{b}_{\text{LSTD}} = \frac{1}{L_1} \tilde{\Phi}^\top \tilde{R}, \quad (60.24)$$

$$\theta = \tilde{A}_{\text{LSTD}}^{-1} \tilde{b}_{\text{LSTD}}. \quad (60.25)$$

In the limit of infinite samples, approximations become exact provided that the sampling policy is ergodic (Lagoudakis and Parr 2003). However, extending the BRM solution to the sample-based case is problematic. In particular, for calculating an unbiased estimate of A_{BRM} , for each pair of s_i and a_i , two next states should be sampled independently. This observation makes the BRM approach hard for domains with limited available samples. Once the new value function is calculated, a new policy can be obtained using Eq. 60.17.

Least-squares policy iteration (LSPI) (Lagoudakis and Parr 2003) is an algorithm based on LSTD evaluation and policy improvement. A key property of the LSPI algorithm is that it does not require access to the model of the MDP in order to solve it. Moreover, samples are gathered through a trajectory of experience. Such a framework is known as reinforcement learning (RL) and is widely used throughout the literature. A simple RL solver algorithm is SARSA (state, action, reward, state, action) (Rummery and Niranjan 1994), in which, given a tuple of experience at time $t + 1$ in the form of $(s_t, a_t, r_t, s_{t+1}, a_{t+1})$, the weights are updated as

$$\theta = \theta + \alpha [r_t + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)] \phi(s_t, a_t), \quad (60.26)$$

where α is the learning rate. The policy at each step is calculated as

$$\pi(s) = \begin{cases} \operatorname{argmax}_a Q(s, a) & \text{with probability } 1 - \epsilon \\ \text{Random}(\mathcal{A}) & \text{with probability } \epsilon \end{cases} \quad (60.27)$$

to satisfy ergodicity (i.e., all states will be visited infinitely often in the limit). It has been shown that, for a fixed policy, right step size parameters, and any linear function approximation, applying Eq. 60.26 will converge to the LSTD solution asymptotically (Tsitsiklis and Roy 1997). There are a vast set of advanced DP and RL methods in the literature (interested readers are referred to Sutton and Barto (1998), Buşoniu et al. (2010), and Bellman (2003)). As expected, solving POMDPs is much more difficult as compared to solving MDPs. As a result, the area for solving real-world POMDP problems has been barely touched upon (Spaan and Vlassis 2005; Zhou and Hansen 2001; Paquet et al. 2005).

60.2.3 Game Theory

The field of game theory presents an alternate way of addressing the multi-agent planning problem by treating the interaction between agents as a game. The basic idea behind game theory is that agents are individual decision-making entities that perform actions to maximize their own local utility based on knowledge of other agents and the environment. As such, game-theoretic frameworks lend themselves naturally to solving autonomous task allocation problems in a decentralized fashion,

motivating significant work in this area (Arslan et al. 2007; Marden et al. 2009; Chapman et al. 2010; Marden and Wierman 2009). Since in game theory agents make individual decisions about their own actions, these frameworks are useful for modeling noncooperative environments; however, enforcing cooperation is difficult because it involves ensuring that individual agent utility functions and incentives are aligned with the global mission goals. Therefore, the main challenge associated with game-theoretic cooperative planning strategies involves designing proper utility functions and negotiation strategies to ensure appropriate levels of coordination and collaboration between agents in order to maximize global mission performance. This section describes current game-theoretic approaches to cooperative multi-agent planning problems, including the design and selection of utility functions and negotiation strategies, and highlights the major associated challenges and limitations.

60.2.3.1 Problem Statement

In the game-theoretic literature, a commonly studied cooperative multi-agent problem is the *vehicle-target assignment problem* (Murphey 1999), which is very similar in nature to the task allocation problem described in Sect. 60.2.1. The vehicle-target assignment problem consists of assigning a set of N_a vehicles to a set of N_t targets with the object of maximizing the global utility. The vehicles may have varying characteristics and the targets different reward values. Using a game-theoretic formulation leads to a decentralized implementation framework where the vehicles are considered self-interested decision-making agents intent on maximizing their own local utility (Arslan et al. 2007). It is desirable to find an “agreeable assignment” (Arslan et al. 2007) where no agent has an incentive to unilaterally deviate (pure-strategy Nash equilibrium (Fudenberg and Tirole 1991)) and to design the agent utilities such that maximizing the local utilities corresponds to maximizing the global utility.

The problem formulation consists of selecting assignments for a set of vehicles $\mathcal{I} \triangleq \{1, \dots, N_a\}$ given a set of targets $\mathcal{J} \triangleq \{1, \dots, N_t\}$. A vehicle’s assignment or action, $a_i \in A_i$, consists of choosing a target from an allowable subset of targets, $A_i \subset \{\mathcal{J} \cup \emptyset\}$, where the action \emptyset is a “null” target or an empty assignment and the total action space for all vehicles is $A \triangleq A_1 \times \dots \times A_{N_a}$. A joint assignment profile $a \in A$ consists of a vector describing the actions of all agents, $a = (a_1, \dots, a_{N_a})$, and is sometimes written as $a = (a_i, a_{-i})$ to highlight agent i ’s action given the actions of the other agents, a_{-i} . Each agent wishes to maximize its own local utility such that for vehicle i ,

$$a_i^* = \operatorname{argmax}_{a_i \in A_i} U_i(a_i, a_{-i}), \quad (60.28)$$

where a_i is vehicle i ’s assignment and a_{-i} is the assignment profile of the other vehicles. Solving these for each agent gives a joint assignment profile $a \in A$ corresponding to a global mission utility $U_g(a)$. If every target has a reward value $R_j(a)$ as a function of the joint assignment profile, then the global utility is the total reward over all targets and is written as

$$U_g(a) = \sum_{j=1}^{N_t} R_j(a). \quad (60.29)$$

In game theory, a framework where maximizing local agent utilities corresponds to maximizing the global utility is referred to as a *potential game* (Monderer and Shapley 1996), and several recent approaches have considered fitting the vehicle-target assignment problem within this architecture (Arslan et al. 2007; Marden et al. 2009; Chapman et al. 2010; Marden and Wierman 2009). A potential game consists of a game where there exists a potential function $\phi(a): A \rightarrow \mathbb{R}$ such that for every vehicle $i \in \mathcal{I}$, for every $a_{-i} \in A_{-i}$, and for every $a'_i, a''_i \in A_i$, the local utility functions satisfy

$$U_i(a'_i, a_{-i}) - U_i(a''_i, a_{-i}) = \phi(a'_i, a_{-i}) - \phi(a''_i, a_{-i}), \quad (60.30)$$

where the potential function is representative of the global utility.

Potential games have several useful properties that can be exploited to obtain near-optimal solutions to the global problem (the reader is referred to Monderer and Shapley (1996)). The most important of these is that potential games are guaranteed to have at least one pure-strategy Nash equilibrium (PSNE), which, in the vehicle-target assignment problem, corresponds to a valid assignment profile where no vehicle has any incentive to deviate from its strategy given the other vehicles' strategies. Several multiplayer learning algorithms that are guaranteed to converge to a PSNE have been recently developed (e.g., fictitious play, spatial adaptive play, and regret matching) (Arslan et al. 2007). However, the main issue with the potential game framework is that for most multi-agent problems, there usually exist many PSNE, and while several current algorithms guarantee convergence to a PSNE, they typically do not find the optimal PSNE (and in practice can produce arbitrarily bad assignment profiles). To mitigate this problem, it is necessary to carefully design the vehicle utilities and the negotiation strategies such that the resulting algorithm converges to a near-optimal PSNE, a challenging task that has generated much interest in the research community (Arslan et al. 2007; Monderer and Shapley 1996).

Designing local utility functions to align agent utility with global utility is difficult, since consideration must be given to what information agents have access to and how much they need to communicate with each other in order to properly represent the mission goals. An obvious choice to align agent utilities with the global utility is the *identical interest utility*, where each vehicle's utility is exactly equal to the global mission utility. Unfortunately, this requires that each vehicle have complete knowledge about the global state, including other vehicles' actions, all target reward functions including targets that are not of interest to the specific agents, and all environmental parameters that may affect any agent. Given that autonomous networked teams typically have limited bandwidth and communication constraints, it is desirable to find a utility function structure that keeps the amount of global information an agent requires to a minimum while still aligning the agent's local utility with the global utility. Better choices for localized utility functions that

have been considered are the *range-restricted utility*, the *equally shared utility*, and the *wonderful life utility* (see Arslan et al. (2007), Monderer and Shapley (1996), and Tumer and Wolpert (2004) for further details). The most popular of these is the wonderful life utility (WLU) due to its computational simplicity and favorable properties. The WLU is defined as

$$U_i(a_i, a_{-i}) = R_j(a_i, a_{-i}) - R_j(\emptyset, a_{-i}) \quad (60.31)$$

for $a_i = j$ and represents the marginal utility obtained by an agent for doing task j given the assignments of the other vehicles. The WLU has the useful feature that the local vehicle utility is equal to the marginal contribution made to the global utility, leading to a potential game with potential function equal to the global utility ($\phi(a) = U_g(a)$). The next section discusses solution algorithms for potential games that ensure convergence to near-optimal equilibria.

60.2.3.2 Solution Algorithms

As mentioned before, depending on the negotiation strategy, stable outcomes of most potential game algorithms might result in arbitrarily bad pure-strategy Nash equilibria (PSNE), motivating the design of negotiation strategies that increase the probability of convergence to a near-optimal PSNE. Furthermore, it is desirable for vehicles to negotiate with each other at every time step given all agents' assignments only, without requiring internal knowledge about other vehicles' utility functions or internal state. Several current negotiation strategies are reviewed in Arslan et al. (2007), including algorithms such as action-based fictitious play, utility-based fictitious play, regret matching (and variants), and spatial adaptive play, and the benefits and drawbacks of each are described.

One negotiation strategy that ensures convergence to a near-optimal PSNE is the spatial adaptive play (SAP) algorithm. The SAP algorithm is described as follows: at stage k , a vehicle is randomly chosen from the set of vehicles (e.g., vehicle i). Vehicle i then proposes a target according to probability distribution $p_i(k)$ that maximizes

$$p_i(k) \left(\begin{bmatrix} U_i(1, a_{-i}(k-1)) \\ \vdots \\ U_i(N_t, a_{-i}(k-1)) \end{bmatrix} \right) + \tau \mathcal{H}[p_i(k)], \quad (60.32)$$

where $\mathcal{H}(\cdot)$ is the entropy function which represents the level of randomization and the parameter τ sets the reward for randomization. The closed-form solution for the maximizing probability distribution $p_i(k)$ is then

$$p_i(k) = \sigma \left(\frac{1}{\tau} \begin{bmatrix} U_i(1, a_{-i}(k-1)) \\ \vdots \\ U_i(N_t, a_{-i}(k-1)) \end{bmatrix} \right), \quad \sigma(\mathbf{x})_i = \frac{e^{x_i}}{e^{x_1} + \dots + e^{x_n}}. \quad (60.33)$$

where $\sigma(\cdot)$ is the soft-max function. The SAP algorithm converges to a near-optimal PSNE with arbitrarily high probability which is tunable by the user through the parameter τ (Arslan et al. 2007). Furthermore, the computational overhead required to run SAP is low, making real-time implementations feasible.

Several extensions to the baseline game-theoretic task assignment formulation have been proposed in the literature. In Marden et al. (2009), weakly acyclic games are introduced to account for time-varying objective functions and action sets, as well as a restricted-action set variant of SAP termed binary restricted SAP. In Marden and Wierman (2009), it has been shown that noncooperative control formulations make it impossible to design budget-balanced agent utilities that guarantee that the optimal control is a PSNE. The proposed solution to address this issue consists of designing a modified agent utility that is conditioned on additional state information and recasting the problem to a stochastic state-based game framework. Finally, to address the problem of dynamic task allocation with task deadlines, Chapman et al. (2010) present a stochastic game formulation approximated by a series of overlapping potential games. The resulting overlapping potential game approximation (OPGA) is shown to be solvable in a distributed manner and is robust to communication restrictions.

60.3 Planning Architectures

There are many important aspects to consider when deciding what type of planning algorithm is most appropriate for a given application. An important observation is to note that, for most problems of interest, the planners being discussed in this chapter will only be able to approximately solve the problem. This is because for most applications, (1) optimality is computationally infeasible, even in the most efficient computation structures (Bertsimas and Weismantel 2005), and (2) the optimal allocation will only be accurate with respect to the objective function, which is often necessarily approximate.

This section introduces the idea that communication between algorithmic modules is a fundamental aspect of partitioning classes of algorithms and will formalize definitions for three communication architectures: centralized, distributed, and decentralized. It is then shown how each of these architectures place constraints on whether the algorithm can run synchronously or not, which may affect overall algorithmic performance. Finally, this section introduces different methods for handling coordination and cooperation in the assignment space, discusses what types of information should be shared among agents, and explains how these choices affect the performance of different algorithms in their respective environments.

The partition introduced in this section is not new, and similar insights have been presented in the literature (Shima and Rasmussen 2009; Smith and Davis 1981). In (Shima and Rasmussen 2009), the authors partition the design space into classes of algorithms according to three factors: message cost, distribution of computation, and severity of task coupling. Each of these three issues is roughly subsumed into the categories presented in this section. Earlier work described in

Smith and Davis (1981) stressed the difference between distributed problem solving (where decisions are made in a distributed fashion) and distributed processing (where data is processed in a distributed way, but decisions are still made in a relatively centralized way), and the term decentralized is used to describe systems that utilize both distributed problem solving and distributed processing. This section redefines these terms to more heavily rely on the communication aspects of the problem; however, the classes of algorithms contained in Smith and Davis (1981) remain consistent with the definitions proposed in this section. Furthermore, Smith and Davis (1981) also introduce a distinction in the level of cooperation required between what is referred to as task-sharing (where the module sub-problems are assumed to be relatively separable) and results-sharing (which requires more intense communication), and this distinction is also mirrored in the discussion on handling cooperation in the assignment space presented at the end of this section.

60.3.1 Centralized

A centralized computation model refers to an algorithm running on a single machine, and where information passing between modules of the algorithm is done through shared memory. Fast centralized algorithms are often implemented using parallelized computation structures that can take advantage of the large number of cores available in modern computer systems. Centralized implementations can also be quite fast for algorithms that are significantly parallelizable, since each module in the algorithm has access to the current global algorithmic state almost instantaneously. This means that there is very little *communication cost* between the modules (communication cost includes both the extra resources needed to facilitate communication and the associated delays introduced). Despite this, some environments may not be ideal for centralized approaches. The following list describes four environments where centralized computation may not be advisable:

1. If large amounts of data have to be transmitted to the centralized solver's location, a centralized architecture may not be ideal. Other architectures could allow processing of the data remotely to identify the "usefulness" of information prior to sending metadata to a centralized location (referred to as distributed processing in Smith and Davis (1981)). Additionally, more autonomous implementations could use this remote data to actually produce candidate assignments for these remote agents without ever communicating with a centralized location (referred to as distributed problem solving in Smith and Davis (1981)), thus creating localized cooperative assignments.
2. The solution speed of centralized solvers is throttled by the rate at which the important information reaches the computation structure(s). If communications are slow, unreliable, or expensive, it becomes harder to justify passing large amounts of possibly irrelevant data through the network.
3. If most of the information needed by each agent to create its cooperative assignments is local, much faster reaction times might be obtained by keeping

all of the computations local as well and sharing only the results of these local computations with other agents through communication.

4. In an abstract sense, distributing the computation on multiple machines might also be preferred if there are very different types of calculations that need to be performed. If, for example, the computation has large portions that can be sped up using an optimized computational structure such as a GPU, it would be desirable to outsource these computations to more appropriate hardware.

If the above criteria are not a concern for a particular application, centralized parallel algorithms are likely to perform quite well.

60.3.2 Distributed

This section defines distributed algorithms as algorithms consisting of separate modules that are able to utilize reliable message passing. Distributed systems can be implemented on a single machine or on separate machines. In a distributed system, this communication between the agents can be either passed over a network or implemented as internal memory passing, but the aspect that defines the algorithm as distributed computation (as opposed to centralized computation) is that it utilizes separate memory partitions between the distributed algorithmic pieces. This introduces an extra layer of complexity over centralized solutions because shared information must be transmitted through a communication channel. Given this description, the defining characteristic of algorithms that are designed to operate in distributed environments is that *strong* message-passing channels are assumed to exist. A connection is defined as strong if each distributed node has knowledge of the existence of all other nodes it is able to communicate with, knows how to transmit messages to each of these nodes, has low message latency between each of these nodes, and has guarantees that messages will arrive reliably.

One application of distributed algorithms is if the computational load is too immense for a single (possibly multi-core) machine. This strategy would utilize some number of machines communicating through messages in a local and reliable way. The trade-off to consider when moving from centralized to distributed computation strategies is that time lost in message communication must be offset by the additional computation available by using multiple machines. Distributed algorithms also perform well (as compared to centralized algorithms) when information is being acquired remotely and external processing can be utilized before metadata is transmitted to other modules. This is because the overall communication load on the system can be reduced dramatically for the same amount of computation. For example, in cooperative planning environments, this could involve an agent observing a local event, changing its own plan based on this newly observed information, and then reliably communicating the results to the rest of the distributed modules. Again, the most important aspect of these distributed algorithms is that they rely on stable communications and depend on sharing information among other modules reliably. If communication links are not sufficiently reliable, performance may degrade significantly, and decentralized assumptions may be more appropriate.

60.3.3 Decentralized

Decentralized architectures are most useful in systems where information sharing is performed exclusively through messages (e.g., separate agents linked via a communication network but with no direct memory sharing). Decentralized algorithms are designed for environments where there are no rigid constraints placed on message delays, network connectivity, program execution rates, and message arrival reliability. This means that decentralized algorithms are the most robust to catastrophic changes in the communication environment. The price of this robustness may be conservative performance when communication conditions are actually favorable, but for truly decentralized environments, this trade-off may be preferable. Fully decentralized algorithms allow a high degree of autonomy for the sparsely connected agents. This is because decentralized architectures do not place rigid rules on how agents must interact; therefore, there is flexibility on how individual agents can make decisions. Given that communications between agents may be weak, decentralized algorithms could allow large teams to interact efficiently, without bogging the entire network down with an overly restrictive infrastructure. As discussed below in Sect. 60.3.4, decentralized architectures are also able to handle asynchronous communications much more naturally than distributed and centralized approaches.

60.3.4 Synchronous Versus Asynchronous

Parallelized computation can be used to increase the performance in cooperative assignment algorithms. Given this, choices can be made about how to organize this parallel computation: there are highly structured, synchronous algorithms that enforce constraints on when computation can be done or more flexible structures that utilize asynchronous computation. Algorithms that use *synchronous* computation define rigid rules about when computation can happen. Often, synchronization takes the form of queuing up computation that may only be executed after certain event driven triggers. This is to ensure that the algorithm has predictable state during program execution. Synchronization is heavily utilized in most iterative algorithms. In these synchronous iterative algorithms, a set of modules often perform parallel computations, share state variables, and then wait until a certain trigger before computing the next iteration of the algorithm. In this process, guarantees can be made about the state of each agent. Furthermore, these synchronous structures are also useful because they allow algorithms to make assumptions about the information state of other modules. The cost of using synchronous algorithms is that, in some environments, it may take significant effort to enforce synchronous behavior. In distributed and decentralized algorithms, the computation triggers are often nonlocal and thus may need to be inferred through inter-module communication. In the literature, the effort involved in enforcing this synchronization has been referred to as the synchronization penalty (Bertsekas and Tsitsiklis 1989). In centralized approaches,

the mechanisms required to enforce synchronization are fairly lightweight, but when information is being shared across a network and modules must spend time waiting for messages to arrive from physically separated machines, this penalty can become severe. Conversely, *asynchronous* computation is used when modules of the algorithm can run relatively independently of one another. Because of this, these structures work well in decentralized algorithms where they can utilize information whenever available and not on a rigid schedule. This introduces a fundamental trade-off between the rigidity of forcing an algorithm to run on a synchronous schedule versus allowing the algorithm to run asynchronously but take a performance hit for losing information assumptions about the state of the other modules. Typically, in centralized and distributed environments, the synchronization penalty may be weak enough that it makes sense to utilize synchronous computation, whereas in decentralized approaches, the synchronization penalty can become crippling, and asynchronous computation often becomes necessary.

60.3.5 Performance Metrics

Once the computational structures of the algorithm are chosen, there are several metrics that the designer will care about during the run time of the algorithm. Depending on the relative importance of each of the following metrics, different algorithms may be preferred:

- *Score performance* specifically refers to how important it is that the final solution optimizes the global cost function. There can be cases where significant coupling exists in the score function, increasing the difficulty of finding a good plan. In these problems, it may be desirable for an algorithm to have strong performance guarantees with respect to the optimal. Conversely, in other scenarios it may be easy to find near-optimal allocations and other considerations may be more important.
- *Run time* specifically refers to how much computational time the entire algorithm takes to complete, and, as will be contrasted below, this is typically thought of as a global measure for the entire team. For off-line solutions, acceptable measures of run time can be in the hours (or possibly days). When algorithms are run in the field, run time is typically thought of in the seconds range.
- *Convergence detection* can be a difficult thing to quantify in general. It is usually trivial to post process when convergence occurred, but in some cases (especially decentralized implementations), it may be difficult to determine if the algorithm has actually converged. This leads to different definitions of what convergence should be. Does the algorithm require global convergence? Does it just require local convergence (only the individual module)? Does the algorithm require only partial convergence (in some cases, being sure about the next task to execute is enough)? The answers to these questions will impact what type of information is communicated as well as how much total communication is actually needed.
- *Convergence time* is typically identical to run time in terms of global convergence metrics, but for local convergence or partial convergence metrics, it measures the

time until this local convergence is detected. With convergence time, typically smaller is better, and the smaller this number is, the faster the planner can react to dynamic changes in the environment. In very dynamic environments, convergence time may be one of the most important metrics for the mission designer.

- *Reaction time to situational awareness* is closely related to convergence time. It looks specifically at the turn around time between acquiring information and incorporating it into the plan cycle. In some algorithms, information cannot be incorporated mid-convergence (while others allow for the inclusion of new information at any time). In designing algorithms, trade-offs will need to be made between convergence time and score performance to enable faster reaction times to situational awareness.

60.3.6 Coordination Techniques

Coupling between the goals of distributed agents in decentralized environments is typically required for most missions. Because of this, the assignment variables that specify mission behavior can contain nontrivial constraints between them. As a result, cooperative allocation algorithms must be able to produce consistent values for these coupled variables. In centralized environments, the problem of checking that constraints between modules are satisfied can be handled trivially by using shared memory. In distributed and decentralized algorithms, the problem becomes more complex because the modules are communicating using messages. There are three main types of coordination approaches to consider:

1. One technique is to create an a priori partition in the assignment space, so each distributed agent can trivially generate conflict-free plans.
2. A second technique, commonly known as *implicit coordination*, involves performing situational awareness (SA) consensus (i.e., consensus on all variables that are not assignments) and hope that, given sufficiently close information, the agents are able to independently create conflict-free allocations.
3. The last technique is to directly incorporate the constraint feasibility of the allocations into the convergence process of the planning algorithm.

In general, cooperative algorithms may use combinations of the three techniques listed above. The following discusses the main factors associated with determining which of these techniques is more appropriate given the application at hand.

1. Creating an a priori partition in the task environment effectively chops up the task space and only allows each agent to bid on a subset of the overall task set. Given a higher-level task allocation or a human operator, it may be reasonable to use this method for small teams in relatively static environments. This is because, for some environments, it may be obvious what agents should be servicing which tasks. However, in environments with large numbers of relatively homogeneous agents, or in dynamic environments, the task partitioning problem can become very complicated. By creating this partition, the algorithm is placing artificial

constraints on which allocations are available, which may result in arbitrarily poor task assignments.

2. The main emphasis of *implicit coordination* is to arrive at *situational awareness consensus* (where situational awareness consensus refers to the process by which all agents agree on all variables relevant to the initial conditions of the task allocation problem) before starting the planning algorithm, then run effectively centralized planners on each agent independently. The basic premise of this method is that a consensus algorithm can generate consistent parameter values across an entire team, in which case each agent will generate identical final allocations. This method has been explored in the literature (Ren et al. 2005, 2007; Ren and Beard 2005; Olfati-Saber and Murray 2004; Alighanbari and How 2008a; Moallemi and Roy 2006; Olshevsky and Tsitsiklis 2006; Hatano and Mesbahi 2005; Wu 2006; Tahbaz-Salehi and Jadbabaie 2006) and is widely used because it is a relatively straightforward way to decentralize a task allocation algorithm. The benefit of using implicit coordination over task space partitioning (see 1 above) is that by not limiting the assignment space a priori, the algorithm is able to account for changes in information explicitly (e.g., dynamic tasks and additional state information). Using task space partitioning, any changes in information are likely to necessitate a repartitioning and redistribution of the task space, and if this is not executed, the resulting assignment is likely to perform poorly. In contrast, with implicit coordination, agents explicitly account for information changes through the situational awareness consensus protocol every time they replan, thus producing more relevant higher-performing assignments. Implicit coordination also has the added benefit that if the task environment is highly coupled (with many agent-to-agent and task-to-task constraints), then the plans produced are able to recognize and exploit this structure, thus producing assignments that include highly coordinated behaviors between the agents.

All of these benefits come with the caveat that the situational awareness consensus must happen before the planner can start producing plans, and, in order to guarantee that agents produce the same assignments, this consensus process may require large amounts of communication bandwidth (Alighanbari and How 2008a). A potential difficulty with algorithms that utilize this implicit coordination strategy is that they often require the planning parameters to be known precisely, thus requiring that the consensus process be conducted until errors in situational awareness become very small. In fact, it is often the case that, if the final estimates of the planning parameters do not converge to within arbitrarily tight bounds, there is no *guarantee* that the resulting assignment will be conflict free.

3. The third technique ignores gaining any insight about the situational awareness of other agents and only requires that assignments between the team remain conflict free. The power of this approach is that all of the consensus effort is spent on achieving consistent values for the agent assignments. This solution is preferable if there are few inter-agent constraints and inter-task constraints (the more coupled the task environment becomes, the more difficult the task consensus problem becomes) or if the communication environment is not necessarily reliable such that it would be difficult to reach complete team-wide consistent situational awareness. For many decentralized applications, the primary goal is achieving a conflict-free distribution

of tasks that performs well, rather than requiring intense cooperation between agents to achieve the best possible assignment (such as the CBBA algorithm discussed in Sect. 60.4.1.1). Given that in these environments the communication links are often non-robust, especially across larger distances, only broadcasting information directly relevant to the assignment constraints may be preferable. There is a trade-off between implicit coordination and algorithms using assignment consensus. The choice is really between deciding if it is easier to converge on a consistent assignment vector or converge to arbitrarily tight bounds on all other significant state variables.

60.3.7 Consensus

As discussed above, a key component of cooperative decision making involves performing *consensus* among agents, which is defined as reaching an agreement on quantities of interest, such as plans, situational awareness, or other desired parameters. Most distributed planning approaches employ *consensus algorithms*, which are sets of rules, or protocols, that determine how information is exchanged between agents to ensure that the team will converge on the parameters of interest.

As a simple illustrative example, the following linear consensus protocol can be used to converge on a continuous parameter z :

$$\begin{aligned}\dot{x}_i(t) &= \sum_{j \in N_i} (x_j(t) - x_i(t)) \quad \forall i, \\ x_i(0) &= z_i \in \mathbb{R},\end{aligned}\tag{60.34}$$

where each agent i computes errors with its set of neighbors N_i and uses these to correct its parameter estimate (Olfati-Saber et al. 2007). Collectively, the team dynamics for n agents can be written as an n th order linear system:

$$\dot{\mathbf{x}}(t) = -\mathcal{L}\mathbf{x}(t),\tag{60.35}$$

where $\mathcal{L} = D - A$ is known as the graph Laplacian, which is computed using an adjacency matrix A describing connectivity between agents (the elements a_{ij} are 1 if j is a neighbor of i and 0 otherwise) and a degree matrix $D = \text{diag}(d_1, \dots, d_n)$, with elements $d_i = \sum_{j \in N_i} a_{ij}$. The maximum degree, denoted as $\Delta = \max_i d_i$, is useful in bounding the eigenvalues of \mathcal{L} , which, for an undirected connected network, can be ordered sequentially as

$$0 = \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n \leq 2\Delta.\tag{60.36}$$

The eigenvalues of \mathcal{L} can be used to predict convergence rates and stability properties of these linear consensus algorithms (in particular, λ_2 is related to speed of convergence, and λ_n provides stability bounds in time-delayed networks).

As shown above, the nontrivial eigenvalues are all positive, and exploiting the fact that Eq. 60.35 describes a linear system, the consensus algorithm is globally asymptotically stable and converges exponentially to an equilibrium with rate given by λ_2 (Olfati-Saber et al. 2007). Furthermore, for the system described above, the algorithm is guaranteed to achieve a unique equilibrium $\bar{z} = 1/n \sum_i z_i$, which is the average of all the agents' initial values.

Recent research has explored the effects of more realistic mission environments on these types of linear consensus algorithms for multi-agent teams. Some examples include analyzing the impact of time-delayed messages and dynamic network topologies on convergence and stability properties of the consensus algorithms. The work in Olfati-Saber et al. (2007) shows that global exponential convergence guarantees can be extended to dynamic networks as long as the network remains connected at each time t . The agents are guaranteed to reach consensus with convergence rate greater than or equal to $\lambda_2^* = \min_t \lambda_2(G(t))$, where $\lambda_2(G(t))$ is the second eigenvalue of the Laplacian for graph $G(t)$. Similar guarantees can be made for time-delayed networks, where messages are received after a delay τ instead of instantaneously. The system dynamics can be modified as follows:

$$\dot{\mathbf{x}}(t) = -\mathcal{L}\mathbf{x}(t - \tau), \quad (60.37)$$

and global exponential convergence guarantees are retained for delays within the range $\tau < \pi/2\lambda_n$. Note that convergence rates and robustness to time-delays can be improved by actively controlling the network structure (modifying G and \mathcal{L}), which is an active area of research (Ren and Beard 2005; Ren et al. 2007; Jadbabaie et al. 2003; Blondel et al. 2005; Olfati-Saber et al. 2007).

Consensus algorithms have been applied to a wide variety of distributed decision-making applications, ranging from flocking to rendezvous (Jadbabaie et al. 2003; Beard and Stepanyan 2003; Lin et al. 2003; Fax and Murray 2004; Ren 2006; Ren et al. 2007; Olfati-Saber et al. 2007). Most of these consensus algorithms are computationally inexpensive and guarantee convergence of the situational awareness, even over large, complex, and dynamic network topologies (Hatano and Mesbahi 2005; Wu 2006; Tahbaz-Salehi and Jadbabaie 2006). A common issue with classical consensus algorithms is that agents' observations are often treated with equal weight, whereas in reality, some agents may have more precise information than others. Extending classical consensus algorithms to account for this uncertainty in local information, Kalman consensus approaches have been developed that approximate the inherent uncertainty in each agent's observations using Gaussian distributions (Ren et al. 2005; Alighanbari and How 2008b). These algorithms produce consensus results that are more heavily influenced by agents with smaller covariance (therefore higher certainty) in their estimates. A limitation of Kalman consensus approaches is that Gaussian approximations may not be well suited to model systems with arbitrary noise characteristics, and applying Kalman filter-based consensus methods to the mean and covariance of other distributions can sometimes produce biased steady-state estimation results (Fraser et al. 2009).

Other Bayesian decentralized data and sensor fusion methods have been explored to determine the best combined Bayesian parameter estimates given a set of observations (Waltz and Llinas 1990; Grime and Durrant-Whyte 1994; Makarenko and Durrant-Whyte 2006). A major challenge, however, is that these decentralized data fusion approaches require *channel filters* to handle common or repeated information in messages between neighboring nodes. These channel filters are difficult to design for arbitrary network structures, and generic channel filter algorithms have not been developed other than for simple network structures (e.g., fully connected and tree networks), thus limiting the applicability of decentralized data fusion methods (Grime and Durrant-Whyte 1994). Recent work has addressed this issue by showing that, through a combination of traditional consensus-based communication protocols and decentralized data fusion information updates, scalable representative information fusion results can be achieved, without requiring complex channel filters or specific network topologies (Olfati-saber 2006; Xiao et al. 2005; Fraser et al. 2009, 2012). In particular, the work in Olfati-saber (2006) utilized dynamic-average consensus filters to achieve an approximate distributed Kalman filter, while (Xiao et al. 2005) implemented a linear consensus protocol on the parameters of the information form of the Kalman filter, permitting agents to execute a Bayesian fusion of normally distributed random variables. However, as previously noted, these Kalman-based methods are derived specifically for normally distributed uncertainties (Olfati-saber 2006; Xiao et al. 2005), and thus can produce biased results if the local distributions are non-Gaussian. Recent work has extended these combined filtering and data fusion approaches to allow networked agents to agree on the Bayesian fusion of their local uncertain estimates under a range of non-Gaussian distributions (Fraser et al. 2012). In particular, the approach exploits *conjugacy* of probability distributions (Gelman et al. 2004) and can handle several different types of conjugate distributions including members of the exponential family (e.g., Dirichlet, gamma, and normal distributions) (Fraser et al. 2009, 2012). The approach in Fraser et al. (2012) is termed *hyperparameter consensus* and has demonstrated flexibility in handling several realistic scenarios, including ongoing measurements and a broad range of network topologies, without the need for complex channel filters.

60.4 Decentralized Algorithms

This section reviews current decentralized approaches proposed in the literature, describing the benefits, challenges, and limitations of each.

60.4.1 Market-Based Approaches

Market-based algorithms are integer programming-based formulations that are able to solve distributed and decentralized cooperative assignment problems (Dias and Stentz 2000; Dias et al. 2006). Many successful market-based approaches use an

auction mechanism (Bertsekas 1989, 2007). Auctions may be run via an auctioneer (Gerkey and Mataric 2002; Mataric et al. 2003; Gerkey and Mataric 2004), where each agent computes the reward associated with a task based on their own local understanding of the world and then uses this reward value to place *bids* on the most desirable tasks. Each agent communicates their bid to the auctioneer, and the auctioneer determines the winner for each task. These types of methods guarantee conflict-free solutions since the auctioneer only selects one agent as the winner. They are distributed because the bids are calculated at spatially separated locations, but they are synchronous in that they rely on one winner at every iteration.

Some auction-based protocols do not need to designate a single agent as the auctioneer but utilize a different protocol where the winner is decided based on a set of self-consistent rules (Castanon and Wu 2003). Other such methods, called distributed auction algorithms (Sariel and Balch 2005; Ahmed et al. 2005; Atkinson 2004; Lemaire et al. 2004), have been shown to efficiently produce suboptimal solutions when reward functions satisfy a property called submodularity. One such method is the consensus-based bundle algorithm (CBBA) (Choi et al. 2009), which is a polynomial-time, market-based approach that uses consensus to reach agreement on the cooperative assignment. The following section describes CBBA and illustrates how distributed auction-based allocation algorithms can produce provably good approximate solutions in distributed and decentralized environments.

60.4.1.1 Consensus-Based Bundle Algorithm (CBBA)

CBBA is a distributed auction algorithm that provides provably good task assignments for multi-agent, multi-task allocation problems. This algorithm has been shown to work well in practice because it can handle complicated constraints in a real-time distributed way. The algorithmic structure of CBBA consists of iterations between two phases: a *bundle-building* phase where each agent greedily generates an ordered bundle of tasks and a *task consensus* phase where conflicting assignments are identified and resolved through local communication between neighboring agents. These two phases are repeated until the algorithm has reached convergence.

To further explain the relevant details of the algorithm, some notation will first be formalized:

1. A *bid* is represented as a triple: $s_{ij} = (i, j, c_{ij})$, where i represents the bidding agent's index, j represents the task's index, and c_{ij} represents the bid value for this agent-task pair.
2. A *bundle* is an ordered data structure internal to each agent i , $\mathbf{b}_i = \{s_{ij_1}, \dots, s_{ij_n}\}$ that consists of all n of its current bids. When new bids are made, they are appended to the end of the bundle; thus, the order in the bundle reflects the relative age of each bid.
3. The *bid space* is an unordered set of bids, defined as $\mathcal{A} = \{s_{i_1 j_1}, \dots, s_{i_N j_N}\}$. This set contains a globally consistent set of the current winning bids in the team. A local bid space \mathcal{A}_i is defined as a set that contains agent i 's current local understanding of the global bid space. In a fully connected network, $\mathcal{A}_i = \mathcal{A}$ after each consensus phase, but in general, the geometry of agents in the network may lead to information propagation latencies and thus nonidentical bid spaces.

Bundle-Building Phase For each agent i , the bundle-building phase is run independently.

1. At the beginning of the bundle-building phase, the previous bundle is cleared and all bids that were won by agent i located in the local bid space, \mathcal{A}_i , are also removed. This step is required for the optimality guarantees of the algorithm, but in most cases, the agent will re-add each of the tasks it has just dropped from \mathcal{A}_i as it is building back up the bundle.
2. For each task j available in the environment, each agent i uses its local internal score function $F_{ij}(\mathbf{b}_i) = c_{ij}$, which is a function of its current bundle, to create a score c_{ij} . These scores are then ordered from highest to lowest.
3. The ordered scores c_{ij} are compared with the winning bid information for the corresponding task j located in the agent's local bid space \mathcal{A}_i . The first (and thus largest) score that would outbid the current winner in the local bid space is chosen as agent i 's next bid. A bid s_{ij} is created and placed at the end of the bundle and replaces the current bid on task j in the local bid space. Steps 2 and 3 are repeated until no tasks are able to outbid \mathcal{A}_i or the maximum bundle length is reached, at which point the bundle-building phase terminates. It is worth noting that in this formulation, the values c_{ij} are used to rank the tasks, and the values s_{ij} are communicated as bids to other agents. Algorithm performance can be increased by explicitly separating these two values (i.e., internal scores vs. external bids) (Johnson et al. 2012), enabling a larger class of allowable (more representative) score functions while still ensuring that properties required for algorithmic convergence are met.

Consensus Phase After the bundle-building phase completes, each agent i synchronously shares its current local bid space \mathcal{A}_i with each of its adjacent neighbors. This local bid space, in combination with time-stamp information, is then passed through a decision table (see Choi et al. 2009, Table 1 for details) that provides all of the conflict resolution logic to merge local bid spaces. In general, the consensus logic prefers larger and more recent bids. If the consensus phase has occurred more than twice the network diameter times without any bids changing, the algorithm has converged and terminates; if not, each agent reenters the bundle-building phase and the algorithm continues.

Score Function One requirement that is fundamental for all of the convergence and performance guarantees of CBBA is that the score functions used must satisfy a diminishing marginal gains (DMG) property. This DMG condition is a subset of the well-studied submodularity condition, was recognized in the original description of CBBA (Choi et al. 2009), and further studied in recent work (Johnson et al. 2012). It is defined as

$$F_{ij}(\mathbf{b}_i) \geq F_{ij}(\mathbf{b}_i \oplus_{\text{end}} s_{ik^*}) \quad \forall k^* \in \{1, \dots, N_i\}, \quad (60.38)$$

where $\mathbf{b}_i \oplus_{\text{end}} s_{ik^*}$ refers to adding a bid s_{ik^*} to an already existing bundle \mathbf{b}_i . Roughly, this condition means that no bids s_{ik^*} can be made that would increase c_{ij} , agent i 's score for task j . Given score functions that satisfy DMG, CBBA is guaranteed to converge to a conflict-free solution despite possible inconsistencies

in situational awareness and to achieve at least 50% optimality (Choi et al. 2009) (although empirically its performance has been shown to be above 90% optimality for some UAV environments (Bertuccelli et al. 2009)). The bidding process of CBBA runs in polynomial time, demonstrating good scalability with increasing numbers of agents and tasks, making it well suited to real-time dynamic environments. The real-time implementation of CBBA has been demonstrated for heterogeneous teams, and the algorithm has been recently extended to account for timing considerations associated with task execution, asynchronous communication environments, cooperative planning missions, and uncertain operation environments (Ponda et al. 2010, 2011, 2012; Whitten et al. 2011; Johnson et al. 2011).

60.4.2 Decentralized Markov Decision Processes

As mentioned previously in Sect. 60.2.2, the centralized multi-agent MDP formulation implicitly assumed that each agent had individual full observability of the joint state. When agents are making decisions and observations locally, this is generally an impractical assumption, since it would require each agent to communicate their observations to every other agent at every time step with zero communication cost (commonly referred to as a *free comm* environment). In realistic missions, however, there are operational costs and constraints associated with communication (e.g., bandwidth or dynamic network topologies) which need to be accounted for when planning. To address this issue, several decentralized MDP formulations have been proposed which extend the centralized multi-agent MDP (or POMDP) framework to explicitly account for communication between agents. However, this additional layer increases the dimensionality of the problem which exacerbates computational intractability. This section reviews some of these decentralized algorithms, discusses associated challenges, and presents approximations that can be made to address computational complexity.

The decentralized MDP (Dec-MDP), originally proposed in Bernstein et al. (2002), relaxes the limiting assumption of individual full observability by replacing it with a *joint full observability* requirement (i.e., together the agents have full observability of the state, but individual agents are not required to know the full state on their own). Agents can share parts of the state with each other through communication after a certain number of time steps, but this additional level of communication increases the computational complexity required by the algorithm (double exponential complexity or NEXP). As a reminder, the complexity hierarchy is given by $P \subseteq NP \subseteq PSPACE \subseteq EXP \subseteq NEXP$ denoting which classes of problems are subsets of other classes with regard to increasing computational complexity. For more details and discussion on complexity classes, the reader is referred to Bernstein et al. (2002), Papadimitriou and Tsitsiklis (1987), and Papadimitriou (2003). Similar to the Dec-MDP, the Dec-POMDP (Bernstein et al. 2002) is the decentralized version of the POMDP, where there is additional uncertainty in the state given information provided by the observations (the global state cannot be uniquely determined given a joint observation). Like the Dec-MDP,

the Dec-POMDP assumes that agents have different partial information about the global state. If it is assumed that each agent communicates its observations to every other agent at every time step with zero cost, then the Dec-MDP and Dec-POMDP reduce to the MMDP or MPOMDP described in Sect. 60.2.2. This situation is referred to as *free comm*, and the complexity of the Dec-MDP/Dec-POMDP reduces to that of its MDP/POMDP counterpart (P or PSPACE complexity, respectively). Therefore, the lack of immediate communication (or isolation) between agents can be associated with a jump in computational complexity (Goldman and Zilberstein 2004). Another framework similar to the Dec-POMDP that has been considered in the literature is the multi-agent team decision problem (MTDP) (Pynadath and Tambe 2002) which also consists of decentralized MDP solutions for cooperating agents. The MTDP and the Dec-POMDP have been shown to be equivalent in terms of computational complexity and expressiveness of representation (Seuken and Zilberstein 2008).

Since communication is a key component of decentralized planning, the above formulations have been extended to explicitly model communication between agents. The resulting algorithms, namely, the Dec-POMDP-COM (Goldman and Zilberstein 2003) and the COM-MTDP (Pynadath and Tambe 2002), treat these communications as actions which agents must make explicit decisions about at every time step. In particular, sending a message is considered an action which incurs an associated cost, and each agent needs to decide what messages to send at every given time, where not sending anything is modeled as a null message with zero cost. The reward function is accordingly modified to include the cost of communication. As such, the problem formulation can be extended to make sequential decisions about which messages to send as well as which actions to perform. The tuple now becomes $\langle \mathcal{S}, \mathcal{A}, P, R, \Omega, \mathcal{O}, \Sigma, C_\Sigma, R_T, \gamma \rangle$, where the additional terms are defined below:

- Σ : Defines the joint message space $\Sigma = \Sigma_1 \times \dots \times \Sigma_n$ composed of a discrete set of message options, where Σ_i is the message space for agent i and joint message vector $\sigma \in \Sigma$ is of the form $\sigma = (\sigma_1, \dots, \sigma_n)$ representing the messages sent by each agent.
- C_Σ : Defines a function quantifying the cost of communication where $C_\Sigma(\sigma) : \Sigma \rightarrow \mathbb{R}$ is the cost of sending message σ and is typically a sum over all individual agent message costs, with a null message having zero cost.
- R_T : Defines a total reward function $R_T(s, a, s', \sigma) : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \times \Sigma \rightarrow \mathbb{R}$ specifying the total rewards and costs associated with applying action $a \in \mathcal{A}$ in state $s \in \mathcal{S}$, transitioning to state $s' \in \mathcal{S}$, and communicating message $\sigma \in \Sigma$. Typically, $R_T(s, a, s', \sigma) = R(s, a, s') - C_\Sigma(\sigma)$.

In this framework, a joint policy $\pi = (\pi_1^A, \pi_1^\Sigma, \dots, \pi_n^A, \pi_n^\Sigma)$ contains individual agent policies $\pi_i = (\pi_i^A, \pi_i^\Sigma)$ composed of local policies for actions and for communications, respectively.

In Seuken and Zilberstein (2008), the computational complexity of the Dec-POMDP, MTDP, Dec-POMDP-COM, and COM-MTDP is analyzed, and all of these algorithms have been shown to be NEXP-complete (nondeterministic exponential time), suffering from bad scalability as the number of agents increases.

The varying degrees of complexity between the different problem formulations are directly connected to the assumptions on observability and communication (Seuken and Zilberstein 2008), motivating the development of approximate problem formulations that make assumptions on independence and communication between agents to reduce the computational complexity. These approximation algorithms exploit the structure of the domain to make intelligent decisions about which assumptions to make given the scenario at hand (independence, feature-based representations, etc.), leading to a trade-off between optimality and computational tractability. It is worth noting that these approximations are made in the problem formulation itself rather than in the solution algorithm employed. The most notable of these approximation algorithms is the transition-independent decentralized MDP (TI-Dec-MDP) (Becker 2004), which assumes that agents are independent collaborating entities connected through a global reward that is a function of all agents' states and actions. The TI-Dec-MDP extends the factored Dec-MDP, where the global state can be broken up into local agent states plus some world state that represents the environment variables of interest and which is independent of agents' states and actions ($\mathcal{S} = \mathcal{S}_0 \times \mathcal{S}_1 \times \dots \times \mathcal{S}_n$, where \mathcal{S}_i is each agent's local state space and \mathcal{S}_0 is the world state space). In this formulation, the transition and observation dynamics for each agent are independent (i.e., only functions of the local agent state and the world state $\mathcal{S}_0 \times \mathcal{S}_i$), and the only coupling between agents is given by the joint reward function. These independence assumptions reduce the computational complexity of the Dec-MDP; however, although this approach scales to higher dimensions better than many others, it requires an extensive list of state transition histories per agent, referred to as *events* (Becker 2004; Redding et al. 2012). Furthermore, the independence assumption does not allow the representation to explicitly model global situations that are functions of the combined agents' states (e.g., vehicle collisions), although these can be prevented by assigning very large negative rewards (which are joint), thus making collision avoidance part of the reward function instead of an explicit constraint. Some other approximation architectures include the decentralized sparse-interaction MDP (Dec-SIMDP) (Melo and Veloso 2011), which deals with computational limitations by separating the parts of the state space where agents need to cooperate from the parts where they can act independently; the group-aggregate Dec-MMDP (Redding et al. 2012), which uses features to compress other agents' state-action spaces to highlight the properties of interest for each agent (e.g., how many agents are in an area of interest vs. where is every agent in the environment); and the auctioned POMDP (Capitán et al. 2011), where each agent solves its own POMDP locally and communicates with other agents via an auction algorithm to achieve consensus on plans. Although these algorithms have demonstrated reduced computational complexity and real-time feasibility for large teams of cooperating agents, the approximation strategies involved are typically ad hoc and problem dependent, and developing good approximation strategies for cooperating agents remains an active area of research.

60.5 Conclusions and Future Directions

This chapter presents autonomous cooperative task allocation and planning methods for heterogeneous networked teams, providing an overview of the numerous approaches that have been considered in the literature. In particular, three standard planning frameworks are discussed: integer programming, Markov decision processes, and game theory. The chapter also outlines various architectural decisions that must be addressed when implementing online planning systems for multi-agent teams, providing insights on when centralized, distributed, and decentralized architectures might be good choices for a given application, and how to organize the communication and computation to achieve the desired mission performance. Algorithms that can be utilized within the various architectures are identified, and the main technical challenges and future research directions are discussed.

As mentioned throughout the various sections in this chapter, one of the major challenges associated with cooperative planning algorithms is maintaining computational tractability, especially for distributed and decentralized systems. Designing efficient approximation algorithms that can be used in real-time dynamic environments remains an active area of research in the integer programming, MDP, and game theory communities. Furthermore, designing algorithms that can handle message delays, dynamic networks, and unreliable communication links involves making trade-offs between performance and robustness which can vary depending on the scenario at hand. Many of the open issues in this field revolve around identifying problem-specific features that can be exploited to improve performance or reduce the computational effort. For example, submodularity in the score functions has recently been used to develop greedy algorithms that provide bounds on the suboptimality of the performance (Singh et al. 2009; Golovin and Krause 2010; Krause et al. 2006). The challenge in this case is ensuring that the problem formulation satisfies the submodularity (or adaptive submodularity) conditions.

Another major consideration is that planning algorithms rely on underlying system models, which are usually approximations of the real systems and thus are often inaccurate. Discrepancies between these planner models and the actual system dynamics can cause significant degradations in mission performance. Thus, the planning systems must be efficiently integrated with online parameter identification and learning algorithms to adapt these models in real time (Redding et al. 2010). This process could also include elements of active learning, wherein part of the task assignment is specifically focused on deciding how best to reduce uncertainty to improve mission performance (Bertuccelli and How 2011). Robust planning and model learning, especially in decentralized and dynamic environments, remains an active area of research.

Much of the literature to date has been devoted to developing algorithms that perform well in a single type of environment. Future algorithms should be able to exploit dynamic environmental conditions and adapt their solutions accordingly. For example, if the communication environment is particularly harsh, an algorithm should be robust enough to handle the situation. If conditions improve, however,

the algorithm should be able to leverage the additional communication structure and information to improve performance. These hybrid adaptive planners would be able to make efficient use of whatever information is available, yet remain robust to worst-case environments.

Finally, the algorithms presented in this chapter were discussed in the context of autonomous operations, but many future applications will require human operators on the loop (as opposed to being in the loop). In those scenarios, future research must develop techniques to efficiently allocate the roles and responsibilities of the operator and the autonomy/planning algorithms to ensure synergistic operations while performing the mission. Determining the objective function structure in the optimization to develop plans that are consistent with the human operator's overall objectives is also typically quite challenging, especially for decentralized operations (Cummings et al. 2012), and thus is a promising area for future research.

Abstract

In this chapter, the consensus-based bundle algorithm (CBBA) is incorporated into a hierarchical concept of operation. In the team CBBA, agents are divided into teams and each team plans for its agents to service a set of tasks. This team planning is carried out in a distributed manner using the traditional CBBA. An “outer-loop” team CBBA strategy is presented that coordinates teams’ plans. The hierarchical structure of the team CBBA facilitates a manageable architecture for large numbers of unmanned agents through

human-centered operations. This is because each team is managed by a human operator with the team CBBA aiding coordination between teams.

61.1 Introduction

Currently deployed unmanned air vehicles (UAV) are individually controlled by a group of operators that actively manage different components of the UAV. One operator might control the motion of the vehicle, either directly through “stick-and-rudder” inputs or through a waypoint navigation mode. Simultaneously, different groups of operators remotely control the onboard sensors and evaluate any received data. Recent research has been focused on inverting this ratio of operators per UAV to have a single operator manage a team of UAVs (Cummings and Bruni 2009; Cummings et al. 2012).

Planning algorithms have been developed to aid the operator with the management of a team of UAVs and current research is improving on these algorithms (Shima and Rasmussen 2009; Rasmussen and Shima 2008; Choi et al. 2009). To date, planners are generally implemented centrally, at a base station. Four main factors motivate this centralized paradigm:

1. Poor inter-UAV communication
2. Inadequate processing capability (applies to the computation and algorithms needed for both planning and sensor data processing)
3. Operators’ desire for a continuous stream of video and images
4. Pilot safety in airspace with both unmanned and manned aircraft

First, trustworthy sense-and-avoid capability will increase safety in airspace with piloted and unmanned aircraft. However, until such capabilities are operational, a human operator is necessary to ensure safe operation in mixed environments, which leads to an architecture with planning performed centrally. Second, in military applications, commanders want as much information as possible to facilitate informed decisions, hence the desire for continual video and image footage. If a system is designed to feed high-bandwidth video data to a central human-processor for evaluation, then it also makes sense to plan centrally since communicating C2 data causes negligible change to bandwidth requirements when compared to the transmitted video and images. The continual video and image feeds are, also, necessary because of the UAV’s inadequate ability to autonomously evaluate sensor data and derive actionable intelligence, e.g., detection and classification (factor 2). Lastly, most UAVs do not possess the onboard processing capability to perform the complex calculations necessary for combinatorial optimization (factor 2), and there is not dependable communication between the UAVs, making a distributed planner impractical since the UAVs cannot reliably coordinate their actions.

Decentralized control of UAVs, where the UAVs operate independently from human monitors, is a long-term goal, and in order to accomplish this, the four factors mentioned above will need to be resolved. In the short term, human operators will need to be closely involved with the UAV operation. As more and more UAVs and UAV teams are deployed simultaneously, one could naively allow separate UAV teams to function independently, where each team is monitored by an operator with

his/her own tasks to accomplish. However, a logical step would be to allow these separate teams to share resources. Ideally, the mission, as a whole, could be realized more efficiently when compared with independent operation.

Thus, it is timely to consider alternative management schemes. More specifically, a system-of-systems management architecture needs to be considered that is capable of dynamic distributed task assignment across multiple autonomous vehicles, ranging from small to large. This requires a new distributed management architecture that can coordinate a large number of intelligent agents accomplishing a large number of tasks in time-critical, dynamically changing environments. Moreover, the management approach must still retain human operators, given mission objectives can vary constantly as does the ground situation. The operators' involvement would be supervisory, with attention focused at the mission execution level. Yet, the operators must also be kept informed of the autonomous vehicles' states and task progress, in order to benefit from the human's unique ability to provide critical intuition and judgment for the execution of successful collaborative missions.

Current stick-and-rudder UAV operation is a conservative first step toward fully autonomous aircraft. It allows a human to make decisions for the UAV, avoiding the problems associated with factors 2 and 4 listed above. The first step toward achieving functional autonomous UAVs is to reduce the workload on the UAV operator(s) by allowing the UAV system to takeover duties that current technology allows a machine to perform robustly. The first step for small UAVs was to allow an onboard autopilot to take over the low-level control of the UAV, ensuring stable flight by moving operator control to a higher level of control, e.g., waypoint navigation and heading/altitude commands (Chao et al. 2010).

Autopilots generally have different modes of operation: one mode for direct remote control (RC) and a separate autopilot mode. Such a system could loosely be classified as an adjustably autonomous system or a system that allows the operator to take direct control of an aircraft but also allows the operator to step back and manage the UAV(s) or even simply monitor the UAV(s). *Adjustable autonomy*, sometimes called incremental autonomy or variable autonomy (see Bonasso et al. 1997; Pell et al. 1998), refers to a system with the ability to continuously change the level of autonomy between full autonomous and manual modes during system operation (Dorais et al. 1998). Adjustable autonomy is different from increment assistance in that an autonomous system is able to function on its own while an "assistance system" solely aids the operator (Baudin et al. 1994).

The idea of adjustable autonomy really goes much farther than the basic modes currently used by autopilots today. Adjustable autonomy really has its roots in the artificial intelligence community, the autonomous system can range from manual control to a fully autonomous mode (Scerri et al. 2002, 2003b). In the UAV setting, this implies the UAV is able to observe itself and its surroundings, place itself, in context, within those surroundings, and in pursuit of its mission's objective make appropriate decisions on actions that effect itself and its surroundings.

To further reduce the operator workload, a team paradigm is needed, which reduces the man-hours needed to operate multiple UAVs (Christoffersen and Woods 2004; Sycara and Sukthankar 2006). In the human factors arena, there has been research performed to investigate the effects of managing a team of robots on the

human operator (Kilgore et al. 2007; Lewis et al. 2010; Crandall et al. 2011; Sycara and Lewis 2004). In order for the robots to function independently as part of a team, the agents must be capable of determining teammates intent, meaning the intent of both robot teammates, as well as human teammates (Grosz and Kraus 2003; Scerri et al. 2003a; Sycara et al. 2006, 2003). However, due to the large scope of this problem, there is a lot of research still needed to make mixed human-robot teams practical.

In this chapter, an overview is given of the team consensus-based bundle algorithm (TCBBA) that was presented in Argyle and Casbeer (2011). TCBBA is a hierarchical and distributed task assignment algorithm based on the paradigm that human operators are responsible for their assigned UAVs. Rather than having humans input tasks to a swarm/cloud of agents and then the autonomy deciding which agent will do which task, here the agents are fixed to an operator and the tasks are shifted between teams. This algorithm follows current rules of engagement and is a novel distributed task assignment algorithm, in that it places end responsibility for the welfare of the agents and the success or failure of the mission directly on the human operator. In the TCBBA, each team is composed of heterogeneous UAVs, and a human operator is responsible for the UAVs assigned to his/her team. Each team of UAVs is given tasks that must be accomplished. These tasks are allotted to specific agents in the team using a distributed algorithm called the CBBA (Choi et al. 2009). The teams try to assign all the tasks while maximizing the total score of some cost function. If there are tasks that are not assigned, a second stage starts. In the second stage, the teams offer and request help to and from neighboring teams. This second stage of bidding consists of a higher-level auction algorithm running “outside” a lower level CBBA auction.

The format of this chapter is as follows: Sect. 61.2 lays out the specific problem that is addressed by the TCBBA. Section 61.3 discusses the multi-team extension to the CBBA, which is followed by analysis in Sect. 61.4. Lastly, simulations results and conclusions are presented in Sects. 61.5 and 61.6.

61.2 Task Assignment Problem

Consider the multi-agent multitask assignment problem where a group of N_a agents attempt to service N_t tasks while trying to maximize a reward. This can be stated as:

$$\begin{aligned}
 &\text{maximize} && \sum_{j=1}^{N_a} \sum_{k=1}^{N_t} c_{jk}(\mathbf{x}_j, \mathbf{p}_j) x_{jk} \\
 &\text{subject to} && \sum_{j=1}^{N_a} x_{jk} \leq 1 \quad \forall k \in \{1, \dots, N_t\} \\
 &&& \sum_{k=1}^{N_t} x_{jk} \leq L_m \quad \forall j \in \{1, \dots, N_a\},
 \end{aligned} \tag{61.1}$$

where $x_{jk} \in \{0, 1\}$ is one if agent j services task k and zero otherwise, $\mathbf{x}_j \in \{0, 1\}^{N_t}$ is a vector whose k th element is x_{jk} , \mathbf{p}_j is the path for agent j and indicates the order agent j will service its assigned tasks, $c_{jk}(\cdot)$ is the non-negative reward, and L_m is the maximum number of tasks per agent.

Due to the curse of dimensionality, an exact solution to the multi-agent multitask problem becomes impractical for large numbers of agents (Bellman 1957). To overcome this problem, current operations have multiple operators controlling either one UAV or possibly a group of UAVs. Each group of operators would service tasks independently. In this setup, a human remains responsible for his or her team of agents. The teams interact, with other teams, through higher-level coordination. Here, the N_t tasks and N_a agents are divided between N_o operators. Each team $i \in \{1, \dots, N_o\}$ tries to service all of its assigned tasks $\mathcal{N}_{ti} \subset \{1, \dots, N_t\}$ with its assigned agents $\mathcal{N}_{ui} \subset \{1, \dots, N_a\}$. The team assignment problem can be stated as:

$$\begin{aligned}
 & \text{maximize} && \sum_{j \in \mathcal{N}_{ui}} \sum_{k \in \mathcal{N}_{ti}} c_{jk}(\mathbf{x}_j, \mathbf{p}_j) x_{jk} \\
 & \text{subject to} && \sum_{j \in \mathcal{N}_{ui}} x_{jk} \leq 1 \quad \forall k \in \mathcal{N}_{ti} \\
 & && \sum_{j \in \mathcal{N}_{ti}} x_{jk} \leq L_m \quad \forall j \in \mathcal{N}_{ui}.
 \end{aligned} \tag{61.2}$$

A problem occurs when a team is unable to perform all of its assigned tasks due to time constraints, resource constraints, or agent capabilities. The TCBBA is a hierarchical task assignment method, that allows neighboring teams to request and provide help when this situation occurs.

61.3 Multi-team Task Assignment

The team consensus-based bundle algorithm (TCBBA) consists of two main stages: local task assignment and task sharing. In the first stage, each team implements the traditional CBBA to create an initial task assignment. If there are tasks that were unable to be assigned, the teams attempt to correct this by implementing the CBBA between the teams.

61.3.1 Local Task Assignment

To create the initial task assignment, each team runs the CBBA introduced in Choi et al. (2009). This description of the CBBA follows the explanation given in Choi et al. (2010). The CBBA is a decentralized task assignment algorithm which

consists of iterations between two phases: a bundle-building phase where each agent generates an ordered bundle of tasks and a consensus phase where conflicting assignments are resolved through communication with nearby agents.

61.3.1.1 Phase 1 (Build Bundle)

The first phase of the CBBA is bundle construction, during which each agent adds tasks to its bundle until it is unable to add any more tasks. Each agent j in team i maintains four data vectors: a bundle $\mathbf{b}_{ij} \in (\mathcal{N}_{ti} \cup \{\emptyset\})^{L_m}$, the corresponding path $\mathbf{p}_{ij} \in (\mathcal{N}_{ti} \cup \{\emptyset\})^{L_m}$, a winning bid list $\mathbf{y}_{ij} \in \mathfrak{R}_+^{N_{ti}}$, and a winning agent list $\mathbf{z}_{ij} \in \mathcal{U}^{N_{ti}}$. Tasks in the bundle are ordered by decreasing marginal scores, while those in the path are ordered based on the order they will be performed. The marginal score of a task is defined as follows: Let $S_{ij}(\mathbf{p}_{ij})$ be defined as the total reward for agent j in team i performing the tasks within \mathbf{p}_{ij} . If a task k is added to the bundle \mathbf{b}_{ij} , it has the marginal score improvement $c_{ijk}(\mathbf{b}_{ij}) = \max_{n \leq |\mathbf{p}_{ij}|} S_{ij}(\mathbf{p}_{ij} \oplus_n \{k\}) - S_{ij}(\mathbf{p}_{ij})$ where $|\cdot|$ is the cardinality of the list and \oplus_n is the operation that inserts the second list after the n -th element of the first list. The bundle is updated by $\mathbf{b}_{ij} = \mathbf{b}_{ij} \oplus_{|\mathbf{b}_{ij}|} \{K_{ij}\}$ with $K_{ij} = \operatorname{argmax}_k (c_{ijk}(\mathbf{b}_{ij}) \times \prod (c_{ijk} > y_{ijk}) \times h_{ijk})$ where $\prod(\cdot)$ is one if the argument is true and zero otherwise, and h_{ijk} is one if agent j can perform task k and zero otherwise. The path is updated by $\mathbf{p}_{ij} = \mathbf{p}_{ij} \oplus_{n_{ijK_{ij}}} \{K_{ij}\}$ where $n_{ijK_{ij}} = \operatorname{argmax}_n (S_{ij}^{\mathbf{p}_{ij} \oplus_n \{K_{ij}\}})$.

61.3.1.2 Phase 2 (Conflict Resolution)

In the conflict resolution phase, three data vectors are transmitted to neighboring agents. Two were used in the bundle construction phase: the winning bid list \mathbf{y}_{ij} and the winning agent list \mathbf{z}_{ij} . The third data vector $\mathbf{s}_{ij} \in \mathfrak{R}^{N_{ai}}$ represents the time stamp of the last communication from each of the other agents within the same team. When agent j receives a message from agent m , it uses \mathbf{z}_{ij} , \mathbf{s}_{ij} , \mathbf{z}_{im} and \mathbf{s}_{im} to determine which agent's information is the most up to date for each task. There are three possible actions agent j can perform on task k : (1) update: $y_{ijk} = y_{imk}$, $z_{ijk} = z_{imk}$; (2) reset: $y_{ijk} = 0$, $z_{ijk} = \emptyset$; and (3) leave: $y_{ijk} = y_{ijk}$, $z_{ijk} = z_{ijk}$.

61.3.2 Task Sharing

After the initial plan has been created, the teams communicate with each other to determine if other teams can perform some of their tasks. This phase of the TCBBA has two variations. In the first version, the initial plan developed by the CBBA is fixed and each team attempts to insert the unassigned tasks into the initial plan. In the second version, the initial plan is only used to determine which tasks were able to be assigned. The plan itself is ignored. In both versions, each team is required to maintain the same data vectors. Furthermore, both versions of the TCBBA have three stages: initialization, creating the bundle, and communication and conflict resolution. The initialization stage is the only stage that is different between the two variations of the TCBBA.

61.3.2.1 Version 1: Insert in Path Initialization

This version of the TCBBA keeps the initial plan that was developed by the CBBA. Algorithm 1 describes how all of the data structures are initialized to accomplish this. After the initial plan has been created, each team identifies which of its allocated tasks were assigned to one of its agents, $\hat{\mathcal{N}}_{ti}$, and which of its tasks were unassigned, $\hat{\mathcal{N}}_{ti} = \mathcal{N}_{ti} \setminus \hat{\mathcal{N}}_{ti}$. Teams exchange their lists of unassigned tasks to come up with the complete list of unassigned tasks $\mathcal{T}^u = (\hat{\mathcal{N}}_{t1} \cup \hat{\mathcal{N}}_{t2} \cup \dots \cup \hat{\mathcal{N}}_{tN_o})$ (see (A1 : 1), where (A1 : 1) refers to line 1 of Algorithm 1). The team bundle $\mathbf{B}_i \in (\mathcal{T}^u \cup \{0\})^{L_m}$, winning bid list $\mathbf{Y}_i \in \mathbb{R}_+^{|\mathcal{T}^u|}$, and winner ID list $\mathbf{Z}_i \in \mathcal{U}^{|\mathcal{T}^u|}$ are initialized to empty values because they only include information on tasks in \mathcal{T}^u (A1 : 3–5). The team time-stamp vector, \mathbf{S}_i , is initialized to zeros. In addition, all of the agents' data vectors are enlarged while maintaining the same information to account for the unassigned tasks (A1 : 6–13).

After the initialization is done, it iterates between the bundle construction stage, described in Algorithm 3, and the communication and conflict resolution stage, described in Algorithms 4 and 5, until consensus has been achieved (A1 : 14–17).

Keeping the initial plan ensures that the final plan is relatively close to the original one. During the build bundle phase (Algorithm 3), the CBBA will attempt to insert the unassigned tasks into the plan without disrupting the current plan. The task will only be inserted if all of the tasks later on in the path can still be completed. This guarantees that any task that was assigned during the initial assignment will still be assigned in the final plan.

Algorithm 1: TCBBA version 1 initialization for team i

input: $\hat{\mathbf{b}}_i, \hat{\mathbf{p}}_i, \hat{\mathbf{y}}_i, \hat{\mathbf{z}}_i, \mathcal{N}_{ti}$
output: $\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i$

- 1: $\mathcal{T}^u = \text{unassignedTasks}(\mathbf{b}_i, \mathcal{N}_{ti})$
- 2: $\mathcal{T}_i = \mathcal{N}_{ti} \setminus \mathcal{T}^u$
- 3: $\mathbf{B}_i = \{\}$
- 4: $\mathbf{Y}_i = \text{zeros}(|\mathcal{T}^u|)$
- 5: $\mathbf{Z}_i = \text{zeros}(|\mathcal{T}^u|)$
- 6: **foreach** $j \in \mathcal{N}_{ui}$ **do**
- 7: $\mathbf{b}_{ij} = \hat{\mathbf{b}}_{ij}$
- 8: $\mathbf{p}_{ij} = \hat{\mathbf{p}}_{ij}$
- 9: $\mathbf{y}_{ij} = \text{zeros}(|\mathcal{T}_i \cup \mathcal{T}^u|)$
- 10: $\mathbf{z}_{ij} = \text{zeros}(|\mathcal{T}_i \cup \mathcal{T}^u|)$
- 11: $\mathbf{y}_{ijk} = \hat{\mathbf{y}}_{ijk} \quad \forall k \in \mathcal{T}_i$
- 12: $\mathbf{z}_{ijk} = \hat{\mathbf{z}}_{ijk} \quad \forall k \in \mathcal{T}_i$
- 13: **end**
- 14: **while** *no consensus* **do**
- 15: $[\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i] = \text{buildBundle}(\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathcal{T}^u, \mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i, \mathcal{T}_i)$
- 16: $[\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i] = \text{communicate}(\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i)$
- 17: **end**

Algorithm 2: Changes to Algorithm 1 for TCBBA version 2 initialization

```

1: foreach  $j \in \mathcal{N}_{ui}$  do
2:    $\mathbf{b}_{ij} = \{\}$ 
3:    $\mathbf{p}_{ij} = \{\}$ 
4:    $\mathbf{y}_{ij} = \text{zeros}(|\mathcal{T}_i \cup \mathcal{T}^u|)$ 
5:    $\mathbf{z}_{ij} = \text{zeros}(|\mathcal{T}_i \cup \mathcal{T}^u|)$ 
6: end

```

Algorithm 3: TCBBA build bundle for team i

```

input:  $\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathcal{T}^u, \hat{\mathbf{b}}_i, \hat{\mathbf{p}}_i, \hat{\mathbf{y}}_i, \hat{\mathbf{z}}_i, \mathcal{T}_i$ 
output:  $\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i$ 

1:  $[\mathbf{b}_i, \mathbf{p}_i, \mathbf{y}_i, \mathbf{z}_i] = \text{CBBA}(\hat{\mathbf{b}}_i, \hat{\mathbf{p}}_i, \hat{\mathbf{y}}_i, \hat{\mathbf{z}}_i, \mathcal{T}_i \cup \mathcal{T}^u)$ 
2: foreach  $j \in \mathcal{N}_{ui}$  do
3:   for  $k = 1$  to  $|\mathbf{b}_{ij}|$  do
4:     if  $\mathbf{b}_{ijk} \in \mathcal{T}^u$  then
5:        $n = |\mathbf{B}_i|$ 
6:       for  $m = |\mathbf{B}_i|$  to 1 do
7:         if  $\mathbf{Y}_{i\mathbf{B}_m} < \mathbf{y}_{ij\mathbf{b}_{ijk}}$  then
8:            $n = m - 1$ 
9:         end
10:       $\mathbf{B}_i = \mathbf{B}_i \oplus_n \mathbf{b}_{ijk}$ 
11:    end
12:     $\mathbf{Z}_{i\mathbf{b}_{ijk}} = i$ 
13:     $\mathbf{Y}_{i\mathbf{b}_{ijk}} = \mathbf{y}_{ij\mathbf{b}_{ijk}}$ 
14:  end
15: end
16: end

```

61.3.2.2 Version 2: Create New Plan Initialization

Modifying Algorithm 1 to ignore the initial plan is very straightforward. The data vectors \mathbf{p}_{ij} , \mathbf{b}_{ij} , \mathbf{y}_{ij} , and \mathbf{z}_{ij} are initialized to empty or zero (A2 : 2–5) instead of the initial plan (A1 : 8–9, 12–13).

This version of the TCBBA does not guarantee that all the tasks that were previously assigned in the initial assignment will be completed. Instead, this version will assign tasks that will maximize its score, even if it has to not perform some previously assigned tasks. The score can be improved further by running Algorithm 2 multiple times recomputing the unassigned tasks each time. This allows the teams to trade tasks to improve the overall score in exchange for more computation time and communication steps.

Algorithm 4: Conflict resolution for team i receiving from team j at time τ

input: $\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i, \mathcal{T}^u$
output: $\mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i$

```

1: SEND:  $\mathbf{Y}_i, \mathbf{Z}_i, \mathbf{S}_i$  to team  $j$ 
2: RECEIVE:  $\mathbf{Y}_j, \mathbf{Z}_j, \mathbf{S}_j$  from team  $j$ 
3: foreach  $k \in \mathcal{T}^u$  do
4:    $\hat{\mathbf{Y}}_i = \mathbf{Y}_{ik}, \hat{\mathbf{Z}}_i = \mathbf{Z}_{ik}$ 
5:    $\hat{\mathbf{Y}}_j = \mathbf{Y}_{jk}, \hat{\mathbf{Z}}_j = \mathbf{Z}_{jk}$ 
6:   Find action (Table 61.1)  $\Rightarrow$  UPDATE, RESET, or LEAVE
   ( $\hat{\mathbf{Y}}_i, \hat{\mathbf{Y}}_j, \hat{\mathbf{Z}}_i, \hat{\mathbf{Z}}_j, \mathbf{S}_i, \mathbf{S}_j$ )
7:   if UPDATE then
8:      $\mathbf{Y}_{ik} = \hat{\mathbf{Y}}_j, \mathbf{Z}_{ik} = \hat{\mathbf{Z}}_j$ 
9:   else if RESET then
10:     $\mathbf{Y}_{ik} = 0, \mathbf{Z}_{ik} = 0$ 
11:   end
12:   if UPDATE or RESET then
13:     for  $m = 1$  to  $|\mathbf{B}_i|$  do
14:       if  $\mathbf{B}_{im} = k$  then
15:          $\mathbf{Y}_{i, \mathbf{B}_{in}} = 0, \mathbf{Z}_{i, \mathbf{B}_{in}} = 0, \mathbf{B}_{in} = \emptyset \quad \forall m \leq n \leq L_m$ 
16:       end
17:     end
18:   end
19: end
20: for  $k = 1$  to  $N_o$  do
21:   if  $k = j$  then
22:      $\mathbf{S}_{ik} = \tau$ 
23:   else
24:      $\mathbf{S}_{ik} = \max(\mathbf{S}_{ik}, \mathbf{S}_{jk})$ 
25:   end
26: end
27: foreach  $j \in \mathcal{N}_{ui}$  do
28:   UpdateAgentList( $j, \mathbf{B}_i, \mathbf{Y}_i, \mathbf{Z}_i$ )
29: end

```

61.3.3 Phase 1: Build Bundle

First, the bids for the unassigned tasks and plans for each agent must be computed. This is done by running a CBBA between all of the agents within the team (A3 : 1). After the agent bundles have been built, the information must be extracted from the agents and put into the team data structures. To do this, it goes through each agent's bundle looking for tasks $\{k\} \in \mathcal{T}^u$ and putting them in the team's bundle \mathbf{B}_i in order of decreasing bid (A3 : 6–12). Sorting the bundle is necessary to satisfy

Algorithm 5: Conflict resolution for team i agent j

input: $\mathbf{B}_i, \mathcal{T}^u, \mathbf{b}_{ij}, \mathbf{p}_{ij}, \mathbf{y}_{ij}, \mathbf{z}_{ij}$
output: $\mathbf{b}_{ij}, \mathbf{p}_{ij}, \mathbf{y}_{ij}, \mathbf{z}_{ij}$

```

1: for  $k = 1$  to  $|\mathbf{b}_{i,j}|$  do
2:   if  $\mathbf{b}_{ijk} \in \mathcal{T}^u$  and  $\mathbf{b}_{ijk} \notin \mathbf{B}_i$  then
3:      $\mathbf{y}_{i,j,\mathbf{b}_{ijm}} = 0, \mathbf{z}_{i,j,\mathbf{b}_{ijm}} = 0$ 
4:      $\forall k \leq m \leq |\mathbf{b}_{ij}| \ \mathbf{b}_{ijm} = \emptyset \quad \forall k \leq m \leq |\mathbf{b}_{ij}|$ 
5:     Update  $\mathbf{p}_{ij}$ : For each task that was removed from  $\mathbf{b}_{ij}$  remove it from  $\mathbf{p}_{ij}$ 
6:   end
7: end

```

the diminishing marginal gain requirement mentioned in Choi et al. (2009). The winning bid list is set to the agent winning bid and the winner ID list is set to i (A3 : 13–14).

61.3.4 Phase 2: Communication

The communication phase consists of three steps: sending and receiving data, resolving conflicts in the team's bundle, and resolving conflicts in the agents' bundles. For team i , the team sends $\mathbf{Y}_i, \mathbf{Z}_i$, and \mathbf{S}_i and receives $\mathbf{Y}_h, \mathbf{Z}_h$, and \mathbf{S}_h from team h . It iterates through each task and determines what action to take. The possible actions are the same used in the CBBA and are repeated in Table 61.1.

Table 61.1 Action rule for agent i receiving from agent j (Choi et al. 2009)

| Sender's \hat{z}_j | Receiver's \hat{z}_i | Condition(s) | Action (Default: LEAVE) |
|-----------------------|-----------------------------|--|-------------------------|
| j | i | if $\hat{y}_j > \hat{y}_i$ | UPDATE |
| | j or 0 | | UPDATE |
| | $\eta \notin \{i, j\}$ | if $\mathbf{S}_{j\eta} > \mathbf{S}_{i\eta}$ or $\hat{y}_j > \hat{y}_i$ | UPDATE |
| i | i or 0 | | LEAVE |
| | j | | RESET |
| | $\eta \notin \{i, j\}$ | if $\mathbf{S}_{j\eta} > \mathbf{S}_{i\eta}$ | RESET |
| $\mu \notin \{i, j\}$ | i | $\mathbf{S}_{j\mu} > \mathbf{S}_{i,\mu}$ and $\hat{y}_j > \hat{y}_i$ | UPDATE |
| | j | if $\mathbf{S}_{j\mu} > \mathbf{S}_{i\mu}$ | UPDATE |
| | | else | RESET |
| | μ or 0 | if $\mathbf{S}_{j\mu} > \mathbf{S}_{i\mu}$ | UPDATE |
| | $\eta \notin \{i, j, \mu\}$ | if $\mathbf{S}_{j\mu} > \mathbf{S}_{i\mu}$ and $\mathbf{S}_{j\eta} > \mathbf{S}_{i\eta}$ | UPDATE |
| | | if $\mathbf{S}_{j\mu} > \mathbf{S}_{i\mu}$ and $\hat{y}_j > \hat{y}_i$ | UPDATE |
| | | if $\mathbf{S}_{j\eta} > \mathbf{S}_{i\eta}$ and $\mathbf{S}_{i\mu} > \mathbf{S}_{j\mu}$ | RESET |
| 0 | i or 0 | | LEAVE |
| | j | | UPDATE |
| | $\eta \notin \{i, j\}$ | if $\mathbf{S}_{j\eta} > \mathbf{S}_{i\eta}$ | UPDATE |

There are three possible outcomes from the decision table (A4 : 6): update, reset, or leave. An update for team i means team i 's information is changed to what team h knows (A4 : 8). A reset re-initializes the bid and winner ID to zero (A4 : 10), and the task is removed from the bundle (A4 : 15–16). A leave makes no change to any of the data vectors. If an update or a reset occurred on task k , then the reward values for the tasks that appear in the bundle after task k are no longer valid and all of the following tasks in the bundle need to be reset (A4 : 15–16). The time-stamp vector is then updated using the current time and \mathbf{S}_j (A4 : 21–27).

After the team information \mathbf{B}_i , \mathbf{Y}_i , and \mathbf{Z}_i has been updated, the individual agent's information needs to be updated (A4 : 26–28). Each agent $j \in \mathcal{N}_{ui}$ goes through its entire bundle \mathbf{b}_{ij} looking for any tasks that were removed from the team's bundle (A5 : 1–2). If it finds one then, for that task and each task that follows it in the bundle, the bid and the winner ID are reset to zero (A5 : 3) and the tasks are removed from the bundle and the path (A5 : 4–5).

61.4 Convergence Time Analysis

It is informative to determine the maximum number of communication steps required for all teams to arrive at a conflict-free solution in a static communication network and worst case scenario. Such analysis cannot be made on Algorithm 2 since it requires knowledge of the number of tasks assigned by each team during each iteration.

In the worst case situation, the diameter of the communication network equals the number of agents. Let D_i be the diameter of the communication network of the agents in team i , N_i be the number of tasks assigned to team i , D_T be the diameter of the team communication network, N_u be the total number of unassigned tasks after the local task assignment phase, N be the total number of tasks, and D be the diameter of the communication network of all the agents.

Choi et al. (2009) showed that the maximum number of communication steps needed for the CBBA to converge to a conflict-free solution is ND . Applying this result to the TCBBA, the number of communications steps needed in the worst case for the initial task assignment is $\max_i(N_i D_i)$. The second stage will have at most $N_u D_T$ iterations, and each iteration will have $\max_i N_u D_i$ communication steps between agents as well as one communication step between teams. The total number of communication steps is

$$N_c = \max_i(N_i D_i) + D_T N_u \left(\max_i(N_u D_i) + 1 \right). \quad (61.3)$$

In the worst case, $\max_i(N_u D_i) \gg 1$ so

$$N_c \approx \max_i(N_i D_i) + D_T N_u^2 \max_i(D_i). \quad (61.4)$$

Assuming that the agents and tasks are divided up equally among the N_o teams then

$$N_i = \frac{N}{N_o} \quad \text{and} \quad D_i = \frac{D}{N_o},$$

and (61.4) becomes

$$N_c = \frac{ND}{N_o^2} + \frac{D_T N_u^2 D}{N_o}. \quad (61.5)$$

Assuming worst case communication between the teams then $N_o = D_T$ and (61.5) becomes

$$\frac{ND}{N_o^2} + N_u^2 D = \left(\frac{N}{N_o^2} + N_u^2 \right) D. \quad (61.6)$$

Comparing (61.6) to the worst case convergence bound for the full CBBA assignment ND gives

$$\left(\frac{N}{N_o^2} + N_u^2 \right) D \leq ND, \quad (61.7)$$

and solving (61.7) for N_u gives the following:

$$N_u \leq \sqrt{1 - \frac{1}{N_o^2}} \sqrt{N}. \quad (61.8)$$

Notice as the number of teams increases, the number of allowed unassigned tasks, N_u approaches \sqrt{N} .

Given the assumption of full communication between the teams in lieu of worst case communication then $D_T = 1$ and (61.5) becomes

$$\frac{ND}{N_o^2} + \frac{N_u^2 D}{N_o} = \left(\frac{N}{N_o^2} + \frac{N_u^2}{N_o} \right) D. \quad (61.9)$$

Comparing (61.9) to the worst case convergence bound for the full CBBA assignment ND yields

$$\left(\frac{N}{N_o^2} + \frac{N_u^2}{N_o} \right) D \leq ND, \quad (61.10)$$

where, as with the analysis of above, (61.10) is solved for N_u to obtain

$$N_u \leq \sqrt{N_o - \frac{1}{N_o}} \sqrt{N}. \quad (61.11)$$

Figure 61.1 shows how the maximum number of unassigned tasks change as the number of teams increase while the number of tasks and agents stay the same. Notice in the worst case team communication case, the maximum number of

Fig. 61.1 Maximum number of unassigned tasks for TCBBA to converge quicker than CBBA in worst case as the number of teams changes ($N_t = 150$, $D = 12$)

Fig. 61.2 Maximum number of unassigned tasks for TCBBA to converge quicker than CBBA in worst case as the number of tasks changes ($N_o = 4$, $D = 12$)

unassigned tasks quickly approaches the maximum value of $\sqrt{N_t}$. In the full team communication case, the number of unassigned tasks quickly exceeds $\sqrt{N_t}$.

Figure 61.2 shows how the maximum number of unassigned tasks changes as the number of tasks increase while the number of teams and agents stay the same. Notice that both the worst case team communication and full team communication increase proportionally to $\sqrt{N_t}$.

61.5 Simulation Results

Four scenarios are used to compare the TCBBA to the CBBA. In each scenario there are three teams of four agents within $1,200 \times 400$ m world. Each team is assigned N_u tasks which take 25 s to complete. There are four types of tasks

$\{A, B, C, D\}$ and four types of agents $\{a, b, c, d\}$. Each agent type is only able to service its corresponding task type and is modeled as a point-mass with a constant speed of $|\mathbf{v}| = 40$ m/s and no turning constraints, i.e., the agent's position is given by

$$\dot{\mathbf{r}} = \mathbf{v},$$

where the direction of \mathbf{v} points toward the next task to be visited. The time-discounted reward for the tasks is

$$S_i^{\mathbf{p}_i} = \sum \lambda_j^{\tau_i^j(\mathbf{p}_i)} c_j, \quad (61.12)$$

where $S_i^{\mathbf{p}_i}$ is the total score of agent i with path \mathbf{p}_i , $\lambda_j = 0.001$ is the discounting factor for task j , $\tau_i^j(\mathbf{p}_i)$ is the estimated time that agent i will service task j when following path \mathbf{p}_i , and $c_j = 100$ is the value of the task. The objective is the maximize the total score over 500 s.

The four scenarios are created by changing two parameters. The first parameter is if the teams have their own region of the map or if they are in the same overlapping region. If the teams are not overlapping, then they each have their own 400×400 m region with team 2 located in the center. If the teams are overlapping then the teams' agents and tasks are distributed randomly throughout the entire world. The second parameter is if there are 50 or 100 tasks per team.

Teams 1 and 3 do not include all types of agents, so they will be forced to cooperate with other teams in order to accomplish their tasks. Team 1 has two type a agents and two type b agents, team 2 has one of each type of agent, and team 3 has two type c agents and two type d agents. Each team is assigned an equal number of each task type which are randomly distributed within the team's assigned region. Providing an incomplete set of agents to teams 1 and 3 guarantees there will be unassigned tasks after the initial CBBA, it also guarantees that the proportion of unassigned tasks to total tasks will be higher than the threshold developed in the previous section. This almost guarantees that the TCBBA will take more communication steps than the CBBA.

Five hundred Monte-Carlo simulations are run for each scenario. In each simulation, the tasks are assigned using five different methods: running Algorithm 1 once, running Algorithm 2 once, running Algorithm 2 until the change in score is less than 2.5 %, running Algorithm 2 until either all the tasks have been assigned or the unassigned tasks list stops changing, and merging all the tasks and agents into one team and running the CBBA. Figure 61.3 shows the mean percent difference in total score between the four TCBBA versions and the CBBA assignment. Figure 61.4 shows the mean percent difference in communication steps needed to arrive at a conflict free solution between the TCBBA and the CBBA. Figure 61.5 shows the mean percent difference in computation time between the TCBBA and CBBA.

The results show several interesting things about the TCBBA. First, as seen in Fig. 61.3, all the variations of the TCBBA consistently have a lower overall score than the CBBA. This difference varies based on the which TCBBA variation is used

Fig. 61.3 Mean percent difference in overall score between TCBBA and CBBA

Fig. 61.4 Mean percent difference in communication steps between TCBBA and CBBA

but is typically within 3 %. What is not shown is that occasionally the TCBBA can do as well as the CBBA but in all 500 runs, it never beat it. Second, the TCBBA always required more communication steps than the CBBA as shown in Fig. 61.4. This result was expected because of the large number of unassigned tasks. Third, there is a point of diminishing returns, such that repeating the second variation of TCBBA until the unassigned task list is empty or unchanging is, generally, not worth

Fig. 61.5 Mean percent difference in computation time between TCBBA and CBBA

the computation. Finally, the amount of computation time required is proportional to the number of communication steps as seen in Fig. 61.5. Because the larger problem is partitioned into a set of smaller problems in the TCBBA, it is interesting to note that the TCBBA can take less time to arrive at a solution than the CBBA when implemented in a centralized manner.

Conclusion

This chapter presents a modification of the consensus-based bundle algorithm that handles the multi-team, multitask problem using a combination of auctions and consensus to achieve feasible, conflict free solutions. While these solutions are less optimal than running the CBBA, typically within 3 %, the TCBBA allows the agents to be divided into separate teams, where, following current rules of engagement, responsibility for each agent/team can be kept under the supervision of a human supervisor.

to reduce computational load, the physical constraints imposed on the vehicle are not to be taken into account. In order to mitigate this issue, this chapter describes a framework allowing integrated mission and path planning for coordinating UAVs using the Dubins theory based on the differential geometry concepts which can consider non-straight path segments. The main advantage of this approach is that the number of design parameters can be significantly reduced while providing the shortest, safe, and feasible path, which leads to a fast design process and more lightweight algorithms. In order to validate the integrated framework, cooperative mission and path-planning algorithms for two missions are developed: (1) road-network search route-planning patrolling every road segment of interest efficiently based on the optimization and approximation algorithm using nearest insertion and auction negotiation and (2) communication-relay route planning between a ground control station and the friendly fleet satisfying the constraints on the UAV speed and the avoidance of nonflying zones. Lastly, the performance of the proposed algorithms is examined via numerical simulations.

62.1 Introduction

The large scale of UAV applications has proliferated vastly within the last few years with the fielding of Global Hawk, Pioneer, Pathfinder Raven, and Dragoneye UAVs, among others (Samad et al. 2007). The operational experience of UAVs has proven that their technology can bring a dramatic impact to the battlefield. This includes, but is not limited to, obtaining real time, relevant situational awareness before making contact; helping commanders to lead appropriate decision making; and reducing risk to the mission and operation.

Groups of UAVs are of special interest due to their ability to coordinate simultaneous coverage of large areas or cooperate to achieve common goals. The intelligent and autonomous cooperation of multiple UAVs operating in a team/swarm offers revolutionary capabilities: improved situation awareness; significant reductions in manpower and risk to humans; the ability to perform in hostile, hazardous, and geometrically complex environments; and cost efficiency. Specific applications under consideration for groups of cooperating UAVs include, but are not limited to, border patrol, search and rescue, surveillance, mapping, and environmental monitoring. In these applications, a group of UAVs becomes a mobile resource/sensor and, consequently, tasks and routes of each UAV need to be efficiently and optimally planned in order to cooperatively achieve their mission. Therefore, this chapter addresses the cooperative mission and path-planning problem, which here is considered as a vehicle-routing problem of multiple UAVs for given missions.

Since general vehicle-routing algorithms approximate their paths to straight lines in order to reduce the computational load, the physical constraints imposed

on the vehicle are not to be taken into account. In order to mitigate this issue, this chapter describes a framework which allows integrated mission and path planning for coordinating UAVs. One of key enablers of this approach is the path-planning scheme which was developed in a previous study (Tsourdos et al. 2010) based on the differential geometry concepts, especially Dubins paths. Path-planning algorithms using differential geometry examine the evolution of guidance geometry over time to derive curvature satisfying UAV constraints. Guidance commands defining a maneuver profile can be then computed using the derived curvature of the guidance geometry. One of the main advantages of this approach is that the number of design parameters can be significantly reduced while maintaining the guidance performance. Therefore, this approach will enable not only a fast design process and more lightweight algorithms but will also generate safe and feasible paths for multiple UAVs. This is required for the integration of operational and physical constraints of the UAVs into the cooperative mission and path-planning solution.

Road-network search and communication-relay problems are also addressed to validate the integrated framework of mission and path planning. The road-network search routing problem enables multiple airborne platforms to efficiently patrol every road segment identified in the map of interest. This problem has been mainly handled in the operational research area (Gibbons 1999; Ahr 2004; Gross and Yellen 2003; Bektas 2006) and can be generally classified into two categories: one is the traveling salesman problem (TSP) which finds a shortest circular trip through a given number of cities, and the other is the Chinese postman problem (CPP) which finds the shortest path to travel along each road in the road network. The TSP using multiple UAVs can be considered as a task assignment problem to minimize the mission time or energy by assigning each target to an UAV, for which binary linear programming (Bellingham et al. 2003), iterative network flow (Chandler et al. 2002), tabu search algorithm (Ryan et al. 1998), and receding horizon control (Ahmadzadeh et al. 2006) have been proposed. Recently, Royset and Sato (2010) proposed a route optimization algorithm for multiple searchers to detect one or more probabilistically moving targets incorporating other factors such as environmental and platform-specific effects. Meanwhile, the CPP is normally used for ground vehicle applications such as road maintenance, snow disposal (Perrier et al. 2007), boundary coverage (Easton and Burdick 2005), and graph searching and sweeping (Alspach 2006; Parsons 1976).

The communication-relay problem described in this chapter is used to extend the mission area of a main friendly fleet (FF) such as aircraft and ground convoys using relatively inexpensive subsystems, swarms of UAVs. Therefore, the focus is on cooperative route planning of multiple UAVs to maintain communication between the FF and a ground control station (GCS). UAVs in this problem are used as an effective communication-relay platform in environments characterized by poor radio frequency connectivity, which includes urban, forested, or mountainous regions where no line-of-sight exists between ground transmitters and receivers (Cerasoli and Eatontown 2007). In the late 1990s, a feasibility study which uses

the UAV as a communication relay develops a Battlefield Information Transmission System (BITS) system (Pinkney et al. 1996). The main objective of this study was to provide beyond line of sight communications within an area of operations without using scarce satellite resources. The study predicted that, with the advances in miniaturization technology and improved transmitter efficiencies, the UAV could carry multifunction and multiband transponders to handle the communication relay within size, weight, and power dissipation budgets. Cerasoli (Cerasoli and Eatontown 2007) assessed the practical effectiveness of a UAV communication relay in an urban area using a ray tracing method. The paper concluded that a UAV at 2,000m provided coverage for over 90 % of the ground receivers with 10 dB of LOS path loss by analysis of UAVs placed at various positions and heights over an approximately 500-m² urban area.

The remainder of this chapter is organized as follows. Section 62.2 introduces an overview of path planning using Dubins paths and explains how to allow for physical constraints of the fixed-wing UAVs in Dubins path planning. Then, Sect. 62.3 proposes road-network search route-planning algorithms for multiple UAVs based on mixed integer linear programming (MILP) optimization and the approximation algorithm using nearest insertion and auction negotiation. Section 62.4 describes route-planning and decision-making algorithms for a group of UAVs in order to guarantee communication between the GCS and the FF. Simulation results and analysis of each problem are also included in each section. Conclusions are given in Sect. 62.4.4.2.

62.2 Path Planning Using Dubins Paths

Several path-planning methodologies based on differential geometry have been proposed: Dubins curves, clothoid arcs, and Pythagorean hodograph curves (Shanmugavel et al. 2007; Tsourdos et al. 2010). This section will briefly introduce the concept of Dubins path planning based on the reference (Shanmugavel 2007; Kim et al. 2011), and the detailed algorithm will be developed to design flyable and safe Dubins path transiting between waypoints for cooperative missions of multiple UAVs. The Dubins path is considered because it is the shortest path, has simple geometry, and is computationally efficient.

Path planning is defined as the geometric evolution of curves between two desired poses in free space, C_{free} . The pose in 2D comprises the position coordinates (x, y) and the orientation θ . A simple case of producing path between two poses is first considered. This can be extended into any number of waypoints/poses:

$$P_s(x_s, y_s, \theta_s) \xrightarrow{r(q)} P_f(x_f, y_f, \theta_f), \quad r(q) \in C_{\text{free}}, \quad |\kappa(t)| \leq \kappa_{\text{max}} \quad (62.1)$$

where P_s and P_f denote a starting and final pose, respectively, $\kappa(t)$ represents the curvature of path $r(q)$ with parameter q , and κ_{max} is the maximum curvature

imposed by the UAV dynamic constraints such as maximum lateral acceleration. Motion in the plane is composed of either rectilinear or turning or angular motions. A straight line provides the shortest rectilinear motion, and the circular arc provides the shortest turning or angular motion. Also, the arc provides a constant turning radius which also satisfies the maximum curvature constraint, that is, the minimum turning radius, which is a function of speed and maximum lateral acceleration. The Dubins path (Dubins 1957) is the shortest path between two vectors in a plane, and the path meets the minimum bound on turning radius. The Dubins path is a composite path formed either by two circular arcs connected by a common tangent or three consecutive tangential circular arcs or a subset of either of these two. The first path is a CLC path, and the second one is a CCC path, where “C” stands for circular segment and “L” stands for line segment. Either of these two curves will form the shortest path between two poses and so is a good approach for UAV path planning. This section focuses on Dubins paths of CLC type, and the details of CCC type paths can be found in Oh et al. (2011a).

62.2.1 Generating Dubins Path

The Dubins path can be produced by solving (Eq. 62.1). However, it is computationally efficient if it is produced by geometric principles owing to its simple geometry that it is formed by two circular arcs connected by their common tangents. Therefore, the principles of analytic geometry are used to produce the Dubins paths. There are two possible tangents between the arcs: (1) an external tangent, where the start and finish maneuvers have same turning directions, and (2) an internal tangent, where the turning maneuvers have opposite turning directions (e.g., if the start maneuver is clockwise, the finish maneuver will be anticlockwise and vice versa). Here, only the Dubins path with an external tangent is derived (the case of an internal tangent is analogous). Referring to Fig. 62.1, the input parameters for producing the Dubins path are:

- i) Initial pose: $P_s(x_s, y_s, \theta_s)$
- ii) Finish pose: $P_f(x_f, y_f, \theta_f)$
- iii) Initial turning radius: $\rho_s (= \frac{1}{\kappa_s})$
- iv) Finish turning radius: $\rho_f (= \frac{1}{\kappa_f})$

1. Find the centers of the turning circles $O_s(x_{cs}, y_{cs})$ and $O_f(x_{cf}, y_{cf})$:

$$(x_{cs}, y_{cs}) = (x_s \pm \rho_s \cos(\theta_s \pm \pi/2), y_s \pm \rho_s \sin(\theta_s \pm \pi/2)) \quad (62.2a)$$

$$(x_{cf}, y_{cf}) = (x_f \pm \rho_f \cos(\theta_f \pm \pi/2), y_f \pm \rho_f \sin(\theta_f \pm \pi/2)) \quad (62.2b)$$

where O_s and O_f are called primary circles represented by C_s and C_f , respectively.

2. Draw a secondary circle of radius $|\rho_f - \rho_s|$ at O_f for $\rho_s \leq \rho_f$.

3. Connect the centers O_s and O_f to form a line c , called center line, where $|c| = \sqrt{(x_{cs} - x_{cf})^2 + (y_{cs} - y_{cf})^2}$.
4. Draw a line $O_s T'$ tangent to the secondary circle C_{sec} .
5. Draw a perpendicular straight line from O_f to $O_s T'$, which intersects the primary circle C_f at T_N , which is called as a tangent entry point on C_f .
6. Draw a line $T_X T_N$ parallel to $O_s T'$, where T_X is called as a tangent exit point on C_s .
7. Connect the points P_s and T_X by an arc of radius ρ_s and T_N and P_f by an arc of radius ρ_f .
8. The composite path is then formed by the starting arc $P_s T_X$, followed by the external tangent line $T_X T_N$ and the finishing arc $T_N P_f$.

The triangle $\triangle O_s O_f T'$ is a right-angled triangle with hypotenuse $O_s O_f$, and the other two sides are $O_f T'$ and $O_s T'$, where $\|O_f T'\| = |\rho_f - \rho_s|$. The included angle between $O_s O_f$ and $O_s T'$ is ϕ_e , where

$$\phi_e = \arcsin \left(\frac{\rho_f - \rho_s}{|c|} \right) \quad (62.3)$$

The slope of the line c is ψ , where

$$\psi = \arctan \left(\frac{y_{cf} - y_{cs}}{x_{cf} - x_{cs}} \right) \quad (62.4)$$

The angles $\phi_{ex} = \angle(X_1 O_s T_X)$ and $\phi_{en} = \angle(X_2 O_f T_N)$ are calculated from Table 62.1 where $\overrightarrow{O_s X_1}$ and $\overrightarrow{O_f X_2}$ are parallel to the positive

Fig. 62.1 Dubins – design of CLC path

Table 62.1 Calculation of tangent exit and entry points

| Start-turn | Finish-turn | ϕ_e | ϕ_{ex} | ϕ_{en} |
|---------------|---------------|--|---------------------------------|---------------------------------|
| Clockwise | Clockwise | $\arcsin \left(\frac{\rho_f - \rho_s}{c} \right)$ | $\phi_e + \frac{\pi}{2} + \psi$ | $\phi_e + \frac{\pi}{2} + \psi$ |
| Anticlockwise | Anticlockwise | $\arcsin \left(\frac{\rho_f - \rho_s}{c} \right)$ | $\phi_e - \frac{\pi}{2} + \psi$ | $\phi_e - \frac{\pi}{2} + \psi$ |

Fig. 62.2 Tangent circles

direction of x -coordinate. The values of ϕ_{ex} and ϕ_{en} , the tangent exit and entry points, are calculated as

$$T_X = (x_{cs} + \rho_s \cos(\phi_{ex}), y_{cs} + \rho_s \sin(\phi_{ex})) \quad (62.5a)$$

$$T_N = (x_{cf} + \rho_f \cos(\phi_{en}), y_{cf} + \rho_f \sin(\phi_{en})) \quad (62.5b)$$

From the figure, it can be seen that the turning maneuvers have clockwise rotations. Similarly, other type of Dubins path using the internal tangent can be produced by drawing the secondary circle of radius equal to $|\rho_s + \rho_f|$. It is worth pointing out that the calculation of the tangent exit and entry points T_X and T_N is central in generating the Dubins path.

For a given pose, there are two circles tangent to it. Referring to Fig. 62.2, the pose P has a right turn R on the arc C_1 and a left turn L on the arc C_2 . If θ_s and θ_f are fixed, four Dubins paths are possible between P_s and P_f , which are $\{RSR, RSL, LSR, LSL\}$, where represents the tangent. However, if the final orientation is taken either $\pm\theta_f$, the number of Dubins paths between P_s and P_f will become eight. Figure 62.3 shows the eight possible Dubins paths: four paths each from the primary circle C_1 to the secondary circles C_3 and C_4 and four from C_2 to C_3 and C_4 .

62.2.2 Conditions for the Existence of Dubins Paths

From Sect. 62.2.1, it can be seen that the existence of the Dubins path is determined by the common tangents between the turning arcs. These tangents vanish under two conditions. The external tangent vanishes when one of the primary circles C_s and C_f contains the other, while the internal one vanishes when the primary circles intersect. Both of these conditions together determine the existence of the Dubins

Fig. 62.3 Dubins paths with θ_f as a free variable

path between given two poses, which in turn are a function of the turning radii and hance curvature:

$$\text{External tangent : } (c + \rho_s) > \rho_f, \rho_f > \rho_s \quad (62.6a)$$

$$\text{Internal tangent : } c > (\rho_s + \rho_f), \rho_f > \rho_s \quad (62.6b)$$

62.2.3 Length of Dubins Paths

The Dubins path is a composite path of two circular arcs and a straight line. Hence, the path length s_{Dubins} is the sum of the lengths of individual path segments. Since the length of the common tangent connecting the arcs is determined by the radii of the arcs, the length is also the function of the turning radii. Hence, the length of the path can be varied by changing the radii (curvatures). Also, any two paths can be made equal in length by simply varying the curvature of the arcs:

$$s_{\text{Dubins}} = s_s + s_t + s_f \quad (62.7a)$$

$$= |\rho_s \alpha_s| + \|T_X T_N\| + |\rho_f \alpha_f| \quad (62.7b)$$

$$s_{\text{Dubins}} = f(\rho_s, \rho_f) \quad (62.7c)$$

where s_{Dubins} is the length of the Dubins path, α_s and α_f are the included angles, $\alpha_s = \phi_{ex}$, $\alpha_f = \phi_{en}$, and $\|T_X T_N\| = \sqrt{(y_N - y_X)^2 + (x_N - x_X)^2}$. Using this length of the Dubins path, a reference velocity for each UAV can be computed in order to control the time taken for the UAV to traverse each path for cooperative mission planning.

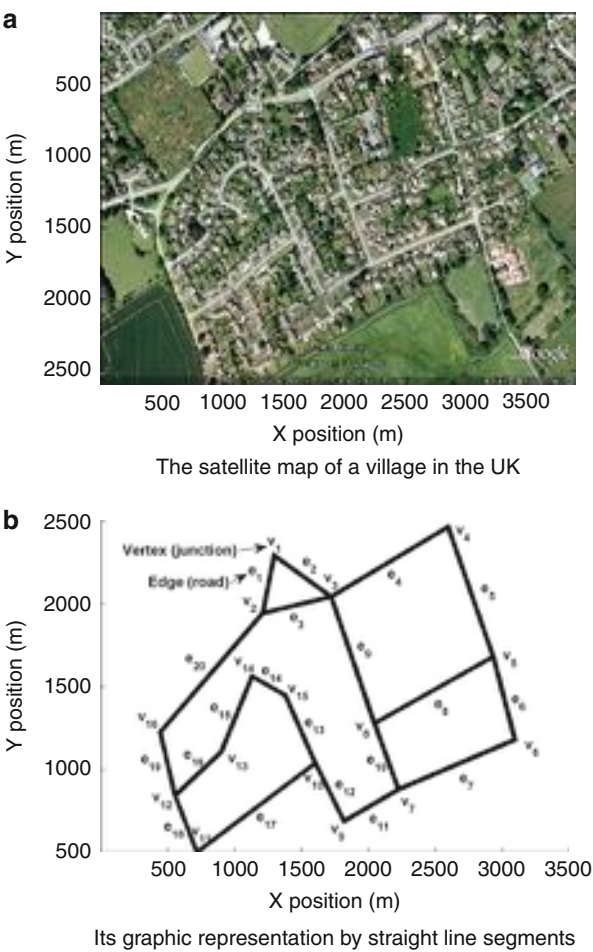

62.3 Cooperative Mission Planning I: Road-Network Search Route Planning

For a road search route-planning mission, a road network is established as a set of straight line connecting a set of waypoints. These waypoints are located either on road junctions or along the roads with sufficient separations between them to allow for accurate representation of a curved road by using a set of straight lines. A sample road network is shown in Fig. 62.4a, which is based on the Google map of a village in the UK. This road network can be translated to a graph composed of straight line segments connecting a set of vertices, as shown in Fig. 62.4b (Oh et al. 2011b). In order to search all the roads within the map of interest, there are generally two typical routing problems (Ahr 2004):

Traveling Salesman Problem (TSP): A salesman has to visit several cities (or road junctions). Starting at a certain city, the TSP finds a route with minimum travel distance on which the salesman traverses each of the destination cities exactly once (and for the closed TSP, leads him back to his starting point). *Chinese Postman Problem (CPP)*: A postman has to deliver mail for a network of streets. Starting at a given point, for example, the post office, the CPP finds a route with minimum travel distance which allows the postman to stop by each street at least once (and for the closed CPP, leading him back to the post office).

Consider the CPP and its variants, which involve constructing a tour of all the roads with the shortest distance of the road network. Typically, the road network is mapped to an undirected graph $G = (V, E)$, having edge weights $w : E \rightarrow R_0^+$, where the roads are represented by the edge set $E = \{e_1, \dots, e_n\}$ and the road junctions are represented by the vertex set $V = \{v_1, \dots, v_m\}$ as numbered in Fig. 62.4b. Each edge $e_i = \{v_{ei,1}, v_{ei,2}\}$ is weighted with its length or the amount of time required to traverse it. The basic CPP algorithm involves first constructing an even graph from the road network which has a set of vertices with an even number of edges attached to them producing a pair of entry and exit points. When the road-network graph has junctions with an odd number of edges, some roads therefore must be selected as exceptions for multiple visits by the postman to make the even graph. The search pattern (tour) of the even graph is calculated by determining the Euler tour of the graph (Gross and Yellen 2003), which visits every edge of the even graph exactly once.

Fig. 62.4 The graphic representation of a road network. **(a)** The satellite map of a village in the UK. **(b)** Its graphic representation by straight line segments

62.3.1 Road-Network Search Route by Multiple Unmanned Aerial Vehicles

The conventional CPP algorithm has been applied to a fully connected road network for use by ground vehicles. However, since UAVs do not have any restrictions such that they must only move along the roads, the CPP algorithm needs to be modified for the case that UAVs search a general road map having unconnected road segments. The modified CPP (mCPP) generates a tour of the road network traveling all the roads once no matter what the type area of interest map is: an even or odd graph. Even searching the area having no road somewhere in it can be tackled by the mCPP algorithm by generating a virtual road pattern with a lawnmower (Maza and Ollero 2007) or spiral-like (Nigam and Kroo 2008) algorithm.

Fig. 62.6 An example of CCC and CLC paths following the road

62.3.2.1 Dubins Path Planning

Once the shortest edge permutations are determined, the next step is to compute and to store the cost (path length or flight time) and to then compute the Dubins paths to connect them. Although the CLC path is being used in general case, this study also explores the CCC path for a densely distributed road environment, because the CLC path cannot be applied in all cases (cf. Sect. 62.2.2). Moreover, to follow the road precisely taking into account the sensor footprint coverage, the path should consist of both CCC and CLC forms of Dubins path. Figure 62.6 shows an example of a road search path using CLC and CCC path for a small sensor footprint, which results in a detour at the road intersection.

62.3.2.2 Generation of the Shortest Edge Permutation

First of all, unordered feasible edge (i.e., road) permutations to be visited by the UAV are generated for all possible cases with a given petal size. The petal size means the maximum number of edges that can be visited by one UAV and is determined by the amount of resources available to it. If the end vertex of one edge and any vertex of the next edge are not connected, they are connected with an additional edge which has a shorter distance. Then, the shortest order-of-visit edge permutations considering the initial position of each UAV are computed under the assumption that a path is represented as a straight line.

62.3.2.3 MMKP Formulation and MILP Optimization

The final step of the proposed algorithm is to allocate the edge permutations to each UAV so as to cover all the roads with a minimum flying time. This can be expressed by a MMKP formulation as

$$\min J = \sum_{i=1}^{N_{\text{UAV}}} \sum_{j=1}^{N_{p_i}} T_{ij} x_{ij} \quad (62.8)$$

$$\text{s.t. } \sum_{i=1}^{N_{\text{UAV}}} \sum_{j=1}^{N_{p_i}} E_{kj} x_{ij} \geq 1, \text{ for } k = 1, \dots, N_{\text{edge}} \quad (62.9)$$

$$\sum_{j=1}^{N_{p_i}} x_{ij} = 1, x_{ij} \in \{0, 1\}, \text{ for } i = 1, \dots, N_{\text{UAV}}, j = 1, \dots, N_{p_i} \quad (62.10)$$

where N_{UAV} , N_{edge} , and N_{p_i} denote the number of UAVs, the edges to be visited, and the permutations generated by the i -th UAV, respectively. T_{ij} represents the mission cost (flight time) of the j -th permutation of the i -th UAV, and E_{kj} represents the matrix whose k -th element of the j -th permutation is 1 if edge k visited; otherwise, 0 and x_{ij} is either 0, implying permutation j of the i -th vehicle is not picked or 1 implying permutation j of the i -th UAV is picked. The first constraint states that the UAVs should visit every edge once or more, and the second constraint represents the allocation of exactly one edge permutation to the each UAV. This MMKP problem is solved using a SYMPHONY MILP solver (Ralphs et al. 2010). It should be noted that, depending on the petal size, the computational burden of the mission cost T_{ij} of all edge permutations can be significant.

62.3.3 Approximation Algorithm

62.3.3.1 Nearest Insertion-Based mDCPP

Due to the complexity of the problem, instead of using the optimization method explained above, an approximation algorithm is developed as a more practical solution to the mCPP (Oh et al. 2011a, 2012). To develop the approximation algorithm, the TSP algorithm is first studied. Although there are a lot of algorithms for the TSP (Rosenkrantz et al. 2009), one heuristic approach, a nearest insertion method, is adopted here since it is fast and easy to implement. The basic idea of the insertion method is to construct the approximate tour by a sequence of steps in which tours are constructed for progressively larger subsets of the nodes of the graph. It produces a tour no longer than twice the optimal regardless of the number of nodes in the problem and runs in a time proportional to the square of the nodes (Rosenkrantz et al. 2009). Having this in mind, the nearest insertion-based mDCPP (NI-mDCPP) algorithm is developed as illustrated in Fig. 62.7. The NI-mDCPP algorithm for the single UAV is described as follows.

Algorithm Description

1. Start from a certain point or road junction and select the nearest road to it using the Dubins path length.
2. Make and grow a tour by finding the nearest road to any of the selected tour roads.

3. Compute the cost of insertion to decide whether to insert before or stack after the closest road to the tour.
4. Insert the selected road in the decided position.
5. 2 ~ 4 are repeated until all roads are included in the tour.

62.3.3.2 Euclidean Distance Order Approximation

To reduce the computation burden further for the dynamic environment, an additional approximation algorithm which uses the Euclidean distance order is incorporated into the NI-mDCPP algorithm. This algorithm is described as follows. First of all, make an ascending order of road list for both the Euclidean distance and the Dubins path length between all pairs of end points of the road network, and find the maximum number, $n_{\text{order,max}}$ which guarantees that road list of Euclidean distance within that number contains the shortest Dubins path. Note that although $n_{\text{order,max}}$ is determined before running the algorithm given information of the road network, a size of $n_{\text{order,max}}$ would remain almost the same against minor changes of road information for an uncertain dynamic environment. Then, when finding the nearest roads, make the ascending order list of distances between the edge of interest and all the other roads using the Euclidean distance first, and find the nearest road whose Dubins path length is the shortest among the roads in the $n_{\text{order,max}}$ Euclidean distance order. In other words, this method computes only $n_{\text{order,max}}$ Dubins path distances instead of computing all the Dubins lengths between one road the other roads.

62.3.3.3 Negotiation for Multiple UAVs

Having developed the NI-mDCPP algorithm for the single UAV, it can be extended to the case of multiple UAVs using auction-based negotiation. The algorithm is described as follows.

Algorithm Description

1. Start with N initial positions or roads of N UAVs.
2. Make and grow a tour by using single NI-mDCPP algorithm while storing the cost (path length or flight time) between selected tour roads and remaining edges (which was needed for finding the nearest vertex).
3. When conflict occurs, that is, more than one UAV wants the same road for the next tour, the auction algorithm using stored cost is used to match UAVs with the task (road) to minimize the cost.

Figure 62.8 illustrates the procedure of the algorithm. Since road 3 is not searched yet in Fig. 62.8d, each UAV sends its cost for the given task (in this case, visiting road 3), and then an auction or bipartite (linear programming) approach is used to match UAVs with the task to minimize the cost. Although overlapping road segments are avoided using the auction algorithm, collision between UAVs might occur during the transition from one road to the next. In that case, if necessary, the path can be replanned either by visiting a new road or by modifying the curvature of the arc of the Dubins path (Tsourdos et al. 2010). For simplicity, it is assumed that the collision avoidance is done by a local flight controller or by operating the UAVs

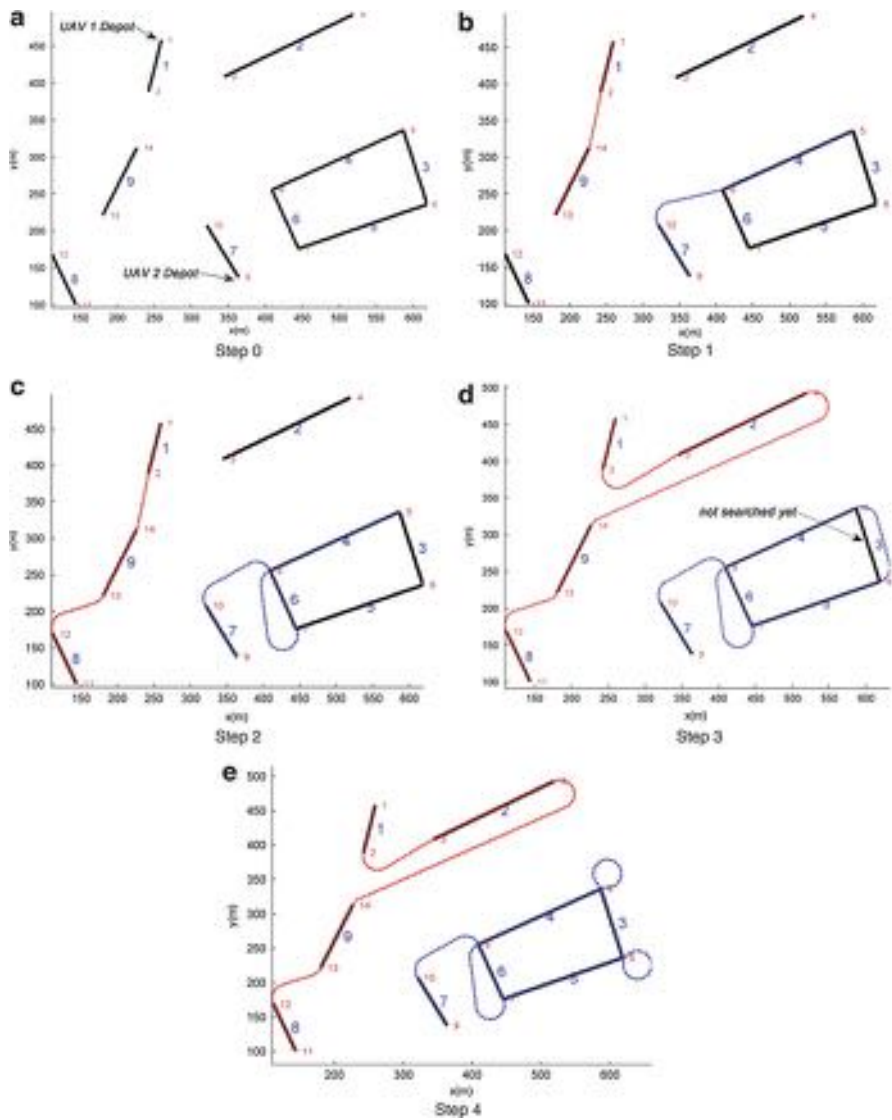

Fig. 62.8 Negotiation procedure for multiple UAVs. (a) Step 0. (b) Step 1. (c) Step 2. (d) Step 3. (e) Step 4

at different altitudes. The proposed algorithm is rather simple but straightforward and can be run in real time. Moreover, by including additional factors such as different minimum turning radii and total path length (or the number of roads) assigned to each UAV into the cost, the auction-based negotiation can be made very flexible and can deal with heterogeneous UAVs.

62.3.4 Numerical Simulations

62.3.4.1 Performance Comparison

To evaluate the performance of the proposed road-network search algorithms for multiple UAVs, numerical simulations are performed for a specific scenario with four UAVs, and the road network shown in Fig. 62.4a. Each UAV has different dynamic constraints given by:

- Minimum turning radius ρ_{\min} : [100 90 80 70] m
- Maximum cruise speed $V_{c,\max}$: [60 50 40 30] m/s

The maximum curvature κ_{\max} of the UAVs are given by $\kappa_{\max} = 1/\rho_{\min}$. The UAVs are assumed to have maximum cruising speed during the entire mission, and the maximum petal size of the edge permutation is set to five. Figure 62.9a shows the result of the road-network search using MILP optimization. The flight path is smooth and flyable due to the Dubins path planning, and since the UAV does not need to only fly along the road, the results include additional paths connecting some of the unconnected roads. The total flight length of all UAVs is 2,798.1 m, and its flight duration is 583.1 s. In this scenario, the total computation time exceeds a reasonable limit (>5 min) using a normal PC system (Core 2 CPU, 2.0 Ghz, and 512 MB RAM). Figure 62.9b shows the search results of the NI-mDCPP algorithm. The NI-mDCPP gives a solution within less than a second having about 12 % longer flight time (653.4 s) than that of the MILP optimization. Considering both the computation time and performance, the NI-mDCPP can be regarded as a preferable approach for the given sample map or a more complex scenario.

62.3.4.2 Monte Carlo Simulation of Approximation Method

To evaluate the properties and performance of the proposed approximation algorithm, Monte Carlo simulations are performed using a random map with different parameters defining the map size and the number of UAVs. The map environment is composed of 10 by 10 vertices, numbered as shown in Fig. 62.10, and the road edges are generated by connecting two randomly selected vertices. To check the impact of the map size on the Dubins path planning, the distance d_{map} between the adjacent vertex is set to be proportional to the minimum turning radius ρ_{\min} of the UAV as

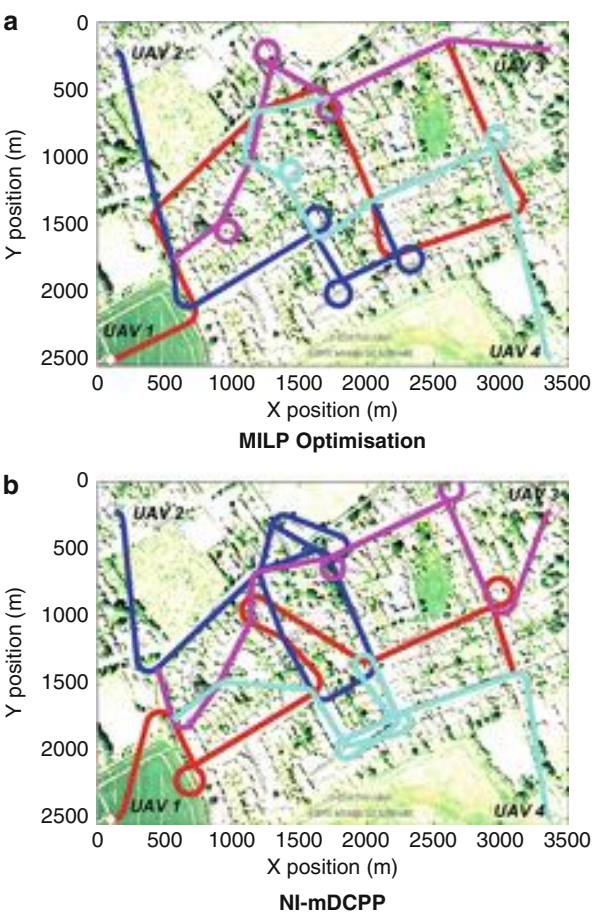

$$d_{\text{map}} = K_s \times \rho_{\min} \quad (62.11)$$

where K_s is the scale factor. Moreover, some of the selected edges whose lengths are longer than three times d_{map} are discarded to get a well-distributed road network and to distribute the roads to each UAV with a similar length. Figure 62.10 shows the sample road network with 20 randomly chosen edges. By Monte Carlo simulations, the effect of three major factors for the road-network search route planning can be investigated. These are:

The distribution density of road network: densely or sparsely distributed road relative to the minimum turning radius of UAVs

The type of path planning: straight line or Dubins path

Fig. 62.9 Road-network search route-planning results using multiple UAVs. **(a)** MILP optimization. **(b)** NI-mDCPP

The number of UAVs: computation time, path length, and the longest path length of a single UAV

This will provide information on priorities for the efficient use of the UAV group in the planning phase of the autonomous search mission.

In the simulations, the UAVs are assumed to have a constant velocity and minimum turning radius of $\rho_{\min} = 50$ m. The simulation results are the average of 50 runs.

Single UAV Case

The first set of simulations are performed using a single UAV with different road map scales. For the rest of this section, the terms of mDCPP and the mECPP are used for the NI-mDCPP and the NI-mECPP, respectively. One of the search route-planning results using the mDCPP for a random map is shown in Fig. 62.11, which covers all the roads satisfying turning constraints of UAVs. Figure 62.12a displays the computation time ratio between the Dubins path (mDCPP) and the

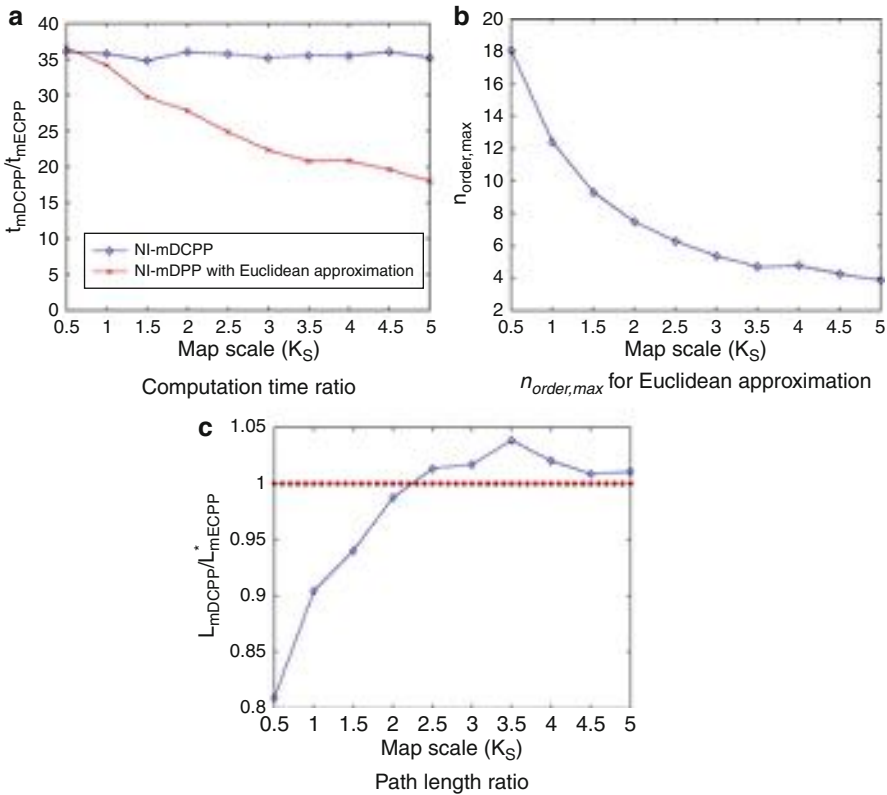

Fig. 62.12 NI-mDCPP results with different map scale factors, average for 50 simulations. (a) Computation time ratio. (b) $n_{order,max}$ for Euclidean approximation. (c) Path length ratio

straight line (mECPP). Regardless of the map scale, the mDcPP algorithm is around consistently 35 times slower than the mECPP. Meanwhile, the computation time of the mDCPP along with the Euclidean distance order approximation, as explained in Sect. 62.3.4, decreases as the map scale increases as a result of a decrease in the maximum order $n_{order,max}$ as shown in Fig. 62.12b. Figure 62.12c compares the total path length to cover the entire road map using the mDCPP and the mECPP. For fair comparison, the length of the mECPP (denoted by L_{mECPP}^*) is computed by road search route using the mECPP algorithm but connecting the roads using a Dubins path. This is because although road search route planning is performed using the mECPP, a real trajectory of the UAV connecting the roads should be of Dubins restricted by its maximum curvature. When the minimum turning radius is relatively small compared to the distance between roads, that is, when the map scale is small, the path length of the mDCPP is shorter than that of the mECPP. However, as the map scale gets bigger, the path length ratio gets closer to one (or even greater than one) since the road search order using Dubins paths is almost the same as using a straight line, as one can expect from Fig. 62.11.

Fig. 62.13 NI-mDCPP road search path with different number of UAVs ($K_s = 2$). (a) 1 UAV. (b) 2 UAVs. (c) 3 UAVs. (d) 4 UAVs. (e) 5 UAVs. (g) 6 UAVs

Multiple UAVs Case

The second simulation is performed using multiple UAVs with different road map scales, and one of the search route-planning results using the mDCPP is shown in Fig. 62.13. The initial position of each UAV is equally distributed around the road area. Figure 62.14 shows the normalized simulation results for

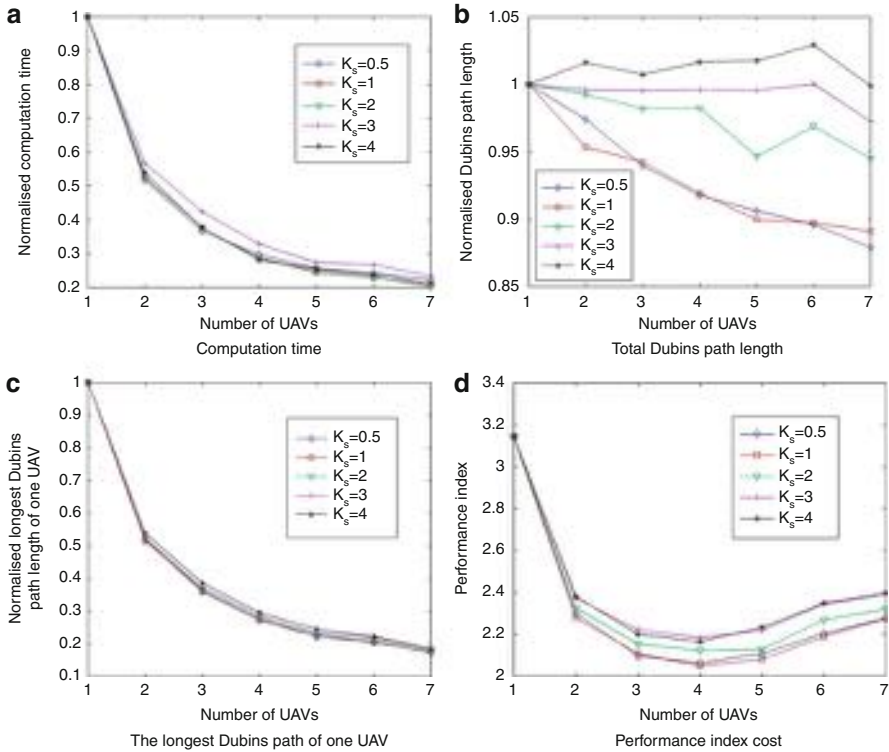

Fig. 62.14 NI-mDCPP results with different number of UAVs ($K_s = 2$), average for 50 simulations. (a) Computation time. (b) Total Dubins path length. (c) The longest Dubins path of one UAV. (d) Performance index cost

a single UAV. In particular, the longest path length (Fig. 62.14c) of the UAV is of interest since it is equivalent to the mission completion time of the entire UAV team. The normalized computation time and the longest path length of the UAV decrease as the size of the UAV team is increased, regardless of the map scale as each UAV takes partial charge of the road search mission cooperatively using the auction-based task assignment. The total path length (Fig. 62.14b) is significantly affected by the map scale. When the map scale is small, the total path length decreases in proportion to the number of UAVs. Whereas in a relatively big map environment, the normalized path length remains close to one since each UAV will fly a long distance from the initial position or from one road to another road. Apparently, the simulation results show that the bigger the UAV team size is, the better performance it shows in terms of the computation time and path length. However, using a large number of UAVs on the team require more operational cost, such as fuel and communication resources. Therefore, the performance index to determine the optimal size of the UAV team for the search mission is proposed as shown in (Eq. 62.12), which includes an additional operational cost for each UAV,

normalized by the number of UAVs (by maximum seven UAVs in this case), \bar{n}_v , and its weighting factor, w_{n_v} :

$$J = w_t \bar{t} + w_l \bar{l} + w_L \bar{L} + w_{n_v} \bar{n}_v \quad (62.12)$$

where w_t , w_l , and w_L represent the weighting factors of computation time, the total path length and the longest path length, of one UAV, respectively. Under the assumption that all of the weighting factors are set to one, the number of UAVs to minimize the performance index J can be selected as four for all map scale factors as shown in Fig. 62.14d.

62.4 Cooperative Mission Planning II: Communication Relay

This section presents the development of trajectory planning for multiple UAVs making use of Dubins path theory in order to maintain and optimize the communication relay between a FF (friendly fleet) performing a main mission and a GCS (ground control station) centrally administrating the whole mission (Kim et al. 2011). To apply Dubins path theory to the optimization of communication between UAVs and with the GCS, various strategic or dynamic constraints have to be considered: mission planning of the FF, the positions of the GCS, any existing nonflying zones, and the limits of UAV dynamics. These constraints affect the decision making of the waypoint sequences of the UAV members. (The final, definitive version of the Section 62.4 of this chapter has been published in Proceedings of the Institution of Mechanical Engineers, Part G: Journal of Aerospace Engineering, 225/1, Jan/2011 (<http://pig.sagepub.com/content/225/1/12.abstract>) by SAGE Publications Ltd, All rights reserved. © 2011, Institution of Mechanical Engineers.)

62.4.1 Waypoint Sequence Decision Making for Communication Relay

The decision making of the UAVs will be based on the waypoint sequence W_F of the FF which is a priori known since the friendly fleet's future movement can be broadcasted to the UAV swarm and the GCS:

$$W_F = [W_{F0}, W_{F1}, W_{F2}, \dots, W_{Fn}] \quad (62.13)$$

where $W_{Fi} = (x_{Fi}, y_{Fi})^T$ and n is the number of waypoints to be passed by the FF. Awareness of the asset speed V_F makes it possible to get the arrival-time sequence T_F at the waypoint sequence defined in (Eq. 62.13):

$$T_F = [t_{F0}, t_{F1}, t_{F2}, \dots, t_{Fn}] \quad (62.14)$$

Fig. 62.15 Decision making on spreading out the UAV members: the distance from the GCS to the FF is shorter than twice of the communication range $k_o R_{com}$

where t_{Fi} is the arrival time at the i -th waypoint. This can be computed using the speed information of the FF which is assumed constant over the mission. Given these waypoint and arrival-time sequences of the FF, the waypoint sequence of N_u UAVs can be determined by considering communication relay between the GCS and the FF.

Let us consider a ratio of the distance from the GCS position $P = (x_p, y_p)^T$ to the FF over the communication range R_{com} as shown in Fig. 62.15 given as

$$k_F = \max_i \frac{|W_{Fi} - P|}{R_{com}}, \quad i \in \{0, 1, \dots, n\} \quad (62.15)$$

It is assumed that each UAV has the same communication range as the GCS.

Firstly, consider the case where the distance from the GCS to the FF is shorter than $(1 + k_o)$ -times the communication range R_{com} , that is, $k_F \leq (1 + k_o)$ as shown in Fig. 62.15 (k_o is given by (Eq. 62.16)). If the FF's next waypoint and arrival time are given in (Eqs. 62.13) and (62.14), the target center position of UAVs, W_{uc} , is assigned as the intersection between a circle of the communication range adjusted by an overlap coefficient k_o and the line-of-sight from the GCS position to the asset's next waypoint W_{Fi} , where

$$W_{uc} = P + k_o R_{com} [\cos \psi_F, \sin \psi_F]^T \quad (62.16)$$

and where

$$\psi_F = \tan^{-1} \frac{y_{Fi} - y_p}{x_{Fi} - x_p} \quad (62.17)$$

The distribution of UAVs on the boundary of the communication range aims at maximizing the coverage of communication when the FF goes out of the

communication range. Note that $0 < k_o \leq 1$ is adjustable to make the boundaries between the communication circles overlap in order to prevent loss of communication. The choice of the design parameter k_o is made by a trade-off analysis.

A target waypoint of an individual UAV is next determined to distribute all of the swarm members relatively to the target center position W_{uc} . All the UAV members should spread out in a single line, as shown in Fig. 62.15, because the other UAVs enable redundant communication channels in an emergency, although in this case, a single UAV is enough to maintain the communication coverage. The distribution line needs to be perpendicular to the line-of-sight $\overrightarrow{PW_{Fi}}$ in order to maximize the lateral communication coverage. Thus, the azimuth of the distribution line relative to the GCS site, ψ_l , is obtained using the azimuth of the FF relative to the GCS site, ψ_F , computed with (Eq. 62.17) to give

$$\psi_l = \psi_F - \pi/2 \quad (62.18)$$

As a result, the position vector of the j -th UAV is decided by a rotational transformation using the number of UAVs N_u , the angle of the distribution line ψ_l , and the target center position W_{uc} :

$$W_u^j = W_{uc} + \begin{bmatrix} \cos(\psi_l) & -\sin(\psi_l) \\ \sin(\psi_l) & \cos(\psi_l) \end{bmatrix} \begin{pmatrix} (-(N_u - 1)/2 + (j - 1))d_s \\ 0 \end{pmatrix} \quad (62.19)$$

where $j \in \{1, 2, \dots, N_u\}$ and d_s is a separation distance between the UAVs at the target waypoint.

In the general case, consider the case where the distance from the GCS to the FF exceeds $(1 + k_o)$ -times the communication range R_{com} , that is, $k_F > (1 + k_o)$ in (Eq. 62.15). To maintain the communication relay, the distribution of the UAVs has to be restructured since a single UAV cannot link the communication between the FF and the GCS. This study adopts a restructuring policy such that some of the UAV members can move to communication-relay positions having the shape of a chain defined by k_F . First, choose the number of UAVs N_m that should move to the new communication-relay positions in order not to lose the communication as

$$N_m = \langle \frac{k_F}{k_o} - 1 \rangle \quad (62.20)$$

where $\langle x \rangle$ rounds the value of x to the nearest integer toward minus infinity. Note that the closer that k_F to k_o is, the fewer UAVs are needed, but the smaller the overlapping areas are. For example, when the FF flies to the waypoint defined by $2k_o \leq k_F < 3k_o$ with the help of a four-UAV swarm, N_m becomes 1; hence, only the fourth UAV member of the swarm should move to the new relay waypoint point W_{ur}^4 , as shown in Fig. 62.16. In a similar manner, generalize the relay position of W_{ur}^k by

$$W_{ur}^k = W_{Fi} + \begin{bmatrix} \cos(\psi_F) & -\sin(\psi_F) \\ \sin(\psi_F) & \cos(\psi_F) \end{bmatrix} \begin{pmatrix} -(N_u - k + 1)k_o R_{com} \\ 0 \end{pmatrix} \quad (62.21)$$

Fig. 62.16 Decision making on spreading out the UAV members: the distance from the GCS to the FF is longer than twice of the communication range $k_o R_{com}$

where $k \in \{N_u - N_m + 1, N_u - N_m + 2, \dots, N_u\}$. In short, N_m number of UAVs move to the relay positions W_{ur}^k as defined in (Eq. 62.21), while the other $N_u - N_m$ number of UAVs are distributed on the line as defined in (Eq. 62.19). In this way, the communication between the GCS and the FF can be maintained in virtue of the reconstruction of the UAV formation no matter that the FF maneuvers beyond the communication boundary of the GCS.

Finally, the following waypoint and arrival time sequences of the j -th UAV can be obtained using (Eqs. 62.19), (62.21), and (62.14):

$$W_U^j = [W_{u0}^j, W_{u1}^j, W_{u2}^j, \dots, W_{un}^j] \quad (62.22)$$

$$T_U^j = [t_{u0}^j, t_{u1}^j, t_{u2}^j, \dots, t_{un}^j] \quad (62.23)$$

where $t_{ui}^j = t_{ai}$ since the UAV has to arrive at the same time as the assets to protect them effectively.

62.4.2 Nonflying Zone Constraint Against UAV

In a battlefield or an urban area, a NFZ (nonflying zone) could exist as an obstacle dangerous to a swarm of UAVs generated by an enemy, a high building/structure, or an airport space. When a threat is detected, the path planner generates an intermediate waypoint so that the threat is avoided. Consider a flyable trajectory $r(q)$ generated for a given set of poses/waypoints. The schematic of the concept

Fig. 62.17 Threat handling by intermediate pose

Fig. 62.18 Case 1: The line between the target waypoints crosses the NFZ

is shown in Fig. 62.17. In the figure, the central hatched circle is the threat. The intermediate waypoints are generated by first drawing a line between the current waypoint p_1 and the next waypoint p_2 . If a line orthogonal to this is constructed, it will intersect the safety circle at two points N and M . These are then designated as the potential intermediate waypoints. If the center C is left to the line p_1p_2 , the intermediate waypoint M is selected on the right-hand side of the threat region and vice versa. Consider two cases relating to the nonflying zone avoidance.

62.4.2.1 Case 1: The Line Between the Target Waypoints Crosses the NFZ

The first case happens when the line between the current waypoint W_{i-1} and the next waypoint W_i cuts a nonflying zone as shown in Fig. 62.18.

Define a vector of positions of target waypoints, the intermediate waypoint to be designed, and the nonflying zone center by

$$W_{i-1} = [x_{i-1}, y_{i-1}]^T \quad (62.24a)$$

$$W_i = [x_i, y_i]^T \quad (62.24b)$$

$$W_i^I = [x_i^I, y_i^I]^T \quad (62.24c)$$

$$P_n = [x_n, y_n]^T \quad (62.24d)$$

The following equation of a line l_i is obtained with a simple geometrical relation between two successive waypoints, W_{i-1} , W_i :

$$y - y_i = \frac{y_i - y_{i-1}}{x_i - x_{i-1}}(x - x_i) \quad (62.25)$$

To check the violation of the NFZ, the distance from the NFZ center to the line l_i is calculated as

$$d = \frac{|(y_i - y_{i-1})(x_n - x_i) - (x_i - x_{i-1})(y_n - y_i)|}{\sqrt{(y_i - y_{i-1})^2 + (x_i - x_{i-1})^2}} \quad (62.26)$$

If $d < \rho_s$, a intermediate target waypoint W_i^I needs to be defined for the UAV to make a detour around the nonflying zone. For this, the tangential line l_t is required, and its gradient can be obtained using the following second-order polynomial equation which represents the relationship between the tangential line l_t and the safety circle radius ρ_s :

$$am^2 + bm + c = 0 \quad (62.27)$$

where the coefficients are defined as

$$a = (x_n - x_{i-1})^2 - \rho_s^2 \quad (62.28a)$$

$$b = 2(x_n - x_{i-1})(y_{i-1} - y_n) \quad (62.28b)$$

$$c = (y_{i-1} - y_n)^2 - \rho_s^2 \quad (62.28c)$$

This equation has two roots, and the root m_t closest to the gradient of the line l_i is chosen. The resulting equation of the line l_t is given by

$$y - y_{i-1} = m_t(x - x_{i-1}) \quad (62.29)$$

The equation of the line l_{n1} is defined using the property that it is perpendicular to the line l_i and is located at the NFZ center P_n :

$$y - y_n = m_{n1}(x - x_n) \quad (62.30)$$

where $m_{n1} = -\frac{x_i - x_{i-1}}{y_i - y_{i-1}}$. Finally, the intermediate target waypoint W_i^I is defined by the intersecting point of the lines l_t and l_{n1} . Solving (Eqs. 62.29) and (62.30) together gives

$$x_i^I = \frac{m_t x_{i-1} - y_{i-1} - m_{n1} x_n + y_n}{m_t - m_{n1}} \quad (62.31a)$$

$$y_i^I = m_t(x_i^I - x_{i-1}) + y_{i-1} \quad (62.31b)$$

$$x_i^I = \frac{m_t x_{i-1} - y_{i-1} - m_{n1} x_n + y_n}{m_t - m_{n1}} \quad (62.32a)$$

$$y_i^I = m_t(x_i^I - x_{i-1}) + y_{i-1} \quad (62.32b)$$

62.4.2.2 Case 2: The Next Target Waypoint Exists Inside the NFZ

For this case, a replacement target waypoint W_i^S needs to be defined as the next target waypoint exists inside the NFZ as shown in Fig. 62.19. In a similar manner to case 1 in Sect. 62.4.2.1, the line l_t tangential to the NFZ safety circle can be obtained using (Eqs. 62.27)–(62.29). Then, define a position vector of the substitute target waypoint as

$$W_i^S = [x_i^S, y_i^S]^T \quad (62.33)$$

The equation of the line l_{n2} is defined using the property that it is perpendicular to the line l_t and goes through the next waypoint W_i :

$$y - y_i = m_{n2}(x - x_i) \quad (62.34)$$

where $m_{n2} = -1/m_t$. Finally, the replacement target waypoint W_i^S is defined as the intersection point of lines l_t and l_{n2} . Solving (Eqs. 62.29) and (62.34) together gives

Fig. 62.19 Case 2: The next target waypoint exists inside the NFZ

Fig. 62.20 Decision making concept on speed constraints: An intersection position exists (*Left*) and does not exist (*Right*) between the maximum arrival circle of the UAV and the protection line

$$x_i^S = \frac{m_t x_{i-1} - y_{i-1} - m_{n2} x_i + y_i}{m_t - m_{n2}} \quad (62.35a)$$

$$y_i^S = m_t (x_i^S - x_{i-1}) + y_{i-1} \quad (62.35b)$$

62.4.3 Speed Constraint of UAV

The UAVs have a maximum speed constraint V_{\max} ; thus, at times they cannot arrive at the next target waypoint W_i in time from the previous waypoint W_{i-1} , as shown in Fig. 62.20. In this case, the next target waypoint has to be replaced by a new waypoint W_i^S . The decision making considers only the case in which there exists an intersection between the maximum arrival circle of the UAV and the communication range of the FF. To check existence of an intersection between the area of the maximum arrival circle and the next waypoint, the distance from the current waypoint W_i to the next waypoint W_{i+1} is calculated as

$$d = |W_i - W_{i+1}|. \quad (62.36)$$

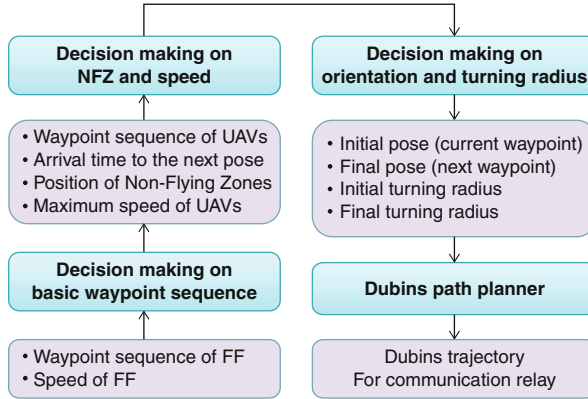

Fig. 62.21 The overall block diagram of the proposed decision-making and path-planning methodology

The radius of the maximum arrival circle is computed as $V_{\max} \Delta t$ where Δt is defined as $t_{ui}^j - t_{u(i-1)}^j$ using (Eq. 62.23). If $d > V_{\max} \Delta t$, an intersection position does not exist between the area of the maximum arrival circle of the UAV and the next waypoint, as shown in Fig. 62.20. In this case, since the UAV has to go inside the FF's communication range in order to maintain the communication relay, the new waypoint W_i should be determined by the intersection between the maximum arrival circle of the UAV and the communication range of the FF.

The starting and final positions have been defined to generate the Dubins path between the target waypoints of the UAVs. To complete the design of the Dubins path, the orientation also need be designed. The orientation of the UAVs between the i -th and $(i + 1)$ -th waypoints is synchronized with that of the friendly fleet in order to keep the line-of-sight stable from the GCS to the FF as

$$\theta_i = \tan^{-1} \frac{y_{Fi} - y_{F(i-1)}}{x_{Fi} - x_{F(i-1)}} \quad (62.37a)$$

$$\theta_{i+1} = \tan^{-1} \frac{y_{F(i+1)} - y_{Fi}}{x_{F(i+1)} - x_{Fi}} \quad (62.37b)$$

Figure 62.21 shows the overall block diagram of the proposed decision-making and path-planning methodology.

62.4.4 Numerical Simulations

62.4.4.1 Simulation Conditions

In order to demonstrate the performance and behavior of the path-planning system, numerical simulations are carried out on a baseline scenario as depicted in Fig. 62.22. The flight plan of the friendly fleet is shown as a bold red (outside

Fig. 62.22 An illustration of basic scenario

Table 62.2 Simulation parameters

| Variable | Description | Value | Unit |
|------------------|-------------------------------------|---|------|
| R_{com} | Communication range | 20 | km |
| P | Position of GCS | $[30, 30]^T$ | km |
| P_n | Positions of NFZ | $\begin{bmatrix} 25 & 35 & 42 \\ 60 & 40 & 54 \end{bmatrix}$ | km |
| ρ_s | Radius of NFZ | 3 | km |
| W_F | Waypoint sequence of FF | $\begin{bmatrix} 5 & 8 & 25 & 42 & 55 & 42 & 32 & 14 & 7 \\ 20 & 55 & 87 & 95 & 59 & 39 & 37 & 33 & 20 \end{bmatrix}$ | km |
| V_F | Speed of FF | 50 | m/s |
| d_s | Separation distance | 2.5 | km |
| V_{max} | Maximum speed of UAV | 50 | m/s |
| n_{max} | Maximum lateral acceleration of UAV | 1 | g |
| k_o | Overlap coefficient | 0.9 | N/A |

the GCS communication range) and blue (inside the GCS communication range) line passing through a series of predefined waypoints. The circumstances are such that the flight of the FF must pass outside of the GCS communication range for a significant period. Figure 62.22 shows that the FF flies up to three times the communication ranges. Three nonflying zones (red dotted circles) are also defined around and outside the GCS communication range. The speed and the flight plan of the FF for the whole mission is known to the UAV members in advance ahead the next waypoint. The UAV group consists of three members (defined by (Eq. 62.16)) whose initial positions are illustrated as triangles. The detailed default parameters can be found in Table 62.2.

Fig. 62.23 Simulation result on basic scenario with two UAVs: position histories of UAVs (x) and friendly fleet (o) (star: GCS, red dotted circle: NFZ, black dotted circle: GCS coverage)

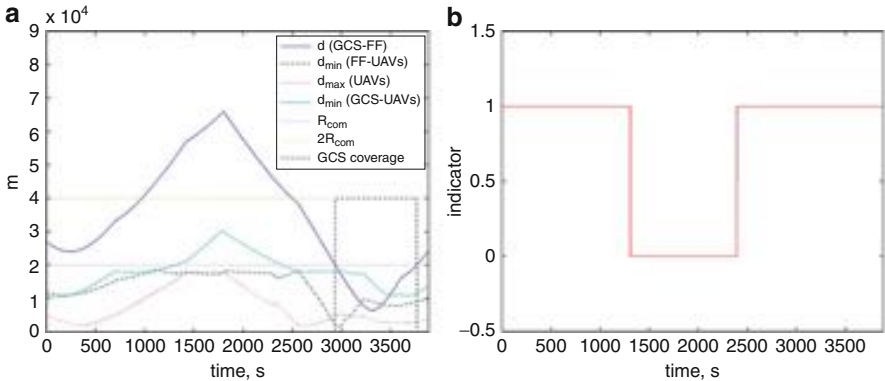

Fig. 62.24 Simulation result on basic scenario with two UAVs: (a) relative distance histories among GCS, UAVs, and friendly fleet and (b) indication on communication relay (1: success, 0: failure)

62.4.4.2 Simulation Results

To effectively compare performance, the proposed algorithm is applied to a two-UAV swarm. Figures 62.23 and 62.24 show that the movements of the UAV members fail to maintain the communication relay for about 1,200 s in the middle of the mission because the distance from the GCS to the UAV members exceeds the communication range R_{com} , which means the GCS loses the communication with the UAV. This implicates that more than two UAVs should be required to maintain the communication relay between the FF and the GCS.

Fig. 62.25 Simulation result on basic scenario with speed and NFZ constraints: position histories of UAVs (x) and friendly fleet (o) (star: GCS, red dotted circle: NFZ, black dotted circle: GCS coverage)

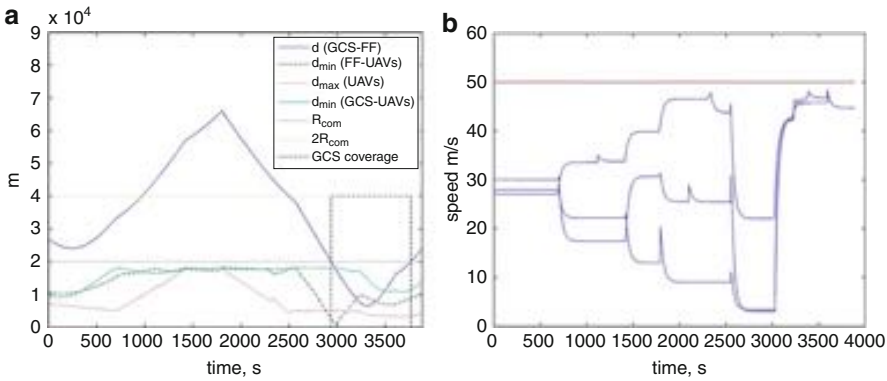

Fig. 62.26 Simulation result on basic scenario with speed and NFZ constraints: (a) relative distance histories among GCS, UAVs, and friendly fleet and (b) speed histories of UAVs (red line: V_{max})

The trajectories of the UAVs avoid entering the NFZ effectively, and at the same time, their speeds do not go over the maximum, as shown in Figs. 62.25 and 62.26. Also, this figure shows that the communication is successfully maintained. It can be shown that the minimum distance from the GCS to the UAVs, the maximum distance between the UAVs, and the minimum distance from the FF to the UAVs are always kept below the communication range R_{com} . Figure 62.27 shows snapshots of the communication boundaries of the UAV members, depicted as the red circles, where the communication between the GCS and the friendly fleet is successfully relayed by restructuring the UAV positions in a chain shape.

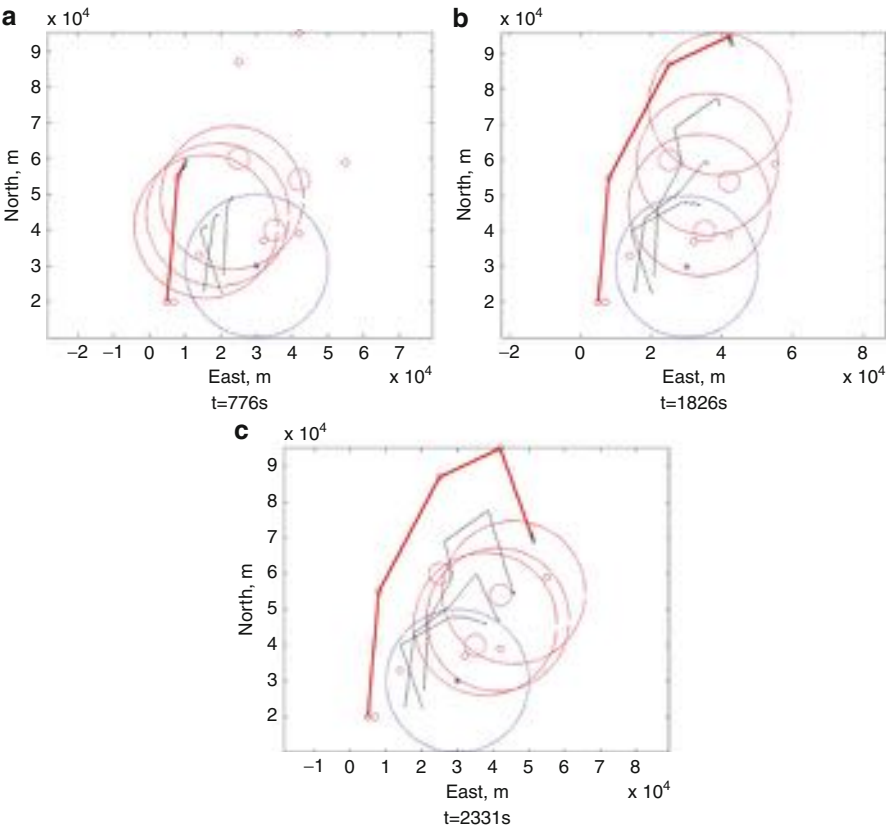

Fig. 62.27 Simulation result on basic scenario with speed and NFZ constraints: snapshots of communication ranges of UAVs. (a) $t = 776$ s. (b) $t = 1,826$ s. (c) $t = 2,331$ s

Conclusions

This chapter has developed a framework enabling cooperative mission and path planning of multiple UAVs in the context of the vehicle-routing problem. The vehicle-routing algorithms often approximate paths of UAVs to straight lines to reduce computational load. In order to resolve this issue, this study focused on integration of the differential geometry concepts, especially Dubins paths, into the vehicle route-planning design procedure to consider non-straight path components. Note that physical and operational constraints of the UAV can be taken into account by these non-straight components of paths. In order to validate this approach, cooperative mission and path-planning algorithms for two missions are developed: road-network search and communication relay. In the road-network search algorithm, the conventional Chinese Postman Problem (CPP) algorithm was firstly explained and modified and applied to the general type of road map which includes unconnected roads. Then, MILP optimization

and the nearest insertion algorithm along with auction negotiation were examined for multiple unmanned aerial vehicles. To realistically accommodate the maneuvering constraints of UAVs, the Dubins path planning was used to solve the modified CPP. The performance of the MILP optimization and the approximation algorithm was then compared for a specific road-network scenario. Particularly, the performance of the approximation algorithm was investigated via a Monte Carlo simulation framework by analyzing the effects of different map sizes, path-planning methods, and the number of UAVs. Based on these results, the efficient UAV team size and path-planning method were suggested for the road search route planning and hence showed that this framework can be applied to a variety of autonomous search missions in the initial phase of mission planning. In the communication-relay problem, a design methodology on vehicle route planning of multiple UAVs to maintain communication between the ground control station and the friendly fleet was proposed. Dubins theory was applied to get flyable paths, and a decision-making algorithm was developed to satisfy the constraints on the UAV speed and the avoidance of nonflying zones, as well as maintaining communication. The performance of the proposed algorithms is examined via numerical simulations.

able to replan for a new path to perform the given tasks without any collision with obstacles or other agents. The path-planning algorithm proposed here is based on the visibility and shortest-path principles in Euclidean space. Instead of typical visibility graph-based methods that scan through all nodes, A^* algorithm is adopted to find an admissible path in a “best-first” approach during the search process. Since the direct outcome from such algorithms may not produce admissible paths in complex environments due to the problems including *cul-de-sac*, additional procedures are conceived to find a solution with a lower cost by avoiding local minima and eliminating any redundant nodes. The path planner is augmented with a potential field-based trajectory planner, which solves for a detouring trajectory around other agents or pop-up obstacles. Task assignment is achieved by a negotiation-based algorithm, which assigns a task with the lowest cost to each agent after comparing all task costs of all participating agents. These algorithms are implemented on MATLAB/Simulink, which can run with simulated vehicle models or actual UAVs through a communication network. In the simulations, the algorithms were validated to perform task assignment and path planning flawlessly. In actual flight tests, the proposed algorithms were tested with a number of fixed-wing UAVs in a fully realistic situation under various reality factors such as communication loss or tracking errors. The flight test shows, even in the presence of such uncertainties and logistic factors, the algorithms were able to perform all of the given tasks without any collision with other agents or obstacles.

63.1 Introduction

Unmanned aerial vehicles (UAVs) have been found highly effective in many applications where human presence in the aircraft is deemed unnecessary or dangerous. Furthermore, as the mission becomes more complicated, it has been suggested to perform the mission more effectively by “sharing the burden” among multiple UAVs. In such scenarios, UAVs are required to fly through the designated waypoints associated with tasks in the given mission. When tasks are performed by multiple agents, the question about “who is doing which task in what order” naturally arises. Also, when multiple UAVs fly together in a given area visiting waypoints, planning a safe and efficient path for each agent is very important. Finally, all agents should be able to avoid obstacles such as terrain or buildings by replanning the path dynamically.

When planning for a mission of a UAV, the flight paths for all UAVs in the scenario are determined by assigning all tasks to participating agents. When the order of the tasks to be performed by each agent is decided, the path for each agent can be easily determined by simply connecting the waypoints associated with the tasks sequentially. However, when the mission area are filled with obstacles, the original path should be modified to pass through the designated waypoints while staying clear from the forbidden zones, which may be known a priori or suddenly “pop-up.” Also, when the UAVs are required to fly close to the ground, they need

to avoid collisions with ground objects or buildings, which are already mapped or detected by onboard sensors such as laser scanners or radars.

Assigning tasks to UAVs is not a straightforward problem especially when the UAVs fly in a dynamic environment where obstacles are not fully mapped a priori or when the sensors for obstacle detection have errors. Mixed Integer Linear Programming (MILP) has been found as a powerful method because it can handle dynamic systems with discrete decision variables and there exist many efficient solvers. Bellingham used MILP for task assignment to handle waypoint visiting problems (Bellingham et al. 2001). However, since the complexity of the problem rapidly grows as the number of variables increases, it is often not suitable for real-time applications. Furthermore, since the MILP is formulated with object functions for the entire system, it needs to be implemented as a centralized system, which may not function well when the central control station or communication links are broken (Bertsekas 1991; Ren et al. 2007; Choi et al. 2009; Sujit et al. 2007; Viguria et al. 2010).

Path planning is another important problem for efficient and collision-free operations for multiple UAVs. A path planner should satisfy completeness, optimality, computational tractability, and scalability. In addition, collision and threat avoidance is required for multi-agent scenarios and there are many algorithms for this problem. Many researches have been conducted on the path-planning problem since 1960s (Latombe 1991; Lavalley 2006; Hart et al. 1968; Redding et al. 2007; Yang et al. 2010). However, the path-planning problem becomes more complicated when solving for dynamic environments with incompletely known obstacles or pop-up threats. For such cases, the planner should be able to find a conflict-free path in real time. Schouwenaars et al. used mixed integer programming for multi-vehicle path planning (Schouwenaars et al. 2001). Richards showed an aircraft trajectory planning with collision avoidance using MILP (Richards et al. 2003).

Also, some variations of MILP have been applied to this problem. Earl and D'Andrea developed an iterative MILP approach (Earl and D'Andrea 2005), and Jain and Grossmann proposed hybrid MILP/CP (constrained programming) models for a class of the optimization problems (Jain and Grossmann 2001). Chang and Shadden introduced the gyroscopic forces for collision avoidance, which is similar to the potential field approach (Chang et al. 2003). More recently, Shim et al. pioneered the dynamic path-planning problem using model predictive control (MPC) algorithm for a collision-avoidance problem of 16 homogeneous rotary UAVs with obstacles (Shim 2008).

In this chapter, a hierarchical framework for efficient path planning and task assignment for multiple UAVs in dynamic environments is presented. For task assignment, a negotiation-based algorithm is proposed. In this approach, each agent initially chooses the task with the lowest cost, which is assumed directly proportional to the distance to the waypoint associated with a task. The choices of all other agents are notified to each agent, and when there are conflicts, i.e., when two or more agents choose the same task, their costs are compared, and the agent with the lowest cost are assigned with the task, while the remaining agents repeat the same negotiation process until all agents are assigned with a task without any

conflicts. The proposed algorithms are computationally light enough to handle real-time path planning in partially known environments.

The task-assignment problem is essentially tightly coupled with the path planning. A path-planning algorithm based on the shortest-path principle in Euclidean space is chosen in this framework, where obstacles are initially modeled as polygons and a path between the two waypoints around obstacles is found using the visibility and the shortest-path principles in Euclidean space. In order to search for an admissible path without scanning over the entire solution set, A^* algorithm is deployed for an effective search. When the solution is found by running the A^* algorithm (and not by an exhaustive search), the solution of the planner may converge to a less optimal or even inadmissible path. Therefore, additional filters such as a *cul-de-sac* filter, a recursive filter, and a Fibonacci filter are introduced. These filters help to alleviate issues due to local minima while eliminating unnecessary segments in a candidate path. In addition, since the path solution found prior to the mission may have conflicts with pop-up obstacles or other agents, it is locally adjusted with a potential field-based collision-avoidance algorithm, which is responsible for solving a detouring trajectory around the obstacles intersecting with the original path solution.

The proposed algorithms are first validated in simulations, where multiple UAVs perform the given tasks while avoiding obstacles and other agents. The proposed algorithm implemented on MATLAB/Simulink is shown to be capable of generating admissible paths in completely/partially known or completely unknown environments. Then the algorithm is validated in a flight test using three fixed-wing UAVs to validate the task-assignment and path-planning algorithms together in an environment with pop-up threats. The proposed algorithms were shown to be capable of real-time path planning and task assignment in outdoor environments even with simulated dynamic obstacles.

63.2 Problem Formulation

In the following, the problem for task assignment for multiple UAVs in dynamic environments is defined. Hereinafter, tasks are defined as a set of actions to accomplish a job, a problem, or an assignment. It can be represented as a number of lower-level goals that are necessary for achieving the overall goal of the system (Pettersson and Doherty 2006; Maza et al. 2011). In this chapter, tasks is defined as visiting a waypoint, through which at least one agent should pass once to complete the associated task. First of all, the rules for the task assignment and the path planning are established as below (Moon and Shim 2010):

- (a) Obstacles are defined as the objects that obstruct the motion. In this research, they are represented as polygons.
- (b) The environment is modeled as a two-dimensional Euclidean space.
- (c) UAVs must avoid all obstacles. In other words, all UAVs must remain in admissible areas, clear from obstacles with a margin. Therefore, paths of all UAVs solved by the proposed procedure should be admissible. Path can intersect, but should not lead to collision among UAVs.

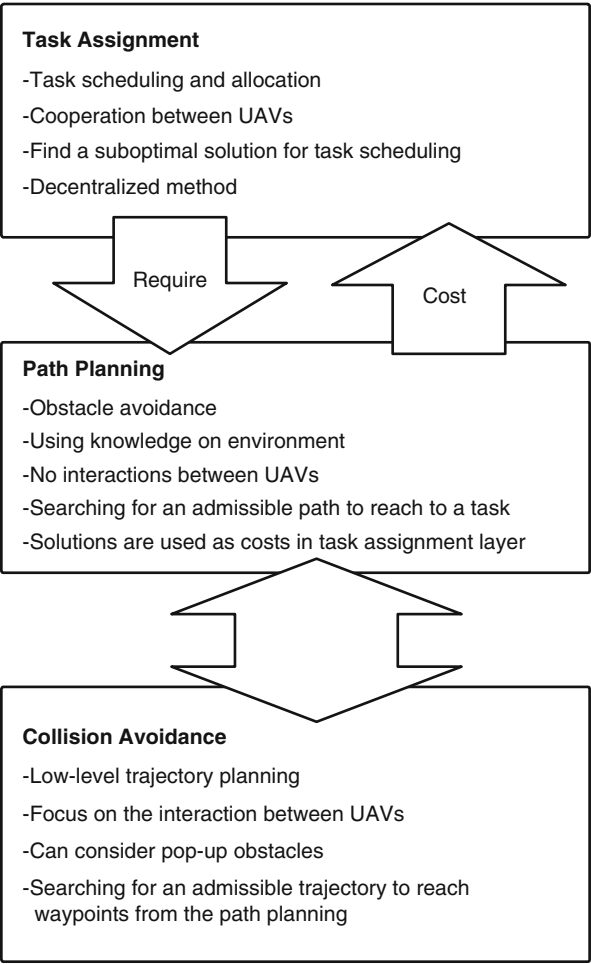

Fig. 63.1 Integration of task assignment, path planning, and collision avoidance

(e) The task assignment and the path planning should run in real time.

In the following, the task-assignment and the path-planning algorithms based on rules listed above are presented.

63.3 Integrated Hierarchical Structure for Multi-UAV Coordination

Figure 63.1 explains how the task-assignment layer, the path-planner layer, and the collision-avoidance layer are integrated altogether. The integration of the task assignment and the path planner is a crucial step for architecting a mission-planning system for multi-agent scenarios (Moon et al. 2013). In this research, the task-

assignment layer needs to communicate with the path planner to compute the cost for task assignment, which is a function of the distance to reach the waypoint. During the task assignment, the path-planning layer is repeatedly queried until a feasible solution for task assignment is found.

The next step is, if any unmapped obstacle is detected while flying along the original path, to find a collision-free path based on the original path. It is noted that the path-planner and the collision-avoidance layer may appear to do a similar task of finding a conflict-free path. The crucial difference is that the collision-avoidance layer finds a path locally detouring from the original path computed by the path planner, which only uses the obstacle information known before starting the mission. Therefore, these two algorithms work in a complementary manner to generate a collision-free path efficiently.

As can be seen in Fig. 63.1, these two procedures are in a hierarchical structure, and the path-planning algorithm is invoked when the situation is in one of the following three cases: (i) before carrying out the mission, (ii) a new task is allocated on an agent participating in the mission, or (iii) new obstacles or threats suddenly appear, or “pop-up.” The collision-avoidance algorithm is activated when the agent flies to the target point while following the path. For multi-UAV scenarios, the collision avoidance between two or more agents should be considered. The avoidance algorithm presented later in this chapter is used to generate a collision-free path.

63.4 Negotiation-Based Task Assignment

During the last decade, many algorithms have been developed for task-assignment problems (Bertsekas 1991; Ren et al. 2007; Choi et al. 2009; Viguria et al. 2010). The task-assignment algorithm presented in this chapter is based on the negotiation algorithm (Moon et al. 2013). The proposed method should generate a feasible solution within a reasonable time for real-time applications. In addition, this algorithm is an *event trigger-based process*, which means that it runs only when an agent sends a message to invoke this algorithm. This is a desirable attribute for decentralized systems running in real time with limited communication bandwidth.

Events can be classified into three cases: (i) a mission is given to the system and the agents start to achieve the goal of the mission, (ii) a task in the given mission is accomplished by an agent, and (iii) the given mission is completely finished. If any of these events occurs during the mission, the presented task-assignment process is activated. Upon activation, all agents can be assigned with the different tasks, and this result is dependent on the conditions of the tasks. On the other hand, the costs for negotiation are defined by using (63.1). This formula consists of two parts: the distance from the current location of an agent to the task location and the characteristics of an agent and the assigned task, i.e., the capability set of an agent and the type of the task. The total cost is a linear combination of these two elements, and there are weights assigned for each term:

| | UAV #1 | UAV #2 | UAV #3 |
|------------------------------------|--------------------------------------|---------------------------------|---------------------------------|
| Task Assignment Requirement | Send the message for task assignment | | |
| Before Negotiation | Calculate the cost individually | Calculate the cost individually | Calculate the cost individually |
| 1st Negotiation | Cost: 40.68 @ Task A | Cost: 40.96 @ Task A | Cost: 42.09 @ Task C |
| | Cost: 40.68 @ Task A | | Cost: 42.09 @ Task C |
| 2nd Negotiation | | Cost: 41.60 @ Task C | Cost: 42.09 @ Task C |
| | Cost: 40.68 @ Task A | Cost: 41.60 @ Task C | Cost: 45.76 @ Task B |

Fig. 63.2 Negotiation-based task allocation for three UAVs with three tasks

$$J_{\text{task}} = w_d J_{\text{dist}} + w_c J_{\text{character}}$$

(63.1)

In (63.1), J_{dist} is the cost related with the distance between the current position of an agent and the location of the given task. If there are multiple tasks with different characteristics, $J_{\text{character}}$ can be given with different costs to affect the behaviors of all agents in this scenario.

The negotiation-based task assignment is performed in the following manner. Initially, each agent chooses its first task, which has the lowest cost from the cost list. Here, without loss of generality, the cost associated with the task is the distance to the task. The choices of all agents are broadcast to other agent, and when there are conflicts, i.e., more than one agents choose the same task, the costs of conflicting agents are compared, and the agent with the lowest cost has the right to claim the task, while other agents without assigned tasks repeat the same compare-and-claim process until all conflicts are resolved.

In Fig. 63.2, an example with three UAVs is given. At first, each UAV chooses their task and the cost is compared. At the first negotiation, UAVs #1 and #2 choose the same task (task A), and they negotiate to find UAV #1 has a lower cost (40.68 vs. 40.96). So UAV #2 chooses a task other than A, which is task C with cost 41.60. This choice now conflicts with that of UAV #3 with cost 42.09, which is higher than the cost of UAV #2. Therefore, UAV #3 is forced to choose task B with cost 45.76.

This approach has no guarantee to converge to the global minimum with an exception that it does converge to the global minimum when the number of the agent

is equal to the number of tasks. However, this algorithm has a low computing loads and suitable for decentralized scenarios with limited communication bandwidth.

63.5 Intersection-Based Path Planning

In Euclidean space, the shortest path between two points is the straight line between them. Denoting these points as \mathbf{x}_s and \mathbf{x}_g , the minimum cost function, i.e., the distance of the shortest path, can be represented as (63.2):

$$\min J = \text{dist}(\mathbf{x}_s, \mathbf{x}_g) = \|\mathbf{x}_s - \mathbf{x}_g\| \quad (63.2)$$

where $\text{dist}(\bullet)$ function is the distance defined in the Euclidean space. However, if there are any obstacles or forbidden region on the line, the cost found by (63.2) is not valid since the path is not admissible.

In order to find an admissible path in this situation, the intersection point by the path from (63.2) and the boundary of the obstacle are used (Moon et al. 2013). The first step of the proposed algorithm is to find the intersection point. If an obstacle in the two dimensional space is modeled as a polygon, then the intersection point \mathbf{x}_m in Fig. 63.3 can be found easily. In such a case, a new path that passes the boundary points of a detected obstacle, $\mathbf{x}_{O_{i1}}$ or $\mathbf{x}_{O_{i2}}$ should be found. Therefore, these two points are the candidates of waypoints for path planning. The proposed algorithm uses A^* approach expressed as (63.3):

$$f(\mathbf{x}) = g(\mathbf{x}) + h(\mathbf{x}) = \|\mathbf{x}_s - \mathbf{x}_w\| + \|\mathbf{x}_g - \mathbf{x}_w\| \quad (63.3)$$

In (63.3), \mathbf{x}_w is the boundary point of detected edge so that the first term of (63.3) is the distance from the starting point to a waypoint candidate and the other is the distance from the waypoint candidate to the goal point. If the detected line is not the first since the operation started, this equation should be modified to (63.4) because the vehicle is already assigned to a waypoint.

Fig. 63.3 Intersection point between shortest path and obstacle

Table 63.1 Pseudo code for path planning**Algorithm 1** Intersection-based path planning (fundamental)

```

1: P ← InitializePath( $x_s, x_g$ )
2:   $x_i \leftarrow x_s$ 
3:   while Dist( $x_g, x_i$ )  $\geq d_{\text{admissible}}$  do
4:      $x_m \leftarrow \text{DrawLine}(x_g, x_i)$ 
5:     if  $x_m$  exist
6:        $x_i \leftarrow \text{SelectOptimalNode}(x_g, x_s, x_1, x_2, \dots, x_i)$ 
7:       P ← AddPath(P,  $x_i$ )
8:     end if
9:      $i \leftarrow i+1$ 
10:  end while

```

$$f(\mathbf{x}) = g(\mathbf{x}) + h(\mathbf{x}) = \sum_{i=1}^N \|\mathbf{x}_i - \mathbf{x}_{(i-1)}\| + \|\mathbf{x}_g - \mathbf{x}_w\| \quad (63.4)$$

In the two-dimensional space, the suboptimal waypoints and the candidate waypoints appear as a pair, and the suboptimal waypoints receive a higher priority for calculation. If multiple obstacles are located in the area, the intersection point which is the closest among the intersection points and the obstacle of that point is considered as the next optimal candidate. As A^* algorithm is used in this procedure, all the nodes found by the intersection method are prioritized, and the best solution is chosen using the priority value. Therefore, those nodes related with the intersection points are applied by this method, and the procedures from (63.2) to (63.4) will be performed until the solved node is the goal point (see Table 63.1).

When A^* algorithm is applied from one root to another, the resulted path is not necessarily optimal. Therefore, a number of additional steps are introduced to refine the path although this process only guarantees to converge to a local minimum. Nonetheless, this process greatly helps to improve the quality of the resulted path, which has much less redundant segments and also avoids getting stuck in a *cul-de-sac*.

Figure 63.4 shows a result obtained using the proposed algorithm. The given environment consists of ten arbitrary-shaped obstacles, which do not have any concave parts that can cause the solver to fall into an infinite loop. Therefore, additional procedures should be added, which will be introduced in the next section. In addition, the configuration space is also considered because UAVs are assumed to occupy certain area (volume), not a point. The dashed line is the solved path, and the lines are the candidate paths to obtain the shortest path. Initially, the algorithm finds a path, which travels to the left side of an obstacle. However, this solution is discarded due to the longer traveling distance around the next obstacle. After several iterations, a new path is found (dashed line), which connects the starting point and the goal point without any conflict with all obstacles.

Fig. 63.4 Result from the algorithm proposed in Table 63.1

63.5.1 Additional Procedures

Although the algorithm proposed in Table 63.1 can generate an admissible path in most cases, it is also possible that the planner may get stuck to local minima. Even if the path is admissible, it may contain extra nodes that make the overall path less optimal. Therefore, in this section, three additional procedures are introduced: *cul-de-sac* filtering, Fibonacci filtering, and recursive filtering. These additional procedures further improve the proposed algorithm to find the optimal path more reliably although these procedures render the overall algorithm computationally more demanding.

63.5.1.1 Cul-de-sac Filtering

Cul-de-sac refers to a dead end where there is no outlet other than the inlet. If the proposed algorithm is applied to the situation with concave obstacles that creates *cul-de-sac*, the algorithm may fall into an infinite loop, thus unable to find any admissible path. Therefore, an additional filter is introduced to resolve this problem (see Table 63.2). In Fig. 63.5, a case with three concave obstacles is considered. The direct output from the intersection-based planning finds a path that falls into the *cul-de-sac* point located on the middle of the diagram. Two paths were generated

Table 63.2 Pseudo code for cul-de-sac filtering

| Algorithm 2 Cul-de-sac filtering | |
|---|--|
| 1: if $x_i = x_{i-1}$ | |
| 2: $x_m \leftarrow x_i$ | |
| 3: $x_n \leftarrow x_{i-1}$ | |
| 4: while $x_m = x_n$ do | |
| 5: $x_n \leftarrow \text{SelectNeighborVertex}(x_i)$ | |
| 6: $x_m \leftarrow \text{SelectOptimalNode}(x_g, x_s, x_1, \dots, x_{i-1}, x_n, x_m)$ | |
| 7: end while | |
| 8: end if | |
| 9: $x_i \leftarrow x_m$ | |

Fig. 63.5 Cul-de-sac filtering

after applying the *cul-de-sac* filtering. When the path on the left is chosen, the other blue path indicated as “Discarded Path” is selected first. However, after running the original algorithm with the *cul-de-sac* filtering, the dashed red line is generated. Figure 63.5 shows the result after applying the *cul-de-sac* filtering algorithm.

63.5.1.2 Recursive Filtering

As the intersection-based path planning considers only one obstacle at a time, if another obstacle is near the one being considered for path planning, the generated

Table 63.3 Pseudo code for recursive filtering**Algorithm 3** Recursive filtering

```

1: if CheckOverlapObstacle( $O_1, O_2, \dots, O_n, x_{i-1}, x_i$ )
2:    $P_s \leftarrow \text{InitializePath}(x_{i-1}, x_i)$ 
3:    $x_j \leftarrow x_{i-1}$ 
4:    $x_m \leftarrow \text{DrawLine}(x_i, x_j)$ 
5:   if  $x_m$  exist
6:      $x_i \leftarrow \text{SelectOptimalNode}(x_i, x_{i-1}, x_j)$ 
7:      $P_s \leftarrow \text{AddPath}(P_s, x_i)$ 
8:   end if
9:    $j \leftarrow j+1$ 
10:   $P \leftarrow \text{MergePath}(P, P_s)$ 
11: end if

```

path may conflict with other obstacles. So the recursive filtering is proposed, which checks if the path around one obstacle passes through any other obstacles. This filtering process checks the path between i -th and the previous node, which can be expressed as

$$\overline{\mathbf{x}_{i-1}\mathbf{x}_i} \cap \bigcup_{j=1}^N O_j \neq \emptyset \quad (63.5)$$

Equation (63.5) implies that the line segment between the previous node \mathbf{x}_{i-1} and the current node \mathbf{x}_i intersects with any obstacles along the line. In such cases, the intersection-based path-planning algorithm is called with \mathbf{x}_{i-1} and \mathbf{x}_i as the input argument for temporary starting and the goal points, respectively, find to a conflict-free path (see Table 63.3). Recursive filtering is performed after running the main planning algorithm and the *cul-de-sac* filtering introduced above. This filtering is frequently required when the given environment is filled with closely located obstacles and consumes a more computation time. Figure 63.6 shows an example of the recursive filtering. Since the line between the starting point and the goal point intersects with the obstacle on the right, the blue path is obtained by the intersection-based algorithm. Since it overlaps with the obstacle on the left, the recursive filtering is applied for the segment between the starting point and the first node, resulting in the red-dashed line, which is conflict-free.

63.5.1.3 Fibonacci Filtering

Fibonacci filtering is named after the well-known Fibonacci sequence from the fact that the current waypoint is computed using the two preceding points. It is developed to eliminate any extra nodes that increase overall cost (i.e., a longer path) when there is an admissible path with a lower cost. In Fibonacci sequence, each number is the sum of the previous two numbers, starting with 0 and 1. Similarly, Fibonacci filtering takes only the previous two nodes as the input argument.

If two nodes \mathbf{x}_{i-2} and \mathbf{x}_i satisfy (63.6), this filtering moves on to the next node. Therefore, Fibonacci filtering is the opposite concept of the recursive filtering described in the previous subsection:

Fig. 63.6 Recursive filtering. *Solid lines (blue):* suboptimal paths before the filtering. *Dashed line (red):* optimal path obtained by the recursive filtering

Table 63.4 Pseudo code for Fibonacci filtering

Algorithm 4 Fibonacci filtering

- 1: if !CheckOverlapObstacle($O_1, O_2, \dots, O_n, x_{i-2}, x_i$)
- 2: $x_{j-1} \leftarrow x_i$
- 3: $i \leftarrow i-1$
- 4: end if

$$\overline{\mathbf{x}_{i-2}\mathbf{x}_i} \cap \bigcup_{j=1}^N O_j = \emptyset \quad (63.6)$$

In (63.6), the line that connects the point before the previous node \mathbf{x}_{i-2} and present node \mathbf{x}_i does not overlap with any obstacles, then the previous point \mathbf{x}_{i-1} should be cancelled out to straighten the generated path. This procedure is performed for all nodes that satisfy (63.6), and repeated until (63.6) is not satisfied for all nodes (see Table 63.4). As is the case with the additional filtering algorithms introduced above, this filtering is more frequently needed if the given environment is complex and more computation time is needed for this algorithm along with other additional filtering algorithms mentioned above. In Fig. 63.7, the first two segments

Fig. 63.7 Fibonacci filtering. *Solid line (blue):* suboptimal paths before the filtering. *Dashed line (red):* optimal path obtained by the Fibonacci filtering

from the starting point on the blue line are less optimal than the first line segment of the red-dashed line due to the extra node, which is eliminated by running the Fibonacci filtering.

63.5.2 Overall Procedure

Table 63.5 is the pseudo code for the all algorithms proposed so far. When the path planning is started, the intersection-based method is first applied and an initial candidate path is found. At this step, the cost function of the candidate paths are computed to run the *A** algorithm to find the path with the least cost. Here, the path may get stuck in *cul-de-sac*, which is avoided by the proposed filtering (recursive filtering). In this process, the path may have extra node, which is then eliminated by the Fibonacci filtering. The filtering procedures are performed after the intersection-based algorithm. When the path reaches to the goal point, this algorithm is terminated.

Figure 63.8 shows the path planning result with the recursive filtering and Fibonacci filtering in addition to the intersection-based method. Here, the recursive filtering process was responsible for finding the optimal path passing by obstacles 1

Algorithm 5 Intersection-based path planning (overall)

```

1:  $P \leftarrow \text{InitializePath}(x_s, x_g)$ 
2:  $x_i \leftarrow x_s$ 
3: while  $\text{Dist}(x_g, x_i) > d_{\text{admissible}}$  do
4:    $x_m \leftarrow \text{DrawLine}(x_g, x_i)$ 
5:   if  $x_m$  exist
6:      $x_i \leftarrow \text{SelectOptimalNode}(x_g, x_s, x_1, x_2, \dots, x_i)$ 
7:     if  $x_i = x_{i-1}$ 
8:        $x_i \leftarrow \text{CulDeSacFiltering}(x_g, x_s, x_1, x_2, \dots, x_i)$ 
9:     end if
10:    if  $\text{CheckOverlapObstacle}(O_1, \dots, O_n, x_{i-1}, x_i)$ 
11:       $P, x_i \leftarrow \text{RecursiveFiltering}(x_g, x_s, x_1, \dots, x_i)$ 
12:    end if
13:    if  $\neg \text{CheckOverlapObstacle}(O_1, \dots, O_n, x_{i-2}, x_i)$ 
14:       $x_{j-1} \leftarrow x_i$ 
15:       $i \leftarrow i-1$ 
16:    end if
17:     $P \leftarrow \text{AddPath}(P, x_i)$ 
18:  end if
19:   $i \leftarrow i+1$ 
20: end while

```

and 2. The Fibonacci filtering is responsible for finding the better (i.e., shorter) path among the three paths ending up near obstacle #3.

63.6 Potential Field-Based Collision Avoidance

Collision avoidance is a dynamic path generation technique, which finds an admissible path to avoid a collision among agents or with obstacles in the environment. The algorithm proposed here is based on the potential field approach with several improvements presented below (Moon et al. 2013). Most algorithms based on the potential field are based on the distance between the vehicle and target points at one time frame. However, in case of moving obstacles, it is desirable to consider the relative direction of motion as well. The proposed algorithm utilizes the cost function for the potential field as the function of the distance and direction of the obstacle using the normal vector as

$$J = fn(\mathbf{x}, \mathbf{v}, \mathbf{n}) \quad (63.7)$$

where \mathbf{x} and \mathbf{v} represent the position and velocity of the vehicle, respectively. \mathbf{n} is the set of normal vectors of the planes on the polyhedra representing the obstacles in the environment. Figure 63.9 illustrates the relationship among a UAV, an obstacle, and a waypoint along with the current and future position and velocity vectors of a UAV and a normal vector \mathbf{n}_i .

Fig. 63.10 Cost function for waypoint tracking

UAV moves in one step along the selected path. This procedure is iterated until the UAV reaches to the target point.

The cost function for the waypoints generated from the path planning can be expressed as (63.8), which can be visualized as shown in Fig. 63.10. Note that (63.8) is not dependent on the vehicle's heading angle. In order to prevent (63.8) from dominating other terms, a denominator that divides by the distance from the waypoint to the current position of an UAV is included:

$$J_{\text{waypoint}} = 1 - \exp\left(\frac{\|\mathbf{x}_{\text{waypoint}} - \mathbf{x}_{t+\Delta t}\|}{\|\mathbf{x}_{\text{waypoint}} - \mathbf{x}_t\|}\right) \quad (63.8)$$

The cost function for the obstacles and threats is expressed as (63.9), which is visualized as in Fig. 63.11, and again it is independent from the vehicle's heading. If the angle between the normal vector of the plane on an obstacle and the vehicle's velocity vector is very small, this indicates that the vehicle approaches to the object and therefore the cost function grows exponentially. However, if this angle is close to 180° , the cost function decreases rapidly because the UAV moves away from the object. The cost function in Eq. (63.9) also includes a denominator to scale the magnitude of the normal vector is included to divide the term by a magnitude vector from the object to the current position of an UAV:

$$J_{\text{obstacle},i} = (0.5 \cos \theta_{\text{obstacle}} + 0.5 + C_{\text{obstacle}}) \exp\left(-\frac{\|\mathbf{n}_i\|}{\|\mathbf{x}_t - \mathbf{x}_{\text{obstacle}}\|}\right) \quad (63.9)$$

where

$$\theta_{\text{obstacle}} = \cos^{-1}\left(\frac{\mathbf{n}_i \cdot \mathbf{v}_t + \Delta t}{\|\mathbf{n}_i\| \|\mathbf{v}_t + \Delta t\|}\right) - \pi$$

Fig. 63.11 Cost function for obstacles and threats

63.7 Simulation and Analysis

In order to evaluate the performance of the proposed algorithm, a series of simulations are conducted. In the proposed hierarchy, since the task-assignment layer cannot function without path planning, the intersection-based path planner is first implemented and validated.

63.7.1 Intersection-Based Path Planning

It is assumed that the UAV has an onboard sensor for detecting obstacles such as the laser scanner, which has finite detection range. In the simulation, 20 randomly shaped obstacles are placed where only ten of them are known a priori. The simulation was constructed in MATLAB running on a PC with Intel CPU Centrino 2 Duo 2.4 GHz.

Figure 63.12 shows the path-planning result when all of the obstacles are known a priori. UAV 1 flies to the goal point without any conflict with obstacles. Whenever obstacles unknown at the initial path-planning phase are discovered during the flight, the path-planning algorithm runs repeatedly in real time to find a conflict-free path (left side of Fig. 63.13). If none of the obstacles were known a priori, the path-planning algorithm runs in real time from the start until the end, building the obstacle

Fig. 63.12 Path planning in totally known environment

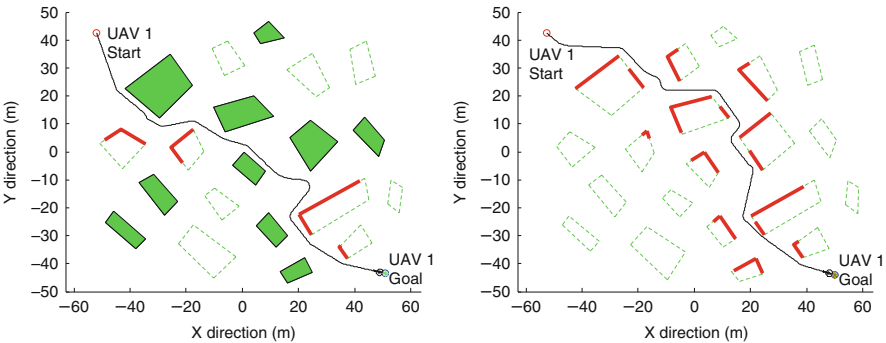

Fig. 63.13 Path planning in partially known environment (*left*) and totally unknown environment (*right*)

map *on the fly* using onboard sensors (right side of Fig. 63.13). Note that the obtained paths in the three cases with identical obstacles but with different sensing methods are different from one another.

It is generally agreed that finding a feasible path in a given environment is a hard problem and finding the optimal solution, whichever the definition of optimality is, is a difficult and there is not a general solution for such work. The proposed algorithm is viable in the sense that it can find an admissible path with a smaller computation load with all obstacles modeled as polygons. Such simplified obstacle is acceptable with path planning for UAVs, which needs to stay clear from obstacles for safety and to avoid turbulence caused by the airflow bouncing back from the obstacles. The proposed algorithm runs very fast in environments with fewer obstacles. However, if the environment is filled with many obstacles, the computation load can be quite heavy because of the additional filtering processes.

Fig. 63.14 Computation time versus elapsed time

Figure 63.14 shows the computation time during the simulation. The case with totally known environment is the blue lines with square marks, and the case with partially known environment is the red lines with plus marks. The totally known environment case does not require much computation except for the first path planning. However, the partially or totally unknown case requires more computation load during the simulation whenever new obstacles are detected ($t = 53$ s).

63.7.2 Negotiation-Based Task Assignment

In the simulation, three UAVs carry out a mission in an area with ten randomly shaped obstacles. Ten task points are arbitrarily placed in the field. As mentioned above, a task is defined as a visit to its associated waypoint. The margin for obstacle avoidance is assumed 2 m here. In this simulation, a simple kinematic model for UAVs were used such that

$$\begin{aligned} V_x &= V \cos \theta \\ V_y &= V \sin \theta \end{aligned} \quad (63.10)$$

where

$$\dot{\theta} \in [-\delta, \delta] \quad (63.11)$$

To evaluate the performance of the proposed algorithm, a set of simulation is conducted. A scenario with three UAVs carrying out a mission in an area

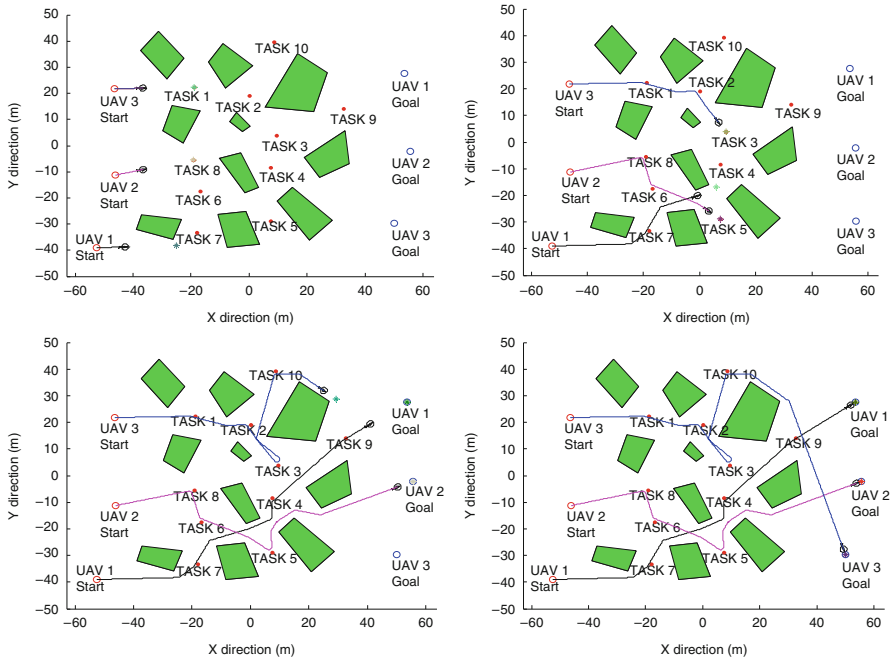

Fig. 63.15 Task assignment in a totally known environment ($t=10,60,120$, and 185 s from *left side of top to right side of bottom*)

with ten randomly shaped obstacles is considered. Ten task points are arbitrarily placed in the field. As mentioned, tasks are defined as a visit to a waypoint. The margin for obstacle avoidance is 2 m. Simple kinematic equations for UAVs were used in this simulation.

Figure 63.15 shows the simulation result. As the mission progresses, ten negotiations occur. UAV 1 is assigned with three tasks (task 4, task 7, and task 9) and participates in the whole negotiation process. UAV #2 is also assigned with three tasks (task 5, task 6, and task 8), and UAV #3 is assigned with four tasks (task 1, task 2, task 3, and task 10) during the mission. At fifth negotiation, UAV #1 sends the information of the determined task to UAV #2 and chooses to undertake task 4 because it is better that UAV #2 carries out task 5. Such a task swapping also occurs at the ninth negotiation process between UAV #1 and UAV #2 (see Table 63.6).

There are nine peaks in the plot of the elapsed time for negotiation process (Fig. 63.16). Although the maximum computation time ($=0.9$ s) of the first process is greater than the iterated time to run the proposed algorithm, it does not affect the real-time performance of the while mission because the task-assignment algorithm is executed offline prior to the mission. Since the computation time to perform each negotiation in the iterative algorithm is very short, the proposed task-assignment algorithm is a viable solution for real-time application. It is also noted that the

Table 63.6

versus computation time

proposed negotiation-based algorithm exhibits a greedy behavior as each agent thrives to minimize its cost at each time frame in a fully decentralized manner so that the overall task-assignment algorithm generally produces suboptimal results than centralized, non-greedy algorithms.

63.8 Flight Experiments and Validations

As the final step, in order to validate the proposed algorithm in a realistic environment, actual flight tests were conducted using a fixed-wing UAV based on a blended wing body (BWB) airframe as shown in Fig. 63.17. The airplane is powered by an electrical motor and a lightweight in-house flight control computer is installed for automatic waypoint navigation. The test UAV’s specification is given in Table 63.7.

The experiment is conducted in the following steps. When the flight computer is initialized, each vehicle is launched using a bungee cord. After the vehicle climbs to

a prescribed altitude, it begins loitering until the experiment session begins. When all agents are airborne and ready to accept the commands for the mission, the ground station starts the task-assignment algorithm, which receives all agents’ position and heading and sends the task commands back to each agent over the wireless network. Each UAV communicates with the ground station through its own onboard modem.

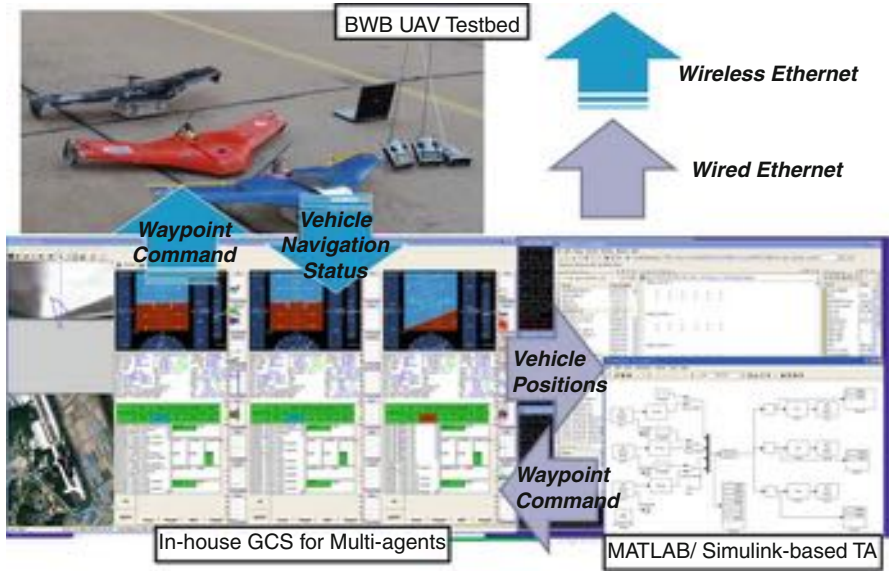

Fig. 63.18 Multi-agent experiment setup using fixed-wing UAVs

When the UAVs receive the task command from the ground, the onboard flight controller steers the vehicle to visit the commanded waypoint. A task is declared completed if the UAV passes the commanded location within a prescribed bound. When the UAV receives a new task request while flying to a task location previously assigned, the flight controller commands the vehicle to fly to the newly received task waypoint, simply ignoring the previous request.

Figure 63.18 illustrates how the entire flight experiment set up is constructed (Moon et al. 2013). The task-assignment and path-planning algorithms are implemented in MATLAB/Simulink, which communicates with the in-house ground station program (called *MVLOG*) capable of handling up to three (as of now) UAVs simultaneously. Each vehicle participating in the scenario sends their current status including the navigation information (position, velocity, attitude, and so on) over wireless communication. The ground station *MVLOG* collects and assembles all the information and sends them to the task-assignment and path-planning modules running on a separate computer connected on a same local network. Upon receiving the current vehicles' status, it executes the task-assignment/path-planning algorithms in real time and sends the updated waypoint commands for all vehicles. *MVLOG* relays this information to all the vehicles over the wireless network. This cycle repeats every second, which is a sufficient time for vehicles flying at 20 m/s performing the scenario considered here. The proposed algorithm is originally intended for fully decentralized scenario, where each agent runs the

Fig. 63.19 A path-planning experiment result

negotiation-based task assignment algorithm onboard and the ground station only functions as an arbiter. In this experiment, however, a fully centralized solver is employed for easier management of experiment.

The first scenario for flight experiment is to avoid two known obstacles represented as green-colored polygons and one unknown obstacle in cyan color as shown in Fig. 63.19. First, the UAV is launched and commanded to fly to a predefined altitude and then loiters until the first waypoint command is received. The launch location is marked with the red circle in Fig. 63.19. From there, the airplane flies to the initial loitering position in $-y$ direction in the graph and loiters along circular patterns. Then, the airplane is commanded to perform the obstacle avoidance by following along the waypoint command sent from the path planner on the ground

Fig. 63.20 Task-assignment scenario for three UAVs with a no-fly zone

as shown in Fig. 63.19, where the airplane flies in $+y$ direction while avoiding the green- and cyan-color obstacles. The cyan-color obstacle pops up when the airplane passes by the green asterisk, which triggers the path planner to plan for a new path that does not collide with the newly detected obstacle. The UAV flies around the obstacles without any collision until it reaches the goal point on the upper side of the graph.

Then, a scenario with three UAVs to visit six task points for reconnaissance with a no-fly zone (blue polygon in Fig. 63.20) is tested. The experiment result is shown in Figs. 63.21 and 63.22, where the trajectories of three UAVs performing the scenario as well as the task points and simulated obstacles are shown. Initially, the three agents are located at the lower right area of the map and then start flying to the upper-left direction upon receiving the task commands (Moon et al. 2013).

Table 63.8 shows how the tasks are assigned to three UAVs during the mission. Based on the initial positions of the agents, tasks are initially assigned to the participating agents as shown in step 1. When task 1 is completed by UAV #1, the remaining tasks are assigned to all UAVs as shown in step 2. This time, UAV #3 completes task 5, and again the remaining tasks are assigned to all other UAVs. This procedure is repeated until all tasks are completed at step 7.

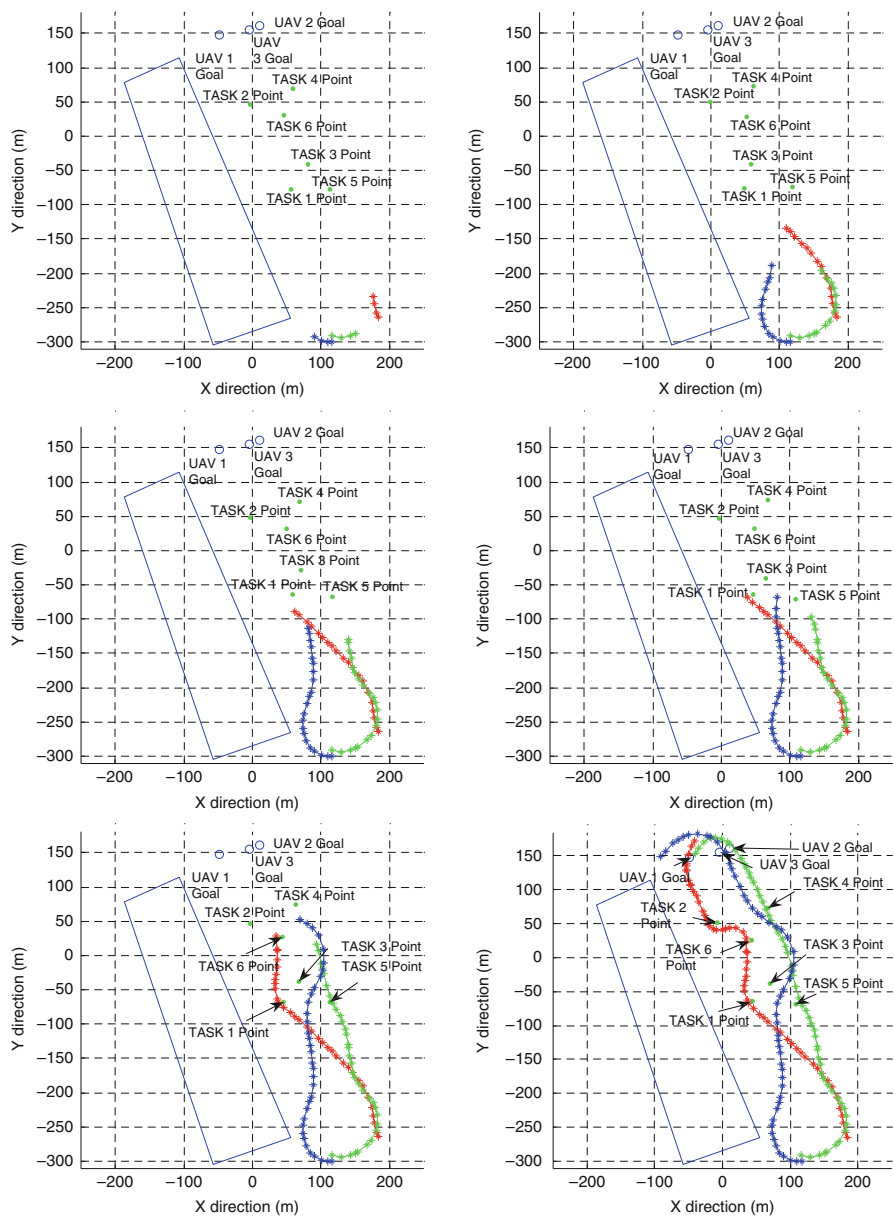

Fig. 63.21 A flight experiment result of a scenario for three UAVs with six tasks with a no-fly zone

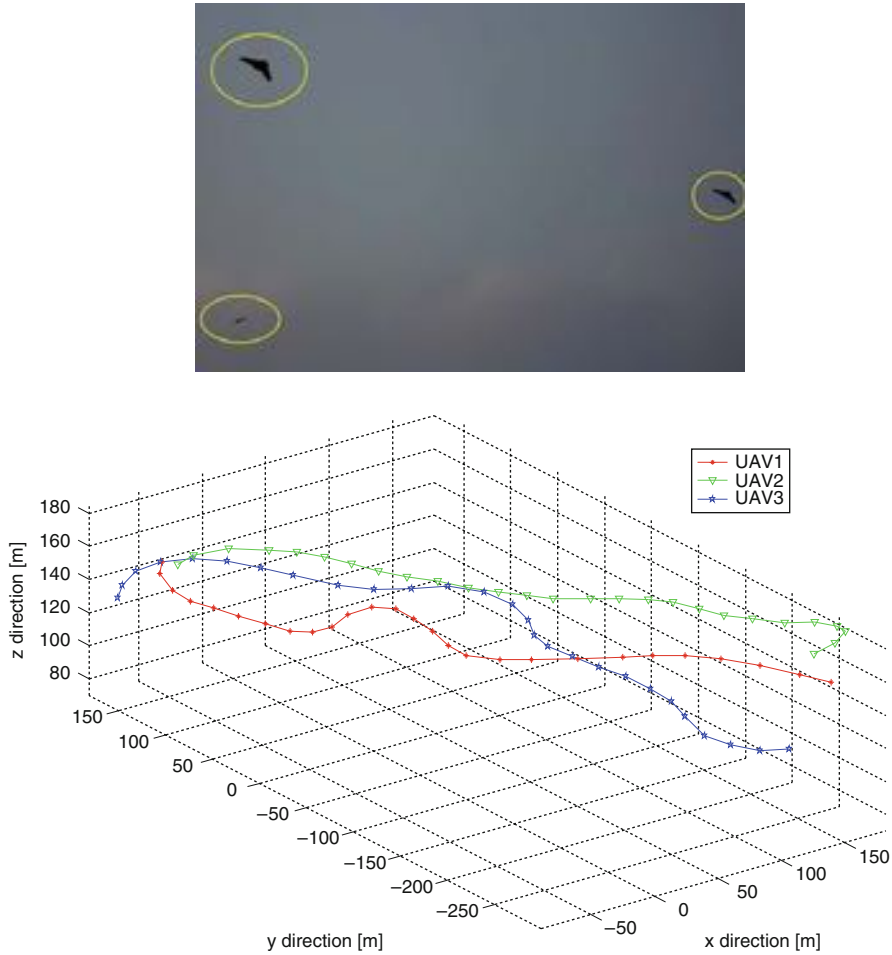

Fig. 63.22 A snapshot and a three-dimensional graph of the trajectories of three UAVs during the experiment in Fig.63.21

In the third scenario, the obstacle avoidance capability against pop-up threat in a multi-agent scenario was evaluated (Moon et al. 2013). Here, two UAVs fly into an area with four pop-up threats, where the UAVs are forbidden to fly over. The flight experiment was conducted following the procedure introduced above. The experiment result is shown in Fig. 63.23, where the three UAVs were commanded to perform the tasks given tasks while avoiding the pop-up threats using the potential field-based collision-avoidance algorithm. From this experiment, the proposed framework is shown to be capable of performing a dynamic task assignment in the presence of pop-up threats as well.

Conclusion

In this chapter, a hierarchical framework for task assignment and path planning with real-time collision avoidance is proposed. The task assignment is based on a negotiation-based algorithm, and the path planner is based on the shortest-path principle combined with A^* search algorithm. Additional procedures to

improve the quality of the obtained paths are also introduced. The real-time collision-avoidance algorithm for pop-up threats or unmapped obstacles is based on potential field, which also considers the relative direction of motion. The proposed framework is first validated in simulations and then in a series of experiments using real fixed-wing UAVs in outdoor environment. The group of UAVs was able to accomplish the given missions by visiting all of the task points even in the presence of known/unknown obstacles and pop-up threats. The proposed algorithm is readily applicable to various multi-UAV scenarios in real environment unlike many algorithms that function only in sterile conditions.

Abstract

This chapter is concerned with dynamically determining appropriate flight patterns for a set of autonomous UAVs in an urban environment, with multiple mission goals. The UAVs are tasked with searching the urban region for targets of interest and tracking those targets that have been detected. It is assumed that there are limited communication capabilities between the UAVs and that there exist possible line of sight constraints between the UAVs and the targets. Each UAV (*i*) operates its own dynamic feedback loop, in a receding-horizon

framework, incorporating local information (from UAV i perspective) as well as remote information (from the perspective of the “neighbor” UAVs) to determine the task to perform and the optimal flight path of UAV i over the planning horizon. This results in a decentralized and more realistic model of the real-world situation. As the coupled task assignment and flight route optimization formulation is NP-hard, a hybrid heuristic for continuous global optimization is developed to solve for the flight plan and tasking over the planning horizon. Experiments are considered as communication range between UAVs varies.

64.1 Introduction

Military forces face ever increasing challenges to provide timely and accurate information on targets of interest, especially those targets that are mobile and elusive in nature. These tasks expand significantly in complexity when the targets are operating in an urban environment. The use of multiple unmanned vehicles to provide this target information allows our military personnel to stay out of the line of fire. However, many remotely controlled UAVs (i.e., swarms) require as many skilled pilots as there are swarm members, and these pilots must be able to deconflict airspace demands, mission requirements, and situational changes in near real time (Bamburger et al. 2006). On the other hand, autonomous unmanned vehicles allow military personnel to focus on more important issues like interpreting the gathered information, as opposed to determining how to acquire the information (Hirsch et al. 2007). Hence, there is a need to build intelligent unmanned vehicles that can plan and adapt autonomously to the environment they perceive. The clear benefit is shortened mission-critical decision chains.

There has recently been much research done in the area of autonomous vehicle control for surveillance-type missions. Almost all of the research has dealt with centralized cooperative control, with little research concerned with the more realistic decentralized problem (Shima and Rasmussen 2009). Steinberg (2006) provided an overview on research and limitations of autonomous technologies for the control of heterogeneous unmanned naval vehicles. Experiments in this paper examined aspects such as multi-vehicle task allocation, dynamic replanning of vehicle tasks, as well as human-in-the-loop management. Constraints considered in the experiments included pop-up threats, adverse weather conditions, and communication issues between the autonomous vehicles, among others. Liang et al. (2010) present a decision support framework to accurately reconstruct the current picture of the battlespace, by correctly identifying target tracks (i.e., target location, movement, identity) as seen by multiple wide area search munitions. Ahmadzadeh et al. (2006) described their Time Critical Coverage planner as a component of the Office of Naval Research Autonomy program, ICARUS. Each autonomous vehicle was modeled as a Dubin’s vehicle (Dubins 1957), whereby the vehicles were assumed to be point masses with constant speed and a prescribed minimum turning radius. The vehicles also had prescribed starting and ending spatial-temporal locations, as well as polygonal obstacles to be avoided throughout flight. The objective was to

determine the flight path of the UAVs to maximize the total sensor footprint over the region of interest. The algorithm utilized to solve this problem was based on sampling a discretized search graph (LaValle 2006).

Ma and Miller (2005) implemented a receding-horizon approach to solve a mixed-integer linear program modeling a trajectory planning problem. They limited their focus to a single vehicle navigating through three-dimensional obstacles and terrain. They considered threat avoidance and made use of the commercial software CPLEX (ILOG CPLEX 2008) to solve their problem. Shetty et al. (2008) considered the strategic routing of multiple unmanned combat vehicles to service multiple potential targets in space. They formulated this as a mixed-integer linear program, and through a decomposition scheme looked at solving the target assignment problem (vehicles to targets) and then determining the tour that each vehicle should take to service their assigned targets (a classical vehicle routing problem). They implemented a tabu-search heuristic to find solutions to their problem. However, they assumed the vehicles were holonomic, which enabled the mixed-integer linear program formulation. Kenefic (2008) utilized techniques from particle swarm optimization (Kennedy and Eberhart 1995) to efficiently define tours for a Dubin's vehicle, visiting multiple ground targets in two-dimensional space. Schumacher and Shima (2009) considered the problem of wide area search munitions, which are capable of searching for, identifying, and attacking targets. Whenever a new target is found, or a new task needs to be assigned, a capacitated transshipment assignment problem is solved, to determine the optimal assignment of munitions to tasks. Note that from one solution to the next solution, the assignment can change significantly.

Sylvester et al. (2004) presented a path-planning algorithm for two non-holonomic vehicles engaged in a docking maneuver. A bijection search method was used to determine the trajectory of the vehicles, such that the minimum turning radius constraint of each vehicle was satisfied. Santilli et al. (1995) and Bicchi et al. (1995) considered planning a path for a non-holonomic autonomous vehicle in the presence of fixed obstacles. Jiang et al. (1999) also presented a path planning algorithm for a non-holonomic vehicle subject to obstacles. This algorithm employed a global and local strategy to find the shortest path in two dimensions that was free of collisions with the obstacles. Schouwenaars et al. (2001) considered fuel-optimal paths for multiple vehicles. They formulated the problem as a mixed-integer linear program. The vehicles needed to move from an initial to final state, while avoiding vehicular collisions, as well as stationary and moving obstacles. Obstacle positions were assumed known a priori.

Kingston and Beard (2007) presented an algorithm to keep moving UAVs equally spaced (angularly) about a stationary target. The UAVs adapted their spacing based on local communication with other UAVs. Velocity bounds were derived so that the UAVs satisfied their kinematic constraints. They extended this approach to the case when the target was moving, but the path and velocity of the target was assumed known throughout. Gu et al. (2006) discussed the problem of cooperative estimation using a team of UAVs. They considered the goal of organizing the team's configuration to achieve optimal position and velocity estimates of a moving ground target. Sinclair et al. (2007) and Doucette et al. (2009) considered a problem

of cooperative control of aerial munitions during the attack phase of a stationary ground target, in order to refine the estimates of the target location. A dynamic programming solution was implemented to determine the paths for the aerial munitions. McLain et al. (2000) presented a cooperative control problem for UAVs to rendezvous at given locations, at the same time. The UAVs considered threat and fuel constraints, in determining their trajectories. A decomposition approach was employed, whereby at the team level, an arrival time was determined, and at the individual UAV level, an optimal path to reach the specified location at the arrival time was determined.

Rafi et al. (2006) presented an approach to have an autonomous vehicle follow a moving ground target. Their technique specified positional updates for the vehicle, in terms of the next time-step turning rate as well as orientation updates for the gimballed camera mounted on the vehicle. They tested their approach using one vehicle and one moving ground target. Sinha et al. (2005) considered cooperative control for tracking of targets by multiple UAVs. An information theoretic criterion was used to determine the future path of each UAV, so that the total information gain (corresponding to the detected targets) was maximized. The UAVs were assumed to have fixed speed, and each UAV determined its angular turn rate to maximize the expected information gain for the next-time step. Akselrod et al. (2007) presented an approach for multi-target tracking of ground targets using UAVs via an hierarchical Markov decision process framework and dynamic programming. Their objective was to maximize the information gained by the UAVs. Sinha et al. (2004) presented a method to determine the location of sensors for tracking of moving ground targets, so as to maximize the resultant information gain. A genetic algorithm was implemented to determine the sensor positions. Of note here is that it was assumed that the targets were moving in the same direction as the sensors and their relative position remained constant over time.

Close-range maneuvering and following of a moving target continue to pose significant research challenges (Rafi et al. 2006). Close-range maneuvering requires real-time dynamic replanning and decision making as well as optimization of many parameters (taking into account the physical constraints of the vehicle). The problem becomes even more complex when the goal is to track a moving target for which the target dynamics is not known. In Hirsch et al. (2012, 2011) and Hirsch and Ortiz-Pena (2010), Hirsch et al. developed a decentralized approach for the autonomous cooperative control of UAVs, with the goal of persistent and accurate tracking of moving ground targets in an urban domain. The UAVs were able to share limited information with neighboring UAVs (other UAVs in their communication region) and had to dynamically replan their flight paths, incorporating predicted target movements and replanned flight paths of their neighbors into their own decision-making process. Line of sight also plays a big role in the flight plan of the UAVs and was incorporated into the problem through the use of Plücker coordinates (Semple and Kneebone 1952; Stolfi 1991). However, it was assumed that the targets were already known.

In this chapter, the approach of Hirsch et al. (2012, 2011) is extended to include, in a decentralized framework, the UAVs actively searching for and detecting

the targets, before tracking of the targets can commence. Since the UAVs have no knowledge of how many targets are present in the environment, at each decision-making step, the UAVs need to determine both the task they will perform (either searching for new targets or tracking those targets already detected) as well as determining the flight route to optimally accomplish their task. This results in a coupled task assignment/route planning mathematical formulation, which is highly nonlinear. A GRASP-SA heuristic is developed to efficiently solve the coupled problem. The solution quality is examined to determine its sensitivity to the communication capability of the UAVs. This chapter is organized as follows. Section 64.2 rigorously defines the problem of interest, discusses the dynamic feedback loop, and formulates the coupled task assignment/route planning problem as a nonlinear mathematical program. A hybrid heuristic for continuous global optimization is described in Sect. 64.3. This heuristic is utilized to solve the optimization problem at each time-step, for each UAV. Experimental results as the communication radius of the UAVs is varied are presented in Sect. 64.4. Section 64.5 provides some concluding remarks and future research directions.

64.2 Programming Formulation

64.2.1 Problem Definition

The overall problem addressed here is to provide (i) continual surveillance over a region of interest and (ii) accurately track all targets detected in this region. Hence, there are two tasks that a UAV can be performing at any given time: searching for targets or tracking those targets already detected. For this problem, there are N homogeneous autonomous vehicles flying at a fixed altitude. The vehicles are modeled as non-holonomic point masses on a two-dimensional plane with a minimum turning radius (i.e., a Dubin's vehicle (Dubins 1957)). The vehicles have minimum and maximum speed restrictions, as well as a maximum communication range, beyond which they cannot share information. Each vehicle has an independent internal representation of the surveillance region as a continuous search uncertainty map. For each location \vec{Y} in the region, the search uncertainty map for a particular UAV stores the uncertainty (from this UAV's perspective) of a target currently at location \vec{Y} . While in search mode, the UAV can update its search uncertainty map using information from its own onboard sensor as well as information from other UAVs currently in search mode (that can communicate with this UAV, i.e., its "neighbor" UAVs). While in tracking mode, the UAV can only update its search uncertainty map using information from neighbor UAVs that are in search mode. Similarly, each UAV has its own internal representation of the targets in the region of interest. When in search mode, the UAV can only update its target map from those neighbor UAVs in track mode. When in track mode, the UAV can update its target map based upon its local sensors as well as information provided from neighbor UAVs in track mode. The one exception to this is if in search mode, it is possible

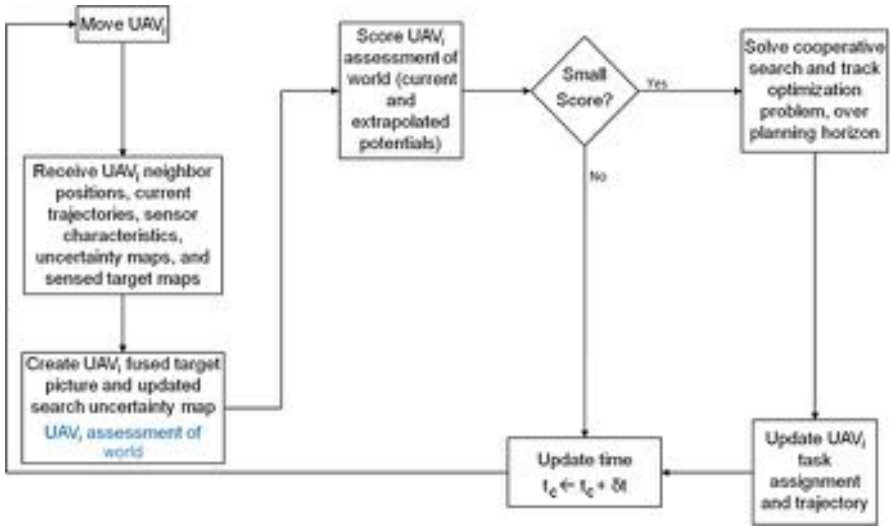

Fig. 64.1 Feedback control loop for UAV_{*i*}

(and hoped) that a UAV will detect a “new” target. When this happens, this target is added to the UAV’s stored target map, and shared with neighbor UAVs.

The vehicles operate in a decentralized manner; at each time-step, every UAV processes an equivalent version of the same dynamic feedback loop, as presented in Fig. 64.1. The feedback loop is discussed from the standpoint of UAV *i*. At the current time, t_c , the first step is for UAV *i* to move according to its planned route and continue to execute its current task (e.g., searching or tracking). Using onboard sensors, UAV *i* either searches its current field of view for new targets or attempts to sense the targets (known to UAV *i*) that are within its line of sight. The neighbors of UAV *i* send information relating to their (a) current positions, trajectories, and tasking; (b) sensor characteristics; (c) search uncertainty maps; and (d) sensed target maps. At this point, UAV *i* creates its assessment of the world, represented as a fused search uncertainty map and a fused target location map. This fused picture is scored in some qualitative manner, based upon the current positions of UAV *i* and its neighbor UAVs, their current planned trajectories and tasking, as well as the extrapolated search uncertainty map and target tracks, over the planning horizon. If the resultant score is small, or if the elapsed time since the last replan for UAV *i* is large, then UAV *i* solves a coupled tasking/route planning optimization problem for itself and its neighbor UAVs, over the planning horizon. The solution to this problem is a tasking for each UAV and route for each UAV to fly in order to accomplish their tasking. The mathematical formulation for this optimization problem is detailed in Sects. 64.2.2–64.2.5. It is worth noting that UAV *i* updates its own flight path and tasking, but does not share any of this computed information with its neighbor

UAVs. The reason for this is that the neighbors are going through this same feedback loop and may be incorporating additional knowledge not available to UAV i . The time is then incremented, and the dynamic loop continues.

64.2.2 Parameters

This section introduces the parameters incorporated into the dynamic tasking and flight plan optimization formulation. For the mathematical formulation to follow, the parameters, decision variables, and constraints are defined for all $\hat{i} \in \mathcal{N}_i(t)$, $t \in [t_c, t_c + \Delta_t]$, $\ell \in \{1, \dots, 5\}$, $h \in \{1, \dots, \mathcal{H}\}$, $j \in \{1, \dots, \mathcal{J}\}$, $u \in \{1, \dots, 4\}$, as appropriate:

t_c = The current time;

Δ_t = The current planning horizon;

C_d = The maximum distance at which any two UAVs can “communicate”, i.e., share information;

$\mathcal{N}_i(t)$ = The neighbors of UAV i , at time t , i.e., $\hat{i} \in \mathcal{N}_i(t) \implies \|P_i(t) - P_{\hat{i}}(t)\|_2 \leq C_d$. N.B.: $i \in \mathcal{N}_i(t)$;

The UAVs of interest (from UAV i ’s perspective) are indexed by $\hat{i} \in \mathcal{N}_i(t)$;

The moving ground targets are indexed by $j \in \{1, \dots, \mathcal{J}\}$;

The buildings (3D, rectangular, opaque obstacles) are indexed by $h \in \{1, \dots, \mathcal{H}\}$;

$\Omega_{\hat{i}}$ = The minimum turning radius of UAV \hat{i} ;

$P_{\hat{i}}^c$ = The current position of UAV \hat{i} (N.B.: $P_{\hat{i}}^c = \{x_{\hat{i}}^c, y_{\hat{i}}^c, z_{\hat{i}}^c\}$);

$S_{\hat{i}}^{\min}$ = The minimum speed of UAV \hat{i} ;

$S_{\hat{i}}^{\max}$ = The maximum speed of UAV \hat{i} ;

ϵ_1^{\min} = The minimum distance allowed between any two UAVs (to avoid UAV collisions);

ϵ_2^{\min} = The minimum distance allowed between any UAV and any known building. Assume this is set to 0, i.e., so that UAVs are constrained to not be within a building, but they can get infinitesimally close to the perimeter of each building.

N.B.: this assumption is valid, as one can always artificially increase the size of the buildings, as appropriate;

$Z_{\hat{i}}$ = The fixed altitude of UAV \hat{i} ;

$\mathcal{B}_h = \{\mathcal{P}_{h\ell}\}_{\ell=1}^5$ = The representation of building h , as a set of 5 rectangular regions (i.e., faces) in \mathbb{R}^3 , all oriented in the same counterclockwise fashion;

$\mathcal{P}_{h\ell} = \{\rho_{h\ell 1}, \dots, \rho_{h\ell 4}\}$ = The ℓ -th oriented rectangle (i.e., face) of building h ;

$\rho_{h\ell u} = \{\bar{x}_{h\ell u}, \bar{y}_{h\ell u}, \bar{z}_{h\ell u}\}$ = The u -th point of the ℓ -th oriented rectangle (i.e., face) of building h ;

$\xi_{h\ell} = \{v_{h\ell}; d_{h\ell}\}$ = The plane containing face $\mathcal{P}_{h\ell}$, represented as a normal vector $v_{h\ell}$ and distance to the origin $d_{h\ell}$ ($v_{h\ell} = [\rho_{h\ell 3} - \rho_{h\ell 2}] \times [\rho_{h\ell 1} - \rho_{h\ell 2}]$, $d_{h\ell} = v_{h\ell} \cdot \rho_{h\ell 1}$);

$\gamma(x, y)$ = A function representing the “importance” level of position (x, y) . The higher this value, the more important it is to provide accurate track of targets near (x, y) ;

$\Lambda_{\hat{i}j}(t)$ = The Plücker coordinate representation (Semple and Kneebone 1952; Stolfi 1991) of the oriented line from the position of UAV \hat{i} at time t , $P_{\hat{i}}(t)$, to the estimated position of target j , at time t , $X_j^i(t)$;

$\Lambda_{\hat{i}}(\vec{Y}, t)$ = The Plücker coordinate representation of the oriented line from the position of UAV \hat{i} at time t , $P_{\hat{i}}(t)$, to position \vec{Y} ;

$\hat{\Lambda}_{h\ell u, u+1}$ = The Plücker coordinate representation of the oriented line from $\rho_{h\ell u}$ to $\rho_{h\ell, u+1}$, with $u + 1 \equiv 1$ when $u = 4$;

$\mathcal{G}(\alpha, \hat{\alpha}) = \alpha_1 \hat{\alpha}_6 - \alpha_2 \hat{\alpha}_5 + \alpha_3 \hat{\alpha}_4 + \alpha_4 \hat{\alpha}_3 - \alpha_5 \hat{\alpha}_2 + \alpha_6 \hat{\alpha}_1$ where $\alpha = \{\alpha_1, \dots, \alpha_6\}$ and $\hat{\alpha} = \{\hat{\alpha}_1, \dots, \hat{\alpha}_6\}$ are the Plücker coordinate representations of two oriented lines;

$R_{\hat{i}}(t)$ = The measurement noise for the sensor onboard UAV \hat{i} , at time t . N.B.:

$R_{\hat{i}}(t) = \begin{pmatrix} \sigma_{r\hat{i}} & 0 \\ 0 & \sigma_{b\hat{i}} \end{pmatrix}$, where $\sigma_{r\hat{i}}$ = the range measurement error for the radar platform on UAV \hat{i} and $\sigma_{b\hat{i}}$ = the bearing measurement error for the radar platform on UAV \hat{i} ;

$F_{\hat{i}}(t)$ = The system dynamics matrix for the sensor onboard UAV \hat{i} , at time t ;

$\bar{Q}_{\hat{i}}(t)$ = The process noise for the sensor onboard UAV \hat{i} , at time t ;

$H_{\hat{i}}(t)$ = The observation matrix for the sensor onboard UAV \hat{i} , at time t ;

$\bar{d}_{\hat{i}}$ = The probability of detection for the sensor onboard UAV \hat{i} ;

χ = The factor by which to increase the search uncertainty map if there is no line of sight to a given position (in Constraint (64.9));

$\mathcal{M}, \bar{\mathcal{M}}$ = Large enough constants (needed for Constraints (64.7), (64.12), (64.13), (64.15), (64.16), (64.18), (64.19), (64.21), (64.22), (64.28), (64.29), (64.31), (64.32), (64.34), (64.35), (64.37), and (64.38)).

64.2.3 Decision Variables

This section defines the main decision variables for the mathematical formulation:

$P_{\hat{i}}(t)$ = The position of UAV \hat{i} , at time t (N.B.: $P_{\hat{i}}(t) = \{x_{\hat{i}}(t), y_{\hat{i}}(t), Z_{\hat{i}}\}$);

$S_{\hat{i}}(t)$ = The speed of UAV \hat{i} , at time t ;

$\theta_{\hat{i}}(t)$ = The heading of UAV \hat{i} , at time t ;

$\{X_{\hat{i}j}(t), \Sigma_{\hat{i}j}(t)\}$ = The estimated position and covariance of target j by UAV \hat{i} , at time t ;

$\{X_j^i(t), \Sigma_j^i(t)\}$ = The fused position and covariance of target j , from UAV i 's perspective, at time t ;

$\bar{\Phi}_{\hat{i}jh\ell u, u+1}(t) = \begin{cases} 1 & \text{if line segment } \Lambda_{\hat{i}j}(t) \text{ is oriented counterclockwise} \\ & \text{with respect to line segment } \hat{\Lambda}_{h\ell u, u+1}, \text{ at time } t \\ 0 & \text{o.w.} \end{cases}$;

$\bar{\Phi}_{\hat{i}jh\ell}(t)$ = The number of line segments representing the ℓ -th face of building h that line segment $\Lambda_{\hat{i}j}(t)$ is oriented counterclockwise with respect to, at time t ;

$\beta_{\hat{i}jh\ell}(t) = \begin{cases} 1 & \text{if line segment } \Lambda_{\hat{i}j}(t) \text{ does not intersect the } \ell\text{-th face} \\ & \text{of building } h \text{ at time } t \\ 0 & \text{o.w.} \end{cases}$;

$\bar{\beta}_{\hat{i}jh}(t)$ = The number of faces representing building h that line segment $\Lambda_{\hat{i}j}(t)$ does not intersect, at time t ;

$$\bar{\psi}_{\hat{i}jh}(t) = \begin{cases} 1 & \text{if there is line of sight from UAV } \hat{i} \text{ to target } j \text{ with respect to} \\ & \text{building } h, \text{ at time } t \\ 0 & \text{o.w.} \end{cases};$$

$\hat{\psi}_{\hat{i}j}(t)$ = The number of buildings that do not restrict line of sight from UAV \hat{i} to target j , at time t ;

$$\psi_{\hat{i}j}(t) = \begin{cases} 1 & \text{if UAV } \hat{i} \text{ has line of sight to target } j, \text{ at time } t; \\ 0 & \text{o.w.} \end{cases};$$

$$b_{\hat{i}} = \begin{cases} 1 & \text{if UAV } \hat{i} \text{ assigned to search mode over the planning horizon} \\ & [t_c, t_c + \delta_t] \\ 0 & \text{if UAV } \hat{i} \text{ assigned to track mode over the planning horizon} \\ & [t_c, t_c + \delta_t] \end{cases};$$

$\Gamma_i(\vec{Y}, t)$ = Search uncertainty map for UAV i at time t and position \vec{Y} ;

$$\bar{\Phi}_{\hat{i}h\ell u, u+1}(\vec{Y}, t) = \begin{cases} 1 & \text{if line segment } \Lambda_{\hat{i}}(\vec{Y}, t) \text{ is oriented counterclockwise} \\ & \text{with respect to line segment } \hat{\Lambda}_{h\ell u, u+1}, \text{ at time } t \\ 0 & \text{o.w.} \end{cases};$$

$\bar{\Phi}_{\hat{i}h\ell}(\vec{Y}, t)$ = The number of line segments representing the ℓ -th face of building h that line segment $\Lambda_{\hat{i}}(\vec{Y}, t)$ is oriented counterclockwise with respect to, at time t ;

$$\beta_{\hat{i}h\ell}(\vec{Y}, t) = \begin{cases} 1 & \text{if line segment } \Lambda_{\hat{i}}(\vec{Y}, t) \text{ does not intersect the } \ell\text{-th face} \\ & \text{of building } h, \text{ at time } t \\ 0 & \text{o.w.} \end{cases};$$

$\bar{\beta}_{\hat{i}h}(\vec{Y}, t)$ = The number of faces representing building h that line segment $\Lambda_{\hat{i}}(\vec{Y}, t)$ does not intersect, at time t ;

$$\bar{\psi}_{\hat{i}h}(\vec{Y}, t) = \begin{cases} 1 & \text{if there is line of sight from UAV } \hat{i} \text{ to position } \vec{Y} \text{ with respect} \\ & \text{to building } h, \text{ at time } t \\ 0 & \text{o.w.} \end{cases};$$

$\hat{\psi}_{\hat{i}}(\vec{Y}, t)$ = The number of buildings that do not restrict line of sight from UAV \hat{i} to position \vec{Y} , at time t ;

$$\psi_{\hat{i}}(\vec{Y}, t) = \begin{cases} 1 & \text{if UAV } \hat{i} \text{ has line of sight to position } \vec{Y}, \text{ at time } t; \\ 0 & \text{o.w.} \end{cases};$$

$$\psi_o(\vec{Y}, t) = \begin{cases} 1 & \text{if neither UAV } i \text{ nor any neighbors of UAV } i \text{ has line of sight} \\ & \text{to position } \vec{Y}, \text{ at time } t \\ 0 & \text{o.w.} \end{cases};$$

64.2.4 Constraints

$$P_{\hat{t}}(t_c) = P_{\hat{t}}^c \quad \forall \hat{t} \quad (64.1)$$

$$\frac{\partial x_{\hat{t}}(t)}{\partial t} = \mathcal{S}_{\hat{t}}(t) \cos [\theta_{\hat{t}}(t)] \quad \forall \hat{t}, t \quad (64.2)$$

$$\frac{\partial y_{\hat{t}}(t)}{\partial t} = \mathcal{S}_{\hat{t}}(t) \sin [\theta_{\hat{t}}(t)] \quad \forall \hat{t}, t \quad (64.3)$$

$$\left| \frac{\partial \theta_{\hat{t}}(t)}{\partial t} \right| \leq \Omega_{\hat{t}} \quad \forall \hat{t}, t \quad (64.4)$$

$$\mathcal{S}_{\hat{t}}^{\min} \leq \mathcal{S}_{\hat{t}}(t) \leq \mathcal{S}_{\hat{t}}^{\max} \quad \forall \hat{t}, t \quad (64.5)$$

$$\|P_{\hat{t}_1}(t) - P_{\hat{t}_2}(t)\|_2 \geq \varepsilon_1^{\min} \quad \forall \hat{t}_1, \hat{t}_2, t \quad (64.6)$$

$$P_{\hat{t}}(t) \cdot v_{h\ell} + d_{h\ell} \geq -\mu_{\hat{t}h\ell}(t)\mathcal{M} \quad \forall \hat{t}, h, \ell, t \quad (64.7)$$

$$\sum_{\ell=1}^5 \mu_{\hat{t}h\ell}(t) \leq 4 \quad \forall \hat{t}, h, \ell, t \quad (64.8)$$

$$\begin{aligned} \frac{\partial \Gamma_i(\vec{Y}, t)}{\partial t} = & \left[\prod_{\hat{t} \in \mathcal{N}_i(t)} (1 - \bar{d}_{\hat{t}})^{b_{\hat{t}}\psi_{\hat{t}}(\vec{Y}, t)} \right] \cdot \Gamma_i(\vec{Y}, t) \\ & + \psi_o(\vec{Y}, t) \cdot \chi \cdot \Gamma_i(\vec{Y}, t) \quad \forall t, \vec{Y} \end{aligned} \quad (64.9)$$

$$\psi_o(\vec{Y}, t) \leq 1 - b_{\hat{t}}\psi_{\hat{t}}(\vec{Y}, t) \quad \forall \hat{t}, t, \vec{Y} \quad (64.10)$$

$$\psi_o(\vec{Y}, t) + \sum_{\hat{t} \in \mathcal{N}_i(t)} b_{\hat{t}}\psi_{\hat{t}}(\vec{Y}, t) > 0 \quad \forall t, \vec{Y} \quad (64.11)$$

$$\mathcal{G}(\Lambda_{\hat{t}}(\vec{Y}, t), \hat{\Lambda}_{h\ell u, u+1}) - (1 - b_{\hat{t}})\bar{\mathcal{M}} \leq \bar{\phi}_{\hat{t}h\ell u, u+1}(\vec{Y}, t)\mathcal{M} \quad \forall \hat{t}, \vec{Y}, h, \ell, u, t \quad (64.12)$$

$$-\mathcal{G}(\Lambda_{\hat{t}}(\vec{Y}, t), \hat{\Lambda}_{h\ell u, u+1}) - (1 - b_{\hat{t}})\bar{\mathcal{M}} < \left(1 - \bar{\phi}_{\hat{t}h\ell u, u+1}(\vec{Y}, t)\right)\mathcal{M} \quad \forall \hat{t}, \vec{Y}, h, \ell, u, t \quad (64.13)$$

$$\bar{\phi}_{\hat{t}h\ell}(\vec{Y}, t) = \sum_{u=1}^4 \bar{\phi}_{\hat{t}h\ell u, u+1}(\vec{Y}, t) \quad \forall \hat{t}, \vec{Y}, h, \ell, t \quad (64.14)$$

$$\beta_{\hat{t}h\ell}(\vec{Y}, t) - (1 - b_{\hat{t}})\bar{\mathcal{M}} \leq 4 - \bar{\phi}_{\hat{t}h\ell}(\vec{Y}, t) \quad \forall \hat{t}, \vec{Y}, h, \ell, t \quad (64.15)$$

$$\beta_{\hat{t}h\ell}(\vec{Y}, t)\mathcal{M} + (1 - b_{\hat{t}})\bar{\mathcal{M}} \geq 4 - \bar{\phi}_{\hat{t}h\ell}(\vec{Y}, t) \quad \forall \hat{t}, \vec{Y}, h, \ell, t \quad (64.16)$$

$$\bar{\beta}_{\hat{t}h}(\vec{Y}, t) = \sum_{\ell=1}^5 \beta_{\hat{t}h\ell}(\vec{Y}, t) \quad \forall \hat{t}, \vec{Y}, h, t \quad (64.17)$$

$$\bar{\psi}_{\hat{t}h}(\vec{Y}, t) - (1 - b_{\hat{t}})\bar{\mathcal{M}} \leq \beta_{\hat{t}h\ell}(\vec{Y}, t) \quad \forall \hat{t}, \vec{Y}, h, t \quad (64.18)$$

$$1 - \bar{\psi}_{ih}(\vec{Y}, t) - (1 - b_i) \bar{\mathcal{M}} \leq 5 - \bar{\beta}_{ih}(\vec{Y}, t) \quad \forall \hat{i}, \vec{Y}, h, t \quad (64.19)$$

$$\hat{\psi}_{\hat{i}}(\vec{Y}, t) = \sum_{h=1}^{\mathcal{H}} \bar{\psi}_{ih}(\vec{Y}, t) \quad \forall \hat{i}, \vec{Y}, t \quad (64.20)$$

$$\psi_{\hat{i}}(\vec{Y}, t) - (1 - b_i) \bar{\mathcal{M}} \leq \bar{\psi}_{ih}(\vec{Y}, t) \quad \forall \hat{i}, \vec{Y}, t \quad (64.21)$$

$$1 - \psi_{\hat{i}}(\vec{Y}, t) - (1 - b_i) \bar{\mathcal{M}} \leq \mathcal{H} - \hat{\psi}_{\hat{i}}(\vec{Y}, t) \quad \forall \hat{i}, \vec{Y}, t \quad (64.22)$$

$$\Sigma_j^i(t) = \left[\sum_{\hat{i} \in \mathcal{N}_i(t)} (1 - b_{\hat{i}}) \psi_{\hat{i}j}(t) \Sigma_{\hat{i}j}^{-1}(t) \right]^{-1} \quad \forall j, t \quad (64.23)$$

$$X_j^i(t) = \Sigma_j^i(t) \cdot \left[\sum_{\hat{i} \in \mathcal{N}_i(t)} (1 - b_{\hat{i}}) \psi_{\hat{i}j}(t) \Sigma_{\hat{i}j}^{-1}(t) X_{\hat{i}j}(t) \right] \quad \forall j, t \quad (64.24)$$

$$\frac{\partial X_{\hat{i}j}(t)}{\partial t} = (1 - b_i) [F_i(t) X_{\hat{i}j}(t) + K_i(t) [\bar{z}_{ij}(t) - H_i(t) X_{\hat{i}j}(t)]] \quad \forall \hat{i}, j, t \quad (64.25)$$

$$\begin{aligned} \frac{\partial \Sigma_{\hat{i}j}(t)}{\partial t} = & (1 - b_i) [F_i(t) \Sigma_{\hat{i}j}(t) + \Sigma_{\hat{i}j}(t) F_i^T(t) + \bar{Q}_i(t) \\ & - K_i(t) R_i(t) K_i^T(t)] \quad \forall \hat{i}, j, t \end{aligned} \quad (64.26)$$

$$K_i(t) = \Sigma_{\hat{i}j}(t) H_i^T(t) R_i^{-1}(t) \quad \forall \hat{i}, j, t \quad (64.27)$$

$$\mathcal{G}(\Lambda_{\hat{i}j}(t), \hat{\Lambda}_{h\ell u, u+1}) - b_i \bar{\mathcal{M}} \leq \bar{\phi}_{ijh\ell u, u+1}(t) \mathcal{M} \quad \forall \hat{i}, j, h, \ell, u, t \quad (64.28)$$

$$-\mathcal{G}(\Lambda_{\hat{i}j}(t), \hat{\Lambda}_{h\ell u, u+1}) - b_i \bar{\mathcal{M}} < (1 - \bar{\phi}_{ijh\ell u, u+1}(t)) \mathcal{M} \quad \forall \hat{i}, j, h, \ell, u, t \quad (64.29)$$

$$\bar{\phi}_{ijh\ell}(t) = \sum_{u=1}^4 \bar{\phi}_{ijh\ell u, u+1}(t) \quad \forall \hat{i}, j, h, \ell, t \quad (64.30)$$

$$b_{\hat{i}} \in \{0, 1\} \quad \forall \hat{i} \quad (64.47)$$

Interpretation of Constraints

Constraints (64.1) prescribe initial positions for each of the UAVs in $\mathcal{N}_i(t)$;

Constraints (64.2) and (64.3) define the motion of UAV \hat{i} , as a function of the speed and heading of the UAV;

Constraints (64.4) restrict the instantaneous change in heading of UAV \hat{i} to be less than $\Omega_{\hat{i}}$ (modeling the UAVs as Dubin's vehicles);

Constraints (64.5) define minimum and maximum speed restrictions UAV \hat{i} ;

Constraints (64.6) enforce no two UAVs being closer than ε_1^{\min} ;

Constraints (64.7) and (64.8) prescribe that no UAV trajectory can intersect with the boundary of any building;

Constraints (64.9)–(64.11) determine the updated search uncertainty map for UAV i at time t ;

Constraints (64.12)–(64.22) are only enforced if UAV \hat{i} is assigned to a search task over the planning horizon $[t_c, t_c + \delta_t]$:

Constraints (64.12) and (64.13) force $\bar{\phi}_{\hat{i}h\ell u, u+1}(\vec{Y}, t)$ to be 1 when line segment $\Lambda_{\hat{i}}(\vec{Y}, t)$ is oriented counterclockwise with respect to the line segment $\hat{\Lambda}_{h\ell u, u+1}$, at time t , and to be 0 otherwise;

Constraints (64.14) count the number of line segments representing the ℓ -th face of building h that line segment $\Lambda_{\hat{i}}(\vec{Y}, t)$ is oriented counterclockwise with respect to, at time t ;

Constraints (64.15) and (64.16) force $\beta_{\hat{i}h\ell}(\vec{Y}, t)$ to be 1 when line segment $\Lambda_{\hat{i}}(\vec{Y}, t)$ does not intersect the ℓ -th face of building h , at time t , and to be 0 otherwise;

Constraints (64.17) count the number of faces of building h that do not inhibit line of sight from UAV \hat{i} to position \vec{Y} , at time t ;

Constraints (64.18) and (64.19) force $\bar{\psi}_{\hat{i}h}(\vec{Y}, t)$ to be 1 when there is line of sight from UAV \hat{i} to position \vec{Y} , at time t , with respect to building h , and to be 0 otherwise;

Constraints (64.20) count the number of buildings that do not inhibit line of sight from UAV \hat{i} to position \vec{Y} , at time t ;

Constraints (64.21) and (64.22) force $\psi_{\hat{i}}(t)$ to be 1 when UAV \hat{i} has line of sight to position \bar{Y} , at time t , and to be 0 otherwise;

Constraints (64.23) and (64.24) determine the fused covariance and state for target j at time t , from UAV i 's perspective, based on those neighbors of UAV i that have line of sight to target j ;

Constraints (64.25)–(64.27) are the continuous time Kalman filter (Kalman-Bucy filter) equations for the state of target j , as seen from UAV \hat{i} , where $\bar{z}_{ij}(t)$ represents the measurement of target j by UAV \hat{i} , at time t (N.B.: a detailed explanation of the Kalman filter equations can be found in Blackman and Popoli (1999), Gelb (1974), and Maybeck (1994));

Constraints (64.28)–(64.38) are only enforced if UAV \hat{i} is assigned to a track task over the planning horizon $[t_c, t_c + \delta_t]$:

Constraints (64.28) and (64.29) force $\bar{\phi}_{ijhlu,u+1}(t)$ to be 1 when line segment $\Lambda_{\hat{i}j}(t)$ is oriented counterclockwise with respect to the line segment $\hat{\Lambda}_{hlu,u+1}$, at time t , and to be 0 otherwise;

Constraints (64.30) count the number of line segments representing the ℓ -th face of building h that line segment $\Lambda_{\hat{i}j}(t)$ is oriented counterclockwise with respect to, at time t ;

Constraints (64.31) and (64.32) force $\beta_{ijht}(t)$ to be 1 when line segment $\Lambda_{\hat{i}j}(t)$ does not intersect the ℓ -th face of building h , at time t , and to be 0 otherwise;

Constraints (64.33) count the number of faces of building h that do not inhibit line of sight from UAV \hat{i} to target j , at time t ;

Constraints (64.34) and (64.35) force $\bar{\psi}_{ijh}(t)$ to be 1 when there is line of sight from UAV \hat{i} to target j , at time t , with respect to building h , and to be 0 otherwise;

Constraints (64.36) count the number of buildings that do not inhibit line of sight from UAV \hat{i} to target j , at time t ;

Constraints (64.37) and (64.38) force $\psi_{ij}(t)$ to be 1 when UAV \hat{i} has line of sight to target j , at time t , and to be 0 otherwise;

Constraints (64.23)–(64.27) prescribe domain restrictions on all of the decision variables.

64.2.5 Objective Function (for UAV i)

The objective function, F , as defined in Eq. (64.48), minimizes the sum of two components. The first component computes the expectant volume of UAV i 's search uncertainty map over the planning horizon, $[t_c, t_c + \delta_t]$. The second component computes the weighted sum of the determinants of the fused covariances for the targets that are known to UAV i , over the planning horizon.

$$F = \min \left[a_s \int_{t_c}^{t_c + \Delta_t} \int_{\mathbb{R}^2} \Gamma_i(\mathcal{Y}, \tau) d\mathcal{Y} d\tau + a_t \int_{t_c}^{t_c + \Delta_t} \sum_{j=1}^{\mathcal{J}} \left[\gamma(X_j^i(\tau)) \left| \Sigma_j^i(\tau) \right| d\tau \right] \right] \quad (64.48)$$

64.2.6 Discussion on Complexity

It is easy to see that our problem of determining the flight plan for a set of autonomous UAVs is a generalization of the standard vehicle routing problem (VRP). While there are many variants to the standard VRP, the general form considers m vehicles, starting at a depot, tasked with delivering goods or services to a set of n customers. Each customer has a certain required demand, and each vehicle has a capacity. In addition, each vehicle must start and end their route at the depot (a tour).

A solution to this problem is a set of tours for which each customer is visited only once while respecting capacity and demand constraints. The objective can be to minimize the total distance traveled by all vehicles, to minimize the maximum distance traveled by any one vehicle, or to minimize the number of vehicles required to service the customers. The VRP is known to be NP-hard (Garey and Johnson 1979), and thus our problem is NP-hard as well.

64.3 Heuristic Algorithm

There are many papers dealing with UAV routing (Shetty et al. 2008; Ma and Miller 2005; Schouwenaars et al. 2001; Sinha et al. 2005) that formulate the problem statement as a linear or mixed-integer linear program (or a formulation that can be linearized in the standard way). This allows the authors to use various proven heuristics to find good routes for the UAVs. However, for UAV routing, incorporating more realistic constraints on the movement of the UAVs necessitates the introduction of nonlinear constraints that cannot be linearized without approximation of the nonlinear constraints. Hence, the need to utilize more generalized heuristics (or meta-heuristics) in the search for near-optimal solutions.

To efficiently solve the optimization problem presented in Sects. 64.2.2–64.2.5, a hybrid heuristic was developed, combining Greedy Randomized Adaptive Search Procedures (GRASP) and Simulated Annealing (SA). GRASP is a multi-start local search procedure, where each iteration consists of two phases, a construction phase and a local search phase (Feo and Resende 1989, 1995; Festa and Resende 2002). In the construction phase, interactions between greediness and randomization generate a diverse set of quality solutions. The local search phase improves upon the solutions found in the construction phase. In this GRASP implementation, only the construction portion is utilized. Simulated Annealing is a heuristic to find good-quality solutions to optimization problems by approximating the cooling process of metals (Kirkpatrick et al. 1983). At each step, a current solution is perturbed. If the perturbation results in a better solution, then the current solution is replaced. If the perturbed solution is worse than the current solution, it still might replace the current solution; replacement will occur with a probability based on the distance between the current and perturbed solution values and the current temperature in the annealing process. As the heuristic progresses, the temperature is lowered, making it more and more unlikely to replace the current solution with a worse perturbed solution.

For our hybrid GRASP-SA heuristic, the GRASP heuristic determines the task assignment for the UAVs, interacting directly with a Simulated Annealing heuristic which determines the routes that the UAVs should fly to accomplish their tasks. The best solution over all of the GRASP multi-start iterations is retained as the final solution. It is important to note that a solution, for a given UAV, is the tasking and flight path for the UAV, as well as the neighbors of the UAV, over the planning horizon. Figure 64.2 provides pseudocode for the GRASP-SA hybrid heuristic, with the function Ξ representing the SA heuristic function.

64.4 Experimental Results

64.4.1 Test Environment

The experiments to follow were carried out on a Hewlett-Packard with an Intel(R) Core(TM) 2 Duo E8400 CPU at 3.00 GHz and 3.71 GB of RAM running Microsoft Windows 7 Enterprise (64-bit). The implementation of the GRASP and Simulated Annealing heuristics as written in the C++ programming language and compiled with Microsoft Visual C++ 2008. The algorithm used for random-number generation is an implementation of the Mersenne Twister algorithm described in Matsumoto and Nishimura (1998).

64.4.2 Experiments

While no specific UAV was modeled, the experiments utilized characteristics of the Raven UAV. The simulations in this study model the UAV sensors as omnidirectional radars measuring range and bearing to the targets. Conversions of the measurement and measurement uncertainty from spherical to cartesian coordinates were done utilizing the standard transformations (Lerro and Bar-Shalom 1993). Table 64.1 displays the parameter values used during the simulation. Thirty-two buildings were modeled in the simulation, each with a height of 100 m, while the altitude of the 4 UAVs was fixed to 10 m. Eight moving ground targets were simulated, with minimum and maximum speeds of 0 and 30 miles h^{-1} , respectively. Three different experiments were performed, varying the communication range of the UAVs. In the “no-comms” case, each UAV had an effective communication radius of 0 m, making them truly independent of all the other UAVs. For the “half-comms” case, each UAVs communication radius was set to 979.5 m, half the length of the simulated region of interest. And in the “unlimited comms” case, each UAV had a communication radius larger than the simulated region of interest, meaning as long as there were no obstructions (e.g., buildings) between two UAVs, they could effectively communicate.

To highlight a small sample of the simulation, Figs. 64.3–64.5 show the results for time steps 44–46 of the unlimited communications case. This is a top-down view,

Fig. 64.4 Simulation results for unlimited communications case, at time-step 45. UAVs 3 and 4 are engaged in the search task, while UAVs 1 and 2 are tracking the target within their sensor coverage

with the yellow rectangles representing the buildings, the small white rectangles representing the targets, the UAVs numbered, and the planned routes of the UAVs emanating from each UAV. UAVs engaged in a search task have routes colored red, while those engaged in a tracking task have routes colored green. The background represents the search uncertainty map, with blue corresponding to a low level of uncertainty and red a high level of uncertainty. The sensor coverage for each UAV is represented by a black circle about each UAV. At time-step 44, UAVs 1, 3, and 4 are engaged in a search task, while UAV 2 is engaged in tracking the target within its sensor coverage. At this time-step, UAV 1 and 2 are close enough together to share information, so UAV 1 knows about the target UAV 2 is currently tracking. At time-step 45, UAVs 3 and 4 continue searching, while UAV 1 switches to a tracking task, to help track the target UAV 2 has been tracking. Time-step 46 sees UAV 1 with a new trajectory, to better keep the target it is tracking within its sensor coverage. UAV 2 is still engaged in tracking, and UAVs 3 and 4 are still engaged in a search task. Note also that UAV 4 has its route planned to reduce the uncertainty shown in the bottom left region of the scenario.

Fig. 64.5 Simulation results for unlimited communications case, at time-step 46. UAVs 3 and 4 are engaged in the search task, while UAV 1 and 2 are continuing to track the target within its sensor coverage. In addition, UAV 1 has changed its trajectory to keep the target within its coverage

One method to measure how the UAV communication range affects the searching algorithm is to observe the minimum search uncertainty value across all UAVs at each location for the simulated region of interest. Figure 64.6 displays the resultant mean minimum search uncertainty map value of the UAVs for the simulated region of interest, at each time-step. The mean search plots tend to show spike and dips. What happens in these cases is that a UAV's search uncertainty map has a group of values that become large in one particular area of the search region. When enough of these values become large, and as long as the UAV is not tasked to track a target, the UAV will eventually plan a route that leads it to search that area of interest. This sudden decrease in many search uncertainty values drives the mean sharply downward. The zero-comms case does not have as many sharp spikes because it has fewer opportunities to switch to tracking (since those UAVs cannot share their state with each other). However, they must conduct their search on their own – this leads to the general upward trend in the zero-comms case in the mean search plot, since they cannot leverage the search information of their neighbors.

Fig. 64.6 The mean minimum search uncertainty map value over all UAVs at each time-step, for the three UAV communication cases

Figure 64.7 displays the number of UAVs engaged in tracking each target, at each time-step. Of note here is that the mean weighted percentage of targets tracked increases from 48.854 when the communications radius is 0m to 70.208 when the communication radius is 979.5m and finally to 80 when the communication radius is infinite. Figure 64.8 displays the mean Mahalanobis distance (Eq. 64.49), between the fused and truthful positions, for each target, for each time-step. As can be seen here, the mean Mahalanobis distance decreases as the communication radius increases. This is because as communication among the UAVs increases, more information on the target kinematics can be shared among the UAVs (and hence fused into each UAVs target map):

$$M_d(x, \bar{x}, \Sigma, \bar{\Sigma}) = (x - \bar{x}) (\Sigma + \bar{\Sigma})^{-1} (x - \bar{x})^T \quad (64.49)$$

As can be seen in the result plots, a push-and-pull effect is occurring. During the search phase, the UAVs want to fly to areas of high uncertainty (and hence reduce the uncertainty there), but as the UAVs detect targets in these high uncertainty regions, they switch their tasking to tracking (because the initial uncertainty of a target contributes more to the objective function than does the search uncertainty). This can be partially alleviated by modifying the decision variable b_i to include a time dimension, $b_i(t)$. This would have the effect of allowing each UAV to switch between tasks over the planning horizon, rather than forcing each UAV to make a decision on a task for the whole planning horizon. This can also be achieved by artificially reducing the size of the planning horizon. Both approaches will increase the complexity and computational throughput and are out of the current scope.

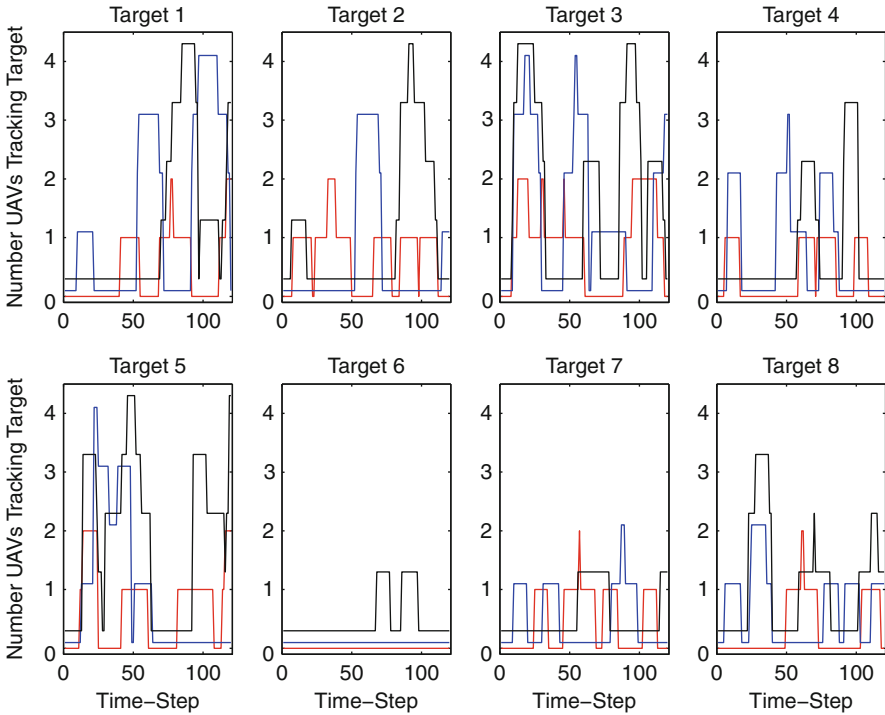

Fig. 64.7 Number of UAVs engaged in tracking each target, at each time-step. The *red* curve denotes the communications radius of 0 m, the *blue* curve denotes the communications radius of 979.5 m, and the *black* curve denotes the infinite communications radius

64.5 Conclusions and Future Research Areas

This chapter considered dynamically updating the tasking and flight paths for UAVs in an urban domain. The UAVs were assumed to be Dubins-like vehicles (i.e., point masses with kinematic constraints) with limited communication capabilities. This resulted in a decentralized approach where each UAV dynamically updated flight plans for itself and its neighbors. As it was an urban domain, the UAVs needed to incorporate obstacle avoidance constraints into the flight plan generation as well as taking into account anticipated future line of sight obstructions to the targets and search region. A dynamic feedback control loop was implemented for each UAV, and a rigorous mathematical formulation was presented for the coupled task assignment/flight path optimization problem each UAV had to solve at each time-step.

This approach was successfully applied to a simulated scenario utilizing a hybrid GRASP-SA heuristic. The influence of communication radius among the UAVs on the resultant objective function value was studied. While it is in general expected

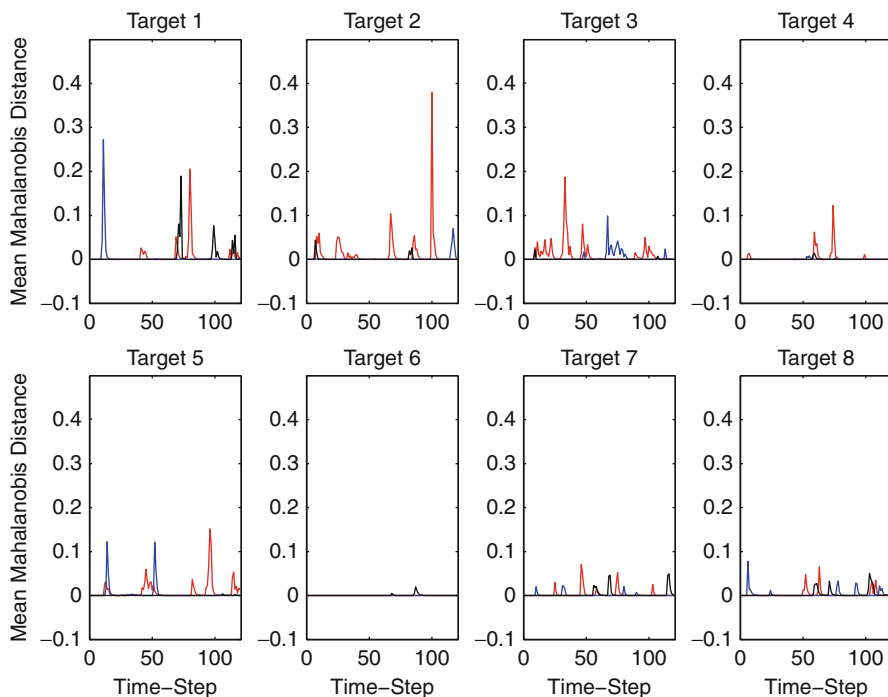

Fig. 64.8 Mean Mahalanobis distance (between the fused position and the truthful position) for each target, for each time-step. The *red curve* denotes the communications radius of 0 m, the *blue curve* denotes the communications radius of 979.5 m, and the *black curve* denotes the infinite communications radius

that the larger the communication radius, the better the performance of the UAVs, as seen from the results, many other factors also influence performance.

It is expected that UAV utilization will continue to increase in scope, both for military and nonmilitary operations. Hence, there is the need to continue to advance the state of the art in autonomous UAV research. Future research directions include applying our general approach to UAVs with heterogeneous sensors (e.g., directional radars, passive sensors) as well as to heterogeneous vehicles, from different domains (e.g., UAVs and UGVs working synergistically). A comparison of the efficiency of our approach, from a computational and functional perspective, to other centralized and decentralized approaches is currently underway. The end goal is geared toward testing these algorithms on real UAVs.

Abstract

Decades of advances in electronics and communication technologies have enabled large-scale, flexible, reconfigurable multiple-UAV systems with a variety of applications ranging from large-scale military surveillance and reconnaissance to environmental monitoring and disaster response. Most of these applications require multiple tasks and service requests to be handled by a large group of UAVs in an efficient manner. Motivated by these problems, this chapter is devoted to a large-scale distributed task/target assignment problem for a fleet of autonomous UAVs. Central to this chapter is an algorithm that uses the delayed column generation approach on a non-convex supply-demand formulation for the problem. The algorithm exploits a computationally tractable distributed

coordination structure, i.e., a market for tasks and targets created by the UAV fleet. The resulting structure is solved via a fleet-optimal dual simplex ascent in which each UAV updates its respective flight plan costs with a linear update of waypoint task values as evaluated by the market. Synchronized and asynchronous distributed implementations of this approximation algorithm is demonstrated in a thorough experimental study involving dynamically changing scenarios with random pop-up targets. Results from the tests performed on an in-house built network mission simulator are also provided for the numerical verification of the algorithm on (a) bounded polynomial-time computational complexity and (b) hard real-time performance for problem sizes on the order of 100 waypoints per UAV.

65.1 Introduction

In the last three decades, the advances in electronics and communications technology provided faster and cheaper computational power which can be seamlessly networked over wide geographies. These advances resulted in a new paradigm in large-scale dynamic systems (Lasdon 1970). In this paradigm, groups of independent dynamic systems, such as unmanned air vehicles, act as a cooperative unit for a diverse set of applications in remote sensing, exploration, and imaging. These systems have been envisioned to provide highly flexible and reconfigurable structures that use individual autonomy to respond to changing environments and operations.

Of particular importance to military applications is the replacement of traditional complex aircraft fighter systems with an array of simpler and lower-cost unmanned air vehicles (UAVs). Figure 65.1 illustrates a dynamic conflict scenario envisioned by the Defense Advanced Research Project Agency (DARPA). In this scenario, unmanned air vehicle fleets are a part of a global coordination network that includes manned aircraft and satellites used together for information gathering, data relay, and target elimination. This network is controlled by a series of distributed logistics centers that identify geographic locations of interest and generate high-level assignments. These locations are transmitted to each vehicle in the airborne platform as waypoints which are described via a series of geographic positions and mission times. Once this information is received, the aim of each unmanned air vehicle is to handle the lower-level operations which include flying through its regions of interest, performing the necessary tasks such as imaging or data collection, and identifying new targets either autonomously or through the logistics centers to which these images and the data are transmitted back to in real time. The efficient operation of this airborne platform relies not only on the each vehicle's ability to autonomously fly through its designated way-points but also on each vehicle's ability to negotiate or coordinate the assignment of newly identified or transmitted targets. With the ever-growing involvement of UAVs in complex

Fig. 65.1 Reconfigurable coordination network envisioned by DARPA (2012). In this network, unmanned air vehicle fleets improve flexibility and offer a high degree of redundancy and reconfigurability in the event of a vehicle failure

application areas (such as dynamically changing urban rescue operations), the types and the number of tasks easily outgrow one vehicle's (or a set of UAV operators' command and control) limited capabilities and thus require a fleet of UAVs working autonomously in a collaborative fashion to achieve desired operational goals. In remote locations, where a minimum amount of ground support (centralized control) is available, it is crucial that the vehicles coordinate their target and task assignments (Toth and Vigo 2002) in dynamically changing scenarios.

In this chapter, a distributed optimization method that allows collaborative task/target assignment across such autonomous UAV fleets is proposed. Specifically, the method considers the cases in which the number of tasks/targets is very large (i.e., on the order of tens to hundreds per UAV) and dynamically change.

For large-scale assignment problems with limited resources (Melhorn and Ziegelmann 2000; Minoux 1987), the optimal/near-optimal allocation of such resources becomes a crucial deciding factor for the success of a mission. The problem of task assignment in optimization framework is inherently a binary integer linear program (Garfinkel and Nemhauser 1972) (a special case of mixed integer linear programming (MILP) (Brickman 1989; Ralphs and Galati 2006; Richards et al. 2003)) and has been used widely for formulating UAV task assignment problems (Schouwenaars et al. 2001; Bellingham et al. 2003). In this work, a structural decomposition of the most general form of this task assignment formulation through column generation is exploited. Essentially, the column generation approach provides a method for breaking up column-dense large-scale optimization problems into subcomponents that are integrated to a growing master problem

which is optimized one step at a time. Together with Desaulniers et al. (2005) a good survey of column generation in integer programming is presented in Barnhart et al. (1998). The reader is referred to Ehrgott and Tind (2007) and Lubbecke and Desrosiers (2005) for the use of column generation technique in the context of integer programming for many problems outlined in these references.

There has been considerable effort in literature to use column generation to solve shortest-path problems (Irnich and Desaulniers 2005), vehicle routing problems with time windows (Kallehauge and Larsden 2005; Donna and Pape 2005; Chabrier 2006), and split-delivery vehicle routing problem (Desaulniers 2010; Archetti et al. 2011). However, these formulations are aimed at solving the centralized assignment problem in a step-by-step, progressive fashion. In comparison, this chapter outlines a distributed implementation structure that is amenable to onboard real-time computation on the UAVs.

Specifically, Sect. 65.2 provides a primitive non-convex supply-demand form of the task assignment problem with extreme point solutions that conveniently correspond to the waypoint selection for each UAV. This column-dense extreme point formulation is used for employing a delayed column generation optimization scheme which involves (a restricted form of) a master and subproblem formulations. Both of these steps are shown to be implementable at the local computer of any of the UAVs requiring only communication for passing flight path information (i.e., specific waypoint selections) and the costs associated with these flight paths. This two-step solution corresponds to a fleet-optimal dual simplex ascent method in which each UAV updates its respective flight plan costs with a linear update of waypoint task values as evaluated in the market created by the UAVs for the targets.

Market architecture that seeks to maximize benefit while minimizing travel distance costs has been used for solving task allocation problem as well. In Zlot et al. (2002), exploration has been performed in a distributed fashion. Specifically, new tasks that can be generated by each of the robots are inserted into their respective plans or subsequently traded across the group. This approach has been further extended to handle task failures, partial malfunctions, and robot death (Dias et al. 2004). Pongpunwattana et al. (2003) combined evaluation computing-based techniques and the distributed structure of market-based algorithm using Vickrey auction where the sale price is the value of the second-highest bid to motivate truthful bids from the participants. In Lemaire et al. (2004), distributed architecture for multi-robot tasks allocation problem is considered, and the Contract-Net protocol has been enhanced with a token-based system which equilibrates the workload between the agents. By considering both single- and multi-task assignment problem, Choi et al. (2009) presented two decentralized algorithms that utilize a market-based decision strategy and a consensus routine based on local communication as the conflict resolution mechanism to achieve agreement on the winning bid values. This work has been further extended to account for tasks with time windows of validity and heterogeneous agent capabilities and constraints (Ponda et al. 2010). Similarly, in the application context of multi-agent task allocation, Sheng et al. (2004) considered disruptions due to limited-range communication, and the

proposed method incorporated a term into utility function to limit the amount of communication loss. Bhattacharya et al. (2010) also presented a distributed implementation of a separable optimization problem with nonlinear constraints arising from coupling between pairs of robots and showed that the algorithm converges to an optimal solution under certain conditions. In Cheng and Kumar (2008), the decentralized algorithm used a local sensing-based control law and time synchronization to distribute all vehicles at regular intervals along a common curve in finite time without needing any communication between neighboring vehicles. Authors also refer the readers to Dias et al. (2006) in which a comprehensive literature survey and their analysis (up to 2005) are given on market-based approaches to multi-agent coordination. Similarly, in this chapter, Sect. 65.3 is devoted to algorithmic implementation details of the proposed method and Sect. 65.4 to the computational results of the standard fleet-optimal shortest-path target assignment problem.

The main contributions of this chapter can be listed as follows. We provide a novel delayed column generation relaxation on a non-convex supply-demand formulation for target-task assignment problem. The algorithm which solves this relaxation exploits a computationally tractable distributed coordination structure, i.e., a market for tasks and targets created by the UAV fleet. The resulting structure is solved via a fleet-optimal dual simplex ascent in which each UAV updates its respective flight plan costs with a linear update of waypoint task values as evaluated by the market. The solution method provides the flexibility of synchronized and asynchronous distributed implementations across dynamically changing scenarios with random pop-up targets. In comparison to existing solution techniques, the method as proposed provides (i) bounded polynomial-time computational complexity and (ii) hard real-time performance for problem sizes on the order of 100 waypoints per UAV. Algorithmic structure and numerical implementation of the results presented in this chapter have previously appeared in Karaman and Inalhan (2008).

65.2 Task Assignment Problem

Consider the task assignment problem of m vehicles to n targets, defined as follows. Let y_{ij} be a binary decision variable that evaluates to one if the i th vehicle is assigned to service target j and evaluates to zero otherwise. For notational convenience, let y_i denote the vector $y_i := [y_{i1} \ y_{i2} \ \cdots \ y_{in}]$. This vector of decision variables simply denotes the set of all targets that are assigned to the i th vehicle. Let $c_i(\cdot)$ denote the cost function that associates a cost to each such vector y_i . Then, the task assignment problem can be written as follows:

Problem A:

$$\begin{aligned} & \text{minimize} && c_1(y_1) + c_2(y_2) + \cdots + c_m(y_m) && (65.1) \\ & \text{subject to} && I \ y_1 + I \ y_2 + \cdots + I \ y_m = 1_{n \times 1} \end{aligned}$$

$$\begin{aligned}
\sum_j y_{1j} &\geq 1 \\
\sum_j y_{2j} &\geq 1 \\
&\vdots \\
\sum_j y_{mj} &\geq 1 \\
y_{ij} &\in \{0, 1\}
\end{aligned}$$

where I denotes the identity matrix of suitable size and $1_{n \times 1}$ denotes the vector of ones of size n . In this formulation, the first set of constraints ensure that every target is serviced exactly once, and the rest ensure that each vehicle services at least one target.

A common choice for the cost function $c_i(y_i)$ is the length of the shortest path through the targets serviced in the assignment y_i . In that case, the objective function in Eq. (65.1) becomes the “shortest fleet path.” However, throughout this chapter, no specific assumptions are placed on the structure of the cost function. In particular, the cost function can be nonlinear (in subscript j that indexes the targets) as in the shortest-path example.

The LP relaxation of the problem described above is obtained by posing the constraint $0 \leq y_{ij} \leq 1$, where $y_{ij} \in \mathbb{R}$, to replace the constraint $y_{ij} \in \{0, 1\}$. Note that the upper bound on y_{ij} is implied by the interconnecting assignment constraint.

The optimization problem described in Problem A lends itself to a distribution solution through the well-known Dantzig-Wolfe decomposition (Vanderback and Savelsbergh 2006). For each vehicle i , define the corresponding polyhedral region $P_i := \{y_{ij} \in \mathbb{R} : \sum_j y_{ij} \geq 1, 0 \leq y_{ij} \leq 1\}$. Then, using the Minkowski resolution theorem, the assignment vector y_i can be described as a convex combination of the extreme points of P_i . More precisely, let y_i^q , indexed by $q \in Q_i$, denote the extreme points of P_i . Then, each y_i can be represented in terms of a new set $\{x_i^q : q \in Q_i\}$ of variables as follows:

$$y_i = \sum_{q \in Q_i} x_i^q y_i^q$$

subject to the convexity constraints

$$\sum_{q \in Q_i} x_i^q = 1; \quad x_i^q \geq 0.$$

This formulation, in particular, leads to a representation of the objective function that is linear in the new decision variables. More precisely, $c_i(y_i) = c_i(x_i^q y_i^q) = x_i^q c(y_i^q) = x_i^q c_i^q$, where c_i^q is a constant independent of the decision variables x_i^q , for all $q \in Q_i$. Define also the constants $d_i^q := I y_i^q$. This transformation to use the new decision variables leads to a new mathematical problem, which, in the terminology of Dantzig-Wolfe decomposition, is known as the *master problem*.

$$\begin{aligned}
& \text{minimize} && \sum_{q \in Q_1} c_1^q x_1^q + \cdots + \sum_{q \in Q_m} c_m^q x_m^q && (65.2) \\
& \text{subject to} && \sum_{q \in Q_1} d_1^q x_1^q + \cdots + \sum_{q \in Q_m} d_m^q x_m^q = b_0 = 1_{n \times 1} \\
& && \sum_{q \in Q_1} x_1^q = 1 \\
& && \vdots \\
& && \sum_{q \in Q_m} x_m^q = 1 \\
& && x_i^q \geq 0 \quad \forall q \in Q_i, \quad i = 1, \dots, m.
\end{aligned}$$

After introducing some new notation, this mathematical program can be stated in more compact form as follows:

Master Problem:

$$\begin{aligned}
& \text{minimize} && c'_1 x_1 + \cdots + c'_m x_m && (65.3) \\
& \text{subject to} && D_1 x_1 + \cdots + D_m x_m = b_0 \\
& && f'_1 x_1 = 1 \\
& && \vdots \\
& && f'_m x_m = 1 \\
& && x_i^q \geq 0 \quad \forall q \in Q_i, \quad i = 1, \dots, m,
\end{aligned}$$

where $f_i = [1 \cdots 1]'$ has suitable length, and $D_i = [d_i^1 \mid d_i^2 \mid \cdots \mid d_i^q \mid \cdots]$, $q \in Q_i$.

Usually, the number of variables in the master problem is much larger than the number of constraints. In such circumstances, one can consider solving the master problem by keeping only a small fraction of the variables that are collectively adequate for forming the basis for a simplex formulation. This problem with a small number of variables is called the *restricted master problem* (RMP), defined as follows:

Restricted Master Problem:

$$\begin{aligned}
& \text{minimize} && \sum_{q \in \bar{Q}_1} c_1^q x_1^q + \cdots + \sum_{q \in \bar{Q}_m} c_m^q x_m^q && (65.4) \\
& \text{subject to} && \sum_{q \in \bar{Q}_1} d_1^q x_1^q + \cdots + \sum_{q \in \bar{Q}_m} d_m^q x_m^q = b_0 \\
& && \sum_{q \in \bar{Q}_1} x_1^q = 1 \\
& && \vdots \\
& && \sum_{q \in \bar{Q}_m} x_m^q = 1 \\
& && x_i^q \geq 0 \quad \forall q \in Q_i, \quad i = 1, \dots, m,
\end{aligned}$$

where the index set \bar{Q}_i is a subset of Q_i .

Let π_j denote the dual variables associated with the n coupling constraints and μ_i denote the dual variables of associated with the convexity constraints. Thus, define a dual variable, π_j , associated with each target and a dual variable, μ_i , associated with each vehicle. And define

$$B := \begin{bmatrix} \bar{D}_1 & \bar{D}_2 & \cdots & \bar{D}_m \\ [1 \cdots 1] & [0 \cdots 0] & \cdots & [0 \cdots 0] \\ [0 \cdots 0] & [1 \cdots 1] & \cdots & [0 \cdots 0] \\ \vdots & \vdots & \ddots & \vdots \\ [0 \cdots 0] & [0 \cdots 0] & \cdots & [1 \cdots 1] \end{bmatrix}.$$

Then, for the restricted master problem, the primal and the dual solutions are given as

$$x_B = B^{-1} b$$

$$[\pi \mu]' = [\bar{c}'_1 \cdots \bar{c}'_m]' B^{-1}.$$

Moreover, the dual formulation of the problem can be defined uniquely as

Dual of the Restricted Master Problem:

$$\begin{aligned} & \text{minimize} && \sum_j \pi_j + \sum_i \mu_i \\ & \text{subject to} && (d_1^q)' \pi + \mu_1 \leq c_1^q, \quad q \in \bar{Q}_1 \\ & && \vdots \\ & && (d_m^q)' \pi + \mu_1 \leq c_m^q, \quad q \in \bar{Q}_m. \end{aligned}$$

To solve the dual of the RMP, consider finding new columns to enter the basis in the simplex method. The *reduced cost* for each column is calculated as follows:

$$c_i^q - [\pi \mu] \begin{bmatrix} d_1^q \\ 0 \\ \vdots \\ 0 \\ 1_i \\ 0 \\ \vdots \\ 0 \end{bmatrix} = c_i^q - \pi d_1^q - \mu_i.$$

When the pivoting rule is such that the column with the least (negative) reduced cost is added to the basis, the problem of finding a column to enter the basis can be posed as an optimization problem:

$$\min_{q \in Q_i} c_i^q - \pi d_i^q - \mu_i.$$

This optimization problem is also called the *subproblem* (SP). Alternatively, using our original notation, the SP can be stated as follows:

$$\min_{y_i} c_i(y_i) - \pi y_i - \mu_i.$$

Now, consider solving the dual of the RMP to determine the optimal task assignment as posed in Problem A. Proceed using a revised simplex method, choosing the columns that forms the basis by solving the SPs, for each i , as described above. Keep in the restricted master problem only those columns that are chosen for the basis using the SPs. This technique roughly described above is usually called *column generation* (see, e.g., Bertsimas and Tsiklis 1997; Desrosiers and Lubbecke 2005; Vanderback 2005; and Desaulniers et al. 2005).

Note that each SP is a binary integer program, a class of problems that is known to be NP hard, hence considered unlikely to admit efficient algorithms. Yet, the special structures of the SPs allow them to be interpreted as a simple search problem, which leads to a polynomial-time (in fact, a linear-time) algorithm that solves the SPs. In contrast, binary integer programs are usually solved using branch-and-bound methods, which require an exponential running time in the worst case.

Thus far, the column generation technique is described in a rather general setting. The next section focusses on a particular task assignment problem instance and describes a distributed implementation in detail. At this point, let us stress that, in that particular setting, the SPs provide an elegant way to update the flight plan: linear updates maintain the “values” of the waypoints formed in a virtual market created by the UAVs. In fact, the dual variable for a waypoint represents its market value. This market interpretation is discussed later in the text.

65.3 Algorithmic Implementation for the Shortest Fleet-Path Problem

To simplify the presentation, let us concentrate on a particular problem where the objective is to minimize the total path length traveled by all UAVs. Let us examine this problem in two phases.

Phase I: Initialization Prior to the initialization of the algorithm, all UAVs communicate their states, i.e., their position and the location of all the targets. Thus, the state of the world and that of the UAVs is known to all UAVs. In the initialization of the phase, each UAV:

- Calculates the distances between the waypoints, which is encoded in an $n \times n$ matrix denoted by V such that V_{ij} is the distance between waypoints i and j .

In the sequel, it is assumed that the necessary conditions are satisfied so that the matrix V becomes symmetric and all its diagonal elements are zero.

- Computes the distance from every UAV to every point, encoded in an $n \times m$ matrix r such that r_{ij} is the distance from the i th UAV to the j th waypoint. With a slight abuse of notation, denote by r_i the $n \times 1$ vector distances from the i th UAV to all the waypoints.
- Forms its flight plan matrix, denoted by D_i , which encodes all possible combination of way-points that it can travel.
- Finds the cost for each waypoint combination in D_i . This can be done, for instance, by computing the shortest path through all waypoints visited in each waypoint combination, using V_i and r_i . The cost of this path is stored in a matrix denoted by c_i for the i th vehicle.
- Creates the restricted master problem matrix B that contains the columns forming the initial basis. For particular choices of m and n , one can always find such a matrix, which can be stored in memory to simplify computations. See, for example, Bertsimas and Tsiklis (1997) for details.
- Communicates the associated flight cost \bar{c}_i for all columns in B to the other UAVs in the fleet.

Note that this initialization scheme is applicable in a class of problems much larger than that described above. In particular, the cost function need not be the shortest path, but may also involve sophisticated measures of fuel consumption, efficiency, risk, as well as mission completion time. In addition, efficient approximation algorithms with rigorous bounds on optimality can often be employed when computing such quantities.

Phase II: Dual Simplex Ascent The second phase of the algorithm is a distributed implementation of the dual simplex ascent over the extreme points. In each iteration, each UAV selects a cost-minimizing waypoint combination for itself via solving its SP. The column corresponding to this waypoint combination is, then, inserted into the master problem to find out whether this column is better for the whole fleet, in terms of cost, when compared to its previous alternative.

Each UAV is engaged in solving its own SP. These calculations are executed simultaneously on every UAV. The results are synchronized afterwards at the end of each iteration. The synchronization ensures that each UAV updates the solution to the master problem identically. Since each UAV executes exactly the same (deterministic) calculations, there is no need to exchange the results for the solution of the master problem. By design, the master problem contains only a few constraints; hence, its solution is obtained relatively fast. More precisely, it amounts to inverting and multiplying matrices with dimensions $(n + m) \times (n + m)$ only a constant number of times.

The procedure described in this section is summarized in Algorithm 1, where both phases of the algorithm are presented in detail. At this point, let us emphasize that the communication requirement for the synchronization step is small for many practical applications. In fact, each UAV must communicate a waypoint combination it would like to visit along with the cost of the selected waypoint combination.

Algorithm 1: Distributed synchronized implementation for i th UAV

```

// PHASE I: Initialization
1 Compute the distances between the way-points to form the  $n \times n$  matrix  $V$ ;
2 Compute the distance to the way-points to form the  $n \times 1$  vector  $r_i$ ;
3 for each way-point combination that the  $i$ th UAV can execute do
4   Compute the column encoding the way-point combination and add to the path matrix
      $D_i$ ;
5   Compute the cost of this path and add to the cost vector  $c_i$ 
6 end
7 Read the initial  $B$  matrix from the memory;
8 Communicate the cost of the corresponding paths in the  $B$  matrix to start the master
   iteration;
// PHASE II: Dual Simplex Ascent
9 repeat
10  Compute the solution to the restricted master iteration and find the dual variables
     vector:  $[\pi \ \mu]' \leftarrow [\tilde{c}'_1 \ \dots \ \tilde{c}'_m]' B^{-1}$ ;
11  Remove the ineffective way-point combinations, if any, with maximum cost;
12  Compute a solution to the SP corresponding to the  $i$ th UAV by updating flight costs:
      $c_i^q \leftarrow c_i^q - \pi d_1^q - \mu_i$ ;
13  Communicate the new way-point combination and its cost. Insert the minimum-cost
     feasible way-point combination to the restricted master problem.
14 until There is no path with negative sub-problem cost;

```

Arguably, this data can be communicated fast and reliably on most modern wireless communication hardware, including even those with stringent power and computation constraints.

The approach presented above is furnished with many other properties suitable for the application at hand. Firstly, solving the SPs require much smaller amount of memory than that required by integer programming techniques, such as the branch-and-bound algorithm tailored to solve the original optimization problem. This property allows implementation on platforms with limited computational capabilities. Secondly, the solution to the master problem is often a feasible solution which can be implemented immediately. Thus, the algorithm provides a feasible solution right after the initialization phase is completed, and it improves this solution if provided more computation time. This anytime flavor of the algorithm makes the algorithm suitable for real-time implementations. Admittedly, the solution to the master problem is not necessarily an integer solution at all times. Yet, any non-integer solution can easily be rounded, for example, with the help of effective randomization (see, e.g., Raghavan and Thompson 1987). Although this may lead to a suboptimal solution, rigorous bounds on optimality can be obtained in some cases (Bertsimas et al. 1999).

In Figs. 65.2 and 65.3, the algorithm is illustrated on an example scenario involving nine targets. As seen in Fig. 65.2, the aggregate cost of the targets serviced by each UAV varies across iterations, as the UAVs decide on which targets to service in a virtual market. Notice, however, that the total cost is a nonincreasing function of the number of iterations; in fact, the total cost is substantially reduced after

Fig. 65.2 Aggregate cost of visiting all targets (*cyan*) and the costs barred by each UAV across iterations of the algorithm

Fig. 65.3 Final waypoint assignment for three UAVs

50 iterations when compared to the first feasible solution. Figure 65.3 shows the final waypoint assignments decide to implement.

The algorithm is also tested on scenarios involving several targets. The results of a Monte Carlo experiment involving over 600 scenarios are shown in Fig. 65.4. As seen from the figure, a scenario involving 250 targets can be solved across 5 UAVs within 50 s.

65.4 Computational Experiments

This section is devoted a thorough computational study where the algorithm described in the previous section is evaluated in terms of its amenability to real-time implementations, using a realistic multi-vehicle simulation system, which is

Fig. 65.4 Computation time per UAV versus the number of targets per UAV obtained from Monte Carlo computational experiments. This plot shows how the computational effort (per UAV) scales with respect to the number of targets (per UAV)

illustrated in Fig. 65.5. The simulation system, described in detail in Cetinkaya et al. (2007), simulates the dynamics governing each vehicle and its control systems separately, using one xPC Target platform for each UAV (Mathworks 2012a). The xPC Target platform can run, in real time, a simulation of the dynamics and the control systems developed using Matlab/Simulink (Mathworks 2012b). The task assignment algorithm is run in a distributed manner, as described in the previous section, on individual computers, which are called the mission coordination computers. The xPC Target simulation platforms, the mission coordination computers, as well as a computer running the world model are connected through a fast TCP/IP network. This network is devoted solely to physics-specific communication. Sending messages between mission coordination computers through this network is not allowed. Rather, the mission coordination computers are connected to one another through a wireless network that simulates the inter-vehicle communication process. The simulator system is particularly designed for evaluating the performance of real-time task assignment algorithms.

To be evaluated on this platform, consider the following real-time implementation of the distributed algorithm described in the previous section. Given the large set of targets obtained from the world model, the UAVs agree on a subset of the targets to execute the algorithmic procedure. Let us choose this subset to be the closest set of k target for some fixed k , which can be chosen depending on the computational resources available to the fleet. Each time one of the targets is serviced, the assignment algorithm is restarted by adding a new target to the input. In this manner, the number of targets in the optimization problem is fixed to k , even

Fig. 65.5 The architecture of the simulation system

if the outstanding number of targets may be very large and may change dynamically, for example, when the operators issue more targets to be serviced.

In Figs. 65.6 and 65.7, the evolution of the mission is shown for 200 and 500 targets, respectively. The computational requirements for this restricted-horizon planning is shown in Fig. 65.8, where a polynomial-time growth is observed.

Fig. 65.8 The numeric computational complexity analysis suggests polynomial-time growth for restricted time horizons

65.5 Conclusion

A distributed task allocation algorithm is designed and implemented for real-time operation in this work. The performance of the distributed algorithm is seen to be well better than the central one. This is attributed to two main reasons, namely, the distributed nature of the algorithm and the polynomial-time subproblem structure. The former reason was expected since the algorithm contains very small communication messages to be exchanged between the decision-making agents and the distribution uses more than one processing units. The latter reason is a good advantage of the decomposition algorithm used; an NP-hard subproblem structure is seen to be polynomial-time solvable for restricted horizons after decomposition.

A test-bed for real-time distributed task allocation algorithms was also presented. This simulator is a general purpose simulator for testing UAV-dependent algorithms. The tests performed on an in-house built network mission simulator provide numerical verification of the algorithm on (a) bounded polynomial-time computational complexity and (b) hard real-time performance for problem sizes on the order of 100 waypoints per UAV.

Abstract

The communication network is a fundamental component of a multi-UAV system. It enables exchanges in command and control messages and allows remotely sensed mission data to be sent to processing centers. Proper control of the network, the topic of this chapter, is critical for the system to function

properly. Following a brief overview, Sect. 66.2 lists some of the main challenges in network communication control. Next, Sect. 66.3 provides background discussion in wireless networking including system architecture, wireless channel performance, topology models, and information routing. Bounds and limitations in cooperative control and decision making because of network limitations are provided in Sect. 66.4. Next, the chapter provides several network control strategies for multi-UAV systems. First, Sect. 66.5 presents motion planning methods to control the topology, and second, Sect. 66.6 describes relay deployment techniques to extend the performance of the network. Finally, Sect. 66.7 provides some closing remarks and directs the reader to further literature on this topic.

66.1 Overview

Network and communication systems such as the Internet, social media, cellphones, and countless other wireless systems have revolutionized human way of life. These same technologies enable teams of multiple human and unmanned agents to share situational awareness and planning strategies to cooperate and improve their performance in executing a set of mission tasks. As such, the communication network is a fundamental component of a multiple unmanned aerial vehicle (UAV) system. Controlling it is often just as important as controlling the vehicles because inadequate communications can significantly degrade team performance. Even though ad hoc networks have been actively studied in the past decades for military (Leiner et al. 1996), home (Negus et al. 2000), and metropolitan (Ritter et al. 2001) network applications, they have only recently started to generate significant interest for cooperative control of multiple robotic air, ground, and sea vehicles.

There are several general architectures to deploy multiple UAVs as a team. UAVs may be connected only to a central node, such as a human-operated control station, which receives information, computes a plan of action, and sends instructions specific to each vehicle (centralized control). Alternately, UAVs may be connected directly to each other, exchange information, and each formulate their own plan without a designated leader (decentralized control) (Stipanović et al. 2004; Choi et al. 2009). Hybrid centralized and decentralized solutions also exist, and UAVs may also cooperate with other manned and unmanned space, air, ground, and sea agents over the network in a joint effort (Chandler et al. 2001; Chandler and Pachter 2001; Marshall et al. 2011) as illustrated in Fig. 66.1. In all cases, team coordination requires agents to exchange their state information, observations of the world, and control decisions such as task allocation or motion planning. Furthermore, if the UAVs are being used to gather information, as is often the case, the collected data may need to be communicated to a designated point for analysis, possibly in real time (Office of the Secretary of Defense 2009).

Because UAVs are highly mobile vehicles, information is most commonly exchanged across the network using wireless communication. Signals containing encoded messages travel between transmitting and receiving radio modules over wireless channels. The quality of the channel is fundamentally based on the strength

Fig. 66.1 A networked multi-UAV team performing a cooperative search mission. UAVs are seen cooperating with ground vehicles, and a communication relay UAV connects the team to the base as well as to other manned aircraft involved in the mission

of the signal at the receiver compared to noise and interference in the environment, a value named the signal to interference and noise ratio (SINR) (Goldsmith 2005). The quality of the link drives the probability that information transmitted will successfully be received, and affects the rate at which information can be exchanged over that channel.

One typical objective in controlling a multi-UAV team is to ensure that the system remains in a state where the communication network can support cooperative planning (or coordination) and data collection requirements. The network itself can be controlled through its topology, which describes the set of interconnections between nodes and how strong those connections are. There are several general methods to control the topology in a team of mobile agents:

1. Wireless channels generally degrade with increasing distance and due to obstacles in the line of sight. Cooperative motion planning can position the vehicles in locations which improve data transfers (Goldsmith 2005).
2. The received signal can be improved by increasing transmission power (Santi 2005), changing the orientation or directing the transmitter (Ahmed et al. 2011), or choosing the proper time and location to transmit (Yan and Mostofi 2010).
3. The topology can be controlled by actively choosing which links should be active and which exchanges are better suited for multiple hop node-to-node transfers (Zavlanos and Pappas 2008).
4. Additional mobile agents can be deployed as communication relays to extend the performance of the underlying network (Zhu et al. 2009).

These control methods can be employed individually or in tandem to achieve the performance required in the communication network. The design trade must

properly consider the benefits, costs, and implications in computation, communication, and vehicle resources associated with each of these methods.

The concept of multi-UAV teams is still fairly new operationally. As such, the methods to control communication in these systems are actively evolving through research studies (discussed in this chapter) and lessons learned from other types of networks. Aerial networking itself has been employed for years in commercial and military aircraft operations (Mulkerin and Zernic 2003). Modern generation strike aircraft and aerial intelligence platforms commonly share mission parameters among themselves via Tactical Data Links for real-time cooperation. These systems however are limited in range, throughput, and interoperability and exhibit delays. Because information sharing has become so crucial in warfare, large-scale UAVs are being deployed as persistent communication relays to better connect aircraft and ground nodes (Jonson et al. 2008). Similar concepts are under active investigation to rapidly provide communications for large-scale disaster recovery scenarios similar to Hurricane Katrina (Federal Communications Commission 2011) or first response in challenging environments such as wild land fire fighting (Zajkowski et al. 2006). It is paramount to understand how best to employ these systems to maximize their network support. Many other multi-unmanned vehicle concepts are being considered for military (U.S. Air Force Chief Scientist AF/ST 2010), exploration (Anderson et al. 2003), and surveying (Leonard et al. 2010) applications which will also implicitly require control of communications to operate.

The purpose of this chapter is to provide an overview of the different elements of network communication control for teams of UAVs. It describes the challenges involved in controlling communications in such multi-agent systems and provides technical fundamentals in wireless communications theory as support. The chapter analyzes recent literature studies about the effects of limited interagent communications on the performance of team cooperation. Furthermore, it reviews recently developed techniques to control network communications in a team using motion control, communication relays, and cooperative task allocation strategies. The objective is to familiarize the reader with this relatively new and rapidly evolving topic.

66.2 Design Challenges

There are numerous and often competing challenges in controlling network communications in a multi-UAV system. The design must properly balance between ensuring that the communication requirements are met without over-constraining the system design and operation. Furthermore, even if designed and controlled properly, network communications still exhibit limitations and uncertainties in performance which impact the system.

The control of network communications follows the same feedback control principles used for many other types of systems. The state, or topology of the network, is sensed and used as feedback, with a model of its dynamics, to predict the outcome of control inputs. Modeling and accurately predicting the performance of

wireless channels is a significant challenge in this process. In general, links degrade with increasing internode distance due to path loss. Signal shadowing occurs due to obstacles in the environment such as buildings, mountains, or even the platform vehicle itself. Furthermore, multipath replicas of the signal reflecting and scattering off these obstacles constructively or destructively interfere with each other at the receiver (see Fig. 66.3). Path loss, shadowing, and multipath fading effects are increasingly detrimental and difficult to predict in more congested operating environments (Santi 2005; Goldsmith 2005; Mostofi et al. 2009). Modeling techniques for these dynamics are provided in Sect. 66.3. Fortunately, large- and medium-scale UAVs often operate in open skies, which mitigates many of these detrimental effects. However, actively studied concepts of mini/micro-UAV teams deployed below the tree line, inside buildings, or in urban settings will be significantly affected by these dynamics (Warwick 2009). Similarly, noise and interference from other emitting sources in the environment can be difficult to predict and can change both in time and by location Wagle and Frew (2011). In some cases, another source may actively seek to interfere or “jam” communications to degrade the system performance as a countermeasure (U.S. Air Force Chief Scientist AF/ST 2010). For similar reasons, measurements of the signal strength, while accurate, may also fluctuate significantly at time scales of only tens or hundredths of a second. The uncertainties in the model and the rapid variation in the measurements pose a significant challenge in the network feedback control loop and lead to limited performance guarantees of the system (Goldsmith 2005).

Given the ability to control the network topology, the problem of efficiently routing information between nodes is a challenge in itself (Goldsmith 2005). Different types of data have different communication requirements, but in general the typical objective is to route data to its destination with minimal delay, over links with sufficient data rate capacity and with minimal number of packets dropped due to error. A wireless network typically operates on one or more communication channels in a specific range of the electromagnetic spectrum. As such, nodes transmitting on the same or neighboring channels interfere with each other, which generates a design trade (Xue and Kumar 2004) best illustrated through a simple example. Assume that a UAV needs to transmit time sensitive data to a distant base. One option is to increase its transmitter power enough to send the data directly to the base, as UAV2 does in Fig. 66.2a. However, this higher transmit power now interferes more with other UAVs also trying to communicate. Furthermore, the long link may be strong enough to reach the base under nominal conditions, but may not be robust to channel fading. Another option then is for the UAV to transmit over a more robust link and at a lower power to another less distant UAV (as UAV2 now does in Fig. 66.2b), which can then relay the message, possibly through additional hops, to the base. This reduces interference from that UAV, but may cause delays in end-to-end delivery of the data, and cost overhead in the network to establish the multi-hop route. The challenge of selecting the best route and power settings is further exacerbated as the number of agents increases, as wireless link qualities continuously fluctuate under fading, and because the network topology is dynamic as agents move around to execute the mission (Goldsmith 2005). This is especially

Fig. 66.2 Network architectures. In (a) all UAVs communicate only with the base, and UAV4 is out of range and disconnected. In (b) connections can be shorter, and UAVs interconnect and can route data via multi-hop

relevant for multi-UAV systems, which can involve vehicles traveling rapidly over large distances.

Multi-agent networks for all types of systems face the communication control challenges described above. The degree to which these challenges affect the system changes based on the domain of operation. For instance, unmanned ground vehicles (UGVs) typically operate in environments with obstacles to line of sight, resulting in channel fading, but they have the ability to stop when a suitable location to transmit is encountered (Zhang and Quilling 2011). Autonomous underwater vehicles (AUVs) have limited underwater communication capabilities and may only be able to exchange coordinated control information once every few hours upon surfacing (Leonard et al. 2010). Unattended ground sensors (UGS) forming a fixed wireless sensor network (WSN) may be less susceptible to dynamic changes in topology but need to be power conscious when transmitting since their battery lifetime is limited (Ibrahim et al. 2009). There are a number of challenges especially relevant for UAVs. First, the size, weight, and power (SWaP) of the UAV radio device can be limited by design constraints of the vehicle and compete with requirements imposed by other onboard systems. Next, unless a vertical flight aircraft is used, the antenna position and orientation, which affects channel quality (Ahmed et al. 2011), is subject to vehicle dynamics. To mitigate this problem, some designs have included multiple receivers on the vehicle meeting SWaP constraints (Kung et al. 2010; Yanmaz et al. 2011). Similarly, a fixed wing vehicle is unable to hold a fixed position considered to be “optimal” for communications. Also interestingly, some lightweight materials commonly used for UAVs, such as carbon fiber, have conductive properties which shield radio signals and can cause loss of link (Krueger 2002). Finally, SWaP constraints in micro-UAVs may limit onboard

computing capability and therefore limit the complexity of the algorithm used for motion control, relay positioning, or task assignment.

Even with proper system design and implementation, the communication network will still have limitations that can significantly degrade the performance of the multi-UAV system. Algorithms to control vehicle motion, transmission power, information routing, and task allocation must rapidly converge to a good solution and require minimal message exchanges to mitigate delays. Command delays, however short, may cause a formation of UAVs to perform inefficiently or *churn* (effectively go unstable), which can have disastrous effects such as vehicle collisions (Schwager et al. 2011). Delayed and dropped messages sent to planning agents, whether centralized or decentralized, can cause inconsistencies in situational awareness and, as a result, flawed planning (Ponda et al. 2010). Similarly, message delays in decentralized planning may prevent agents from reaching consensus on a plan (Johnson et al. 2011). These limitations, therefore, have implications on the system architecture, choice of algorithms, and performance guarantees for multi-UAV systems.

66.3 Communications and Networking

This section provides the technical background in wireless communications and networking that will be utilized by many of the multi-agent network control methods in this chapter.

66.3.1 System and Network Architectures

The design and control of the communication network depends on the system architecture and data transfer requirements. For instance, traditional cellular phone networks form a hub-and-spoke model between a fixed base station and mobile users in its area. Telephone voice data requires minimal delay to be effective, but does not need high data rates and has some error tolerance. Conversely, data networks for Internet downloads require high and bursty (sporadic) data rates and dynamic bandwidth allocation between a gateway, routers, and end users. These networks can tolerate some delays but should be relatively error-free (Modiano 2012).

A multi-UAV system network typically needs to support two types of data. The first type consists of command and control messages including state information (telemetry), observations of the world (e.g., estimated target location), and control data (e.g., waypoints or task allocation). These messages have low bandwidth requirements but must be exchanged with minimal delay and error for effective team coordination. Second, information gathered from sensors such as video, still images, atmospheric samples, and other types of remote sensing data may also need to be transmitted to designated processing, exploitation, and dissemination (PED) centers (Christmann and Johnson 2007). Again, communication requirements depend on

the data type, but live video, for instance, requires minimal delay and high data rates and has some fault tolerance (Modiano 2012).

A multi-UAV system architecture built on centralized control, where vehicles remain within transmission range of the command and control node, can operate using a hub-and-spoke network model, similar to a cellular system (Fig. 66.2a). Some implementations can even extend command and control range by using a low data rate satellite communication system (Marshall et al. 2011). However, many of the applications envisioned for multi-UAV teams require greater topology flexibility, with internode information exchanges and relaying (Fig. 66.2b). This second architecture (Fig. 66.2b) closely follows concepts of ad hoc networks, which have received significant interest in many disciplines (Santi 2005), and applies to most of the systems studied in this chapter.

Network architectures are generally abstracted to a multilayer design, where each layer is individually responsible for a different role in communicating information. Modern ad hoc networks typically consist of (1) a *physical layer* responsible for sending bits across a wireless channel, (2) an *access layer* to deconflict channel usage from multiple users, (3) a *network layer* to route information from node to node, (4) a *transport layer* to regulate flow and retransmissions, and (5) the *application layer* which uses and creates data (Modiano 2012). While understanding these layers is important in network design, many of the applications discussed in this chapter, along with latest research in ad hoc networks, push for cross layer design optimization (Goldsmith 2005; Xiao et al. 2004; Kaabi and Filali 2010; Hiertz et al. 2010). As such, further discussion of these layers is limited in this chapter, and the reader is referred to Bertsekas and Gallager (1992) and Kawadia and Kumar (2005) for more details.

66.3.2 Wireless Channels

In wireless networks, data is exchanged over communication channels by sending information encoded and modulated from a transmitter, over the air using a signal, to a receiver which demodulates and decodes to process the data. The strength of the received signal power compared to surrounding noise, or signal-to-noise ratio (SNR), γ , is a critical parameter in assessing the quality of the link. This value is commonly modeled with the simplified relationship:

$$\text{SNR: } \gamma = \frac{gP}{N_o W} \quad (66.1)$$

$$g = K \left(\frac{d_o}{d} \right)^\alpha \quad (66.2)$$

where P is the transmission power, $\frac{N_o}{2}$ is the power spectral density of the environment noise, and W is the bandwidth of the signal. The channel gain g is generally modeled as Eq. (66.2) in its most simple form, in which K is a gain based

on equipment characteristics, d is the Euclidean distance between the transmitter and receiver, and α is the path loss exponent which equals 2 in free space and up to 6 in environments congested with obstacles (Goldsmith 2005). This relationship represents the path loss dynamics experienced in wireless channels, in which γ decreases with increasing distance.

The next effect to consider is shadowing of the signal due to obstacles in the line of sight. A practical way to model shadowing in uncertain environments is to vary γ according to a lognormal distribution with variance σ^2 which depends on the density of obstacles in the environment (Goldsmith 2005). A convenient method to express this is to convert the channel gain in Eq. (66.2) into decibels (g_{dB}), where shadowing now becomes a Gaussian-distributed random variable centered on the path loss gain:

$$g_{dB} = K_{dB} - 10\alpha \log \left(\frac{d}{d_o} \right) - \mathcal{N}(0, \sigma_{dB}^2) \quad (66.3)$$

The distribution has been shown to be spatially correlated to X_c , the typical size of obstacles in the area. The spatial covariance $A(x)$ in the distribution between two points separated by distance x can be expressed as

$$A(x) = \sigma_{dB}^2 e^{-x/X_c} \quad (66.4)$$

This expression can be used to predict the amount of time a moving vehicle may undergo deep shadowing fades, or determine how to reposition the vehicle to exit a shadowed area (Mostofi et al. 2009; Mostofi 2009).

Multipath fading, which occurs because of constructive and destructive interference from scatterings and reflections of the signal by the obstacles, can be modeled using a nonstationary random process centered on channel gain g subject to path loss and shadowing in Eq. (66.3). Models using Rayleigh, Rician, or Nakagami distributions with a tunable fading parameter have been shown to follow empirical measurements of this dynamic (Mostofi et al. 2009; Goldsmith 2005). Multipath fading values can be added to the g_{dB} expression in Eq. (66.3) and then used to predict the overall SNR using Eq. (66.1). This dynamic can vary significantly over small distances and is often modeled without spatial correlation for simplicity (Mostofi et al. 2009). The three dynamics can be seen using experimentally measured wireless channel signal strength measurements in Fig. 66.3 obtained from (Mostofi et al. 2009).

Many field experiments have studied the dynamics of link performance in greater detail. Research in Wagle and Frew (2011) used data collected from aerial links to measure an additional temporal correlation factor in the above dynamics. A study in Ahmed et al. (2011) observed that link qualities vary depending on the relative orientations between the transmitter and receiver, even when using omnidirectional radio modules. Multiple antenna configurations were similarly used in Kung et al. (2010) and Yanmaz et al. (2011) to improve the overall reception for the vehicle through diversity.

Fig. 66.3 Measured dynamics of a wireless channel. The *solid blue curve* represents the signal strength, which varies at a small scale due to multipath fading. Spatially correlated shadowing can be seen by averaging locally (*light gray curve*). The average of the large-scale variations then follows distance-dependent path loss (*dashed line*) (Figure and caption copyright Mostofi et al. (2009))

Relationships in Eqs. (66.1)–(66.4) model the dynamics of a single wireless channel. In a multi-user network, multiple agents simultaneously communicating on the same or neighboring channels interfere with each other. In this case, SNR is often rewritten as the signal to interference and noise ratio (SINR) represented by γ_{ij} for the channel from node i to j (Ribeiro 2011)

$$\text{SINR: } \gamma_{ij} = \frac{g_{ij} P_{ij}}{(N_o W)_j + \frac{1}{\rho} \sum_{(m,n) \neq (i,j)} g_{mj} P_{mn}} \quad (66.5)$$

Here, the interference caused by other nodes m transmitting to n adds to the noise at receiver j in the denominator. While some of these effects can be mitigated through signal code processing ($\frac{1}{\rho}$), a common method of deconfliction is to divide channel usage by time (TDMA) where $\rho = 1$ (Ribeiro 2011).

The SNR in Eq. (66.1) or SINR in Eq. (66.5) is a fundamental indicator of wireless link performance and can be used to predict operationally relevant data transmission metrics. First, the theoretical *capacity* of the channel can be evaluated using Shannon's equation:

$$c_{ij} = W_{ij} \log_2(1 + \gamma_{ij}) \quad (66.6)$$

which represents its data rate in *bits/sec*. While this value is an upper bound, and actual data transmissions are often set to significantly lower rates due to fading (Goldsmith 2005), it is a useful indicator in applications where information throughput must be considered. Another important performance metric is the *bit error rate* (BER) or the probability an information bit will be dropped, which can require packet retransmissions and inefficient data flow. BER decreases with increasing γ , and the relationship depends on the specific modulation scheme.

Equation (66.7) represents the relationship for a common modulation method, where Q is defined in Goldsmith (2005):

$$\text{BER}_{ij} = Q(\sqrt{2\gamma}) \quad (66.7)$$

Many of the communication network control methods discussed in this chapter have an objective to optimize or meet some threshold values for capacity, BER_{ij} , or even information delay which relates to c_{ij} (Xiao et al. 2004). The models listed in this section highlight the challenges associated with predicting and controlling wireless channel performance due to dynamic uncertainties in fading and coupling with other agents using the network.

66.3.3 Network Topology and Consensus

Another relevant challenge, especially in ad hoc networks, involves optimizing the network topology (i.e., determining which nodes need to form interconnections), to achieve the desired connectivity for information flow. The network topology can be represented as a graph $G = (V, E)$ with a set of n nodes $V = \{1, 2, \dots, n\}$ and edges $E \subseteq V \times V$ indicating connectivity between nodes. The graph can be represented using an *adjacency matrix*, A , with $n \times n$ elements a_{ij} , where $a_{ij} = 1$ if i can communicate with j and $a_{ij} = 0$ otherwise. Each row of the adjacency matrix can be read directly to identify the set of neighbors for every agent. In some formulations, $a_{ij} = w$, where $w \in [0, 1]$, depending on the quality of the link and topology properties. The *neighborhood* of agent i , $N_i = \{j \in V : a_{ij} \neq 0\}$, is defined as the set of agents that agent i can communicate with directly (Olfati-Saber et al. 2007). For instance in the network in Fig. 66.2b, the neighbors of UAV4 are $N_4 = \{2, 3, 5\}$. Theoretical formulations have established bounds on how many agents each node should be connected to for the network to become asymptotically disconnected or connected (Xue and Kumar 2004). For this reason, many multi-vehicle systems control the network so that each agent remains connected to a specific number of neighbors (Atay and Bayazit 2008; Zhu et al. 2009; Goddemeier et al. 2011; Razafindralambo and Simplot-Ryl 2011; Reich et al. 2008; Zavlanos et al. 2011). Many of these schemes are discussed in Sects. 66.5 and 66.6.

Analyzing the network topology provides useful insights on how information propagates throughout the network and how the team of agents reaches consensus on quantities of interest such as plans, parameters, and situational awareness. The stability and convergence properties of most consensus algorithms can be predicted by analyzing the spectral properties of the network graph *Laplacian*, \mathcal{L} , for a given network structure (Olfati-Saber et al. 2007). The Laplacian is another related matrix representation of the network topology and is formulated as

$$\mathcal{L} = D - A \quad (66.8)$$

using the adjacency matrix A and the *degree matrix*, $D = \text{diag}(d_1, \dots, d_n)$, with elements $d_i = \sum_{j \in N_i} a_{ij}$, representing the outgoing connections of each agent (sum over its neighbors). The maximum degree of the graph, $\Delta = \max_i d_i$, is useful in determining spectral properties of the network Laplacian. In particular, all of the eigenvalues of the Laplacian \mathcal{L} in the complex plane are bounded by a closed disk of radius Δ centered at $\Delta + 0j$. Assuming the graph is undirected, where $a_{ij} = a_{ji}$, the Laplacian \mathcal{L} is symmetric, and therefore its eigenvalues lie on the real line within the set $[0, 2\Delta]$. These can be ordered sequentially as

$$0 = \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n \leq 2\Delta. \quad (66.9)$$

The first (smallest) eigenvalue of \mathcal{L} is always zero ($\lambda_1 = 0$) since every row sum is $\sum_j l_{ij} = 0$, and is known as the trivial eigenvalue. The second eigenvalue, λ_2 , is known as the *algebraic connectivity* or *Fiedler value* of the graph and is always positive for *strongly connected* graphs where a single- or multi-hop path exists from any agent to every other agent. The algebraic connectivity λ_2 determines the speed of convergence for most consensus algorithms, and as such, many multi-vehicle applications attempt to maximize this value by controlling the network topology (Ibrahim et al. 2007, 2009; Yan and Mostofi 2010; Michael et al. 2009; Zavlanos et al. 2011) (see Sects. 66.5 and 66.6). The last eigenvalue, λ_n , is related to stability guarantees for reaching an equilibrium in time-delayed networks, providing associated bounds on the maximum allowable delays (Olfati-Saber et al. 2007). Further details on consensus algorithms are provided in Sect. 66.4.1.

It must be noted that graph theoretic methods are simplifications of multi-UAV network representations, since connectivity is often assumed to be binary and links are considered active if agents are within a threshold distance of each other (Santi 2005). These methods usually do not consider realistic wireless channel dynamics as described in the previous subsection or some of the complexities in information routing discussed next. Nevertheless, they do provide helpful mathematical interpretations of the potential performance of the network and are useful in guiding the system design to achieve configurations more suitable for information exchange (Michael et al. 2009).

66.3.4 Information Routing

Since envisioned multi-UAV team applications require similar flexibility to ad hoc wireless network architectures, network routing becomes a significant challenge that must be considered in controlling the system. Given the wireless channel properties and network topology, information must be routed along links with sufficient capacities, and arrive at its destination with minimum error (BER) and delay, as dictated by data requirements. Routing is an active area of research in the wireless networking community (Al-Karaki and Kamal 2004). If the network involves multiple channels on different frequencies, as is often the case, the problem extends to finding the optimal route and channel allocation (Kaabi and Filali 2010). Strategies range from decentralized, highly adaptable methods to more centralized

optimized schemes (Goldsmith 2005). Understanding how a particular network system routes information is necessary to adequately control communications in a team of UAVs, as it may affect where agents are positioned to provide a suitable topology.

Several industry standards (802.11s, 802.15, 802.16) drive the design and operation of mesh networking modules commonly used in ad hoc networks (Kaabi and Filali 2010; Hiertz et al. 2010). These standards rely on decentralized routing mechanisms. A commonly used protocol is Ad hoc On-Demand Distance Vector (AODV) (Perkins and Belding-Royer 1999). In AODV, a node which needs to transmit broadcasts a “request to send” message which identifies the destination node. Neighbors receive the message, compute a cost metric (discussed later), and rebroadcast the message. The process continues, where cost is computed at every hop, until the destination is reached. Each node stores its lowest cost originator. Once a designated amount of time has elapsed, the destination node sends a unicast response to its lowest cost originator, which similarly relays the response to backtrack the lowest cost route. Other similar routing techniques include Dynamic Source Routing (DSR) (Perkins and Belding-Royer 1996), Optimized Link State Routing (OLSR) (Adjih et al. 2004), and B.A.T.M.A.N (Garroppo et al. 2010). Different metrics are implemented depending on the objectives, which include lowest hop count, expected transmission count (ETX in Eq. (66.10), Salonidis et al. 2007; Decouto et al. 2005), and airtime metric (C_{Aij} in Eq. (66.11), Ribeiro 2008). Here, p_{pkt} is the packet loss ratio (based on BER), O is overhead, B_t is the test-frame length, and r is the data rate (based on capacity):

$$ETX_{ij} = \frac{1}{1 - p_{pkt}} \quad (66.10)$$

$$C_{Aij} = \left(O + \frac{B_t}{r} \right) \frac{1}{1 - p_{pkt}} \quad (66.11)$$

The protocols listed above are implemented in practice, such as on Zigbee modules common in robotics research (Bhatia and Kaushik 2008), because of their rapid response to changes in wireless channel performance and topology. A significant drawback to them, however, is that information from different nodes is routed mostly independently of other nodes and tends to use the same high-performance routes. This can lead to congestion in high data rate applications and unfairness in node usage (Salonidis et al. 2007). Researchers have proposed different network optimization schemes to address this, which invoke conservation of information flow at each node and link utilization constraints. For instance, authors in Toumpis and Gitzenis (2009) optimize routing fairness by considering interference between nodes and using electrical flow analysis. Similarly, convex optimization methods have optimized routing through simultaneous link scheduling and transmitter power allocation (Xiao et al. 2004; Cruz and Santhanam 2003). While these schemes produce better routing solutions, they mostly consider static networks and would require frequent recomputation in a dynamic environment to adapt to realistic changes in the topology (Goldsmith 2005).

66.4 Coordination Under Communication Constraints

For multi-UAV teams to cooperatively execute a set of objectives, the communication network must exchange command and control messages and, when necessary, remotely sensed data. The inability to communicate sensed data, such as live video, to the designated processing centers may render the multi-UAV system ineffective for its mission. Worse however, failure to properly exchange command and control messages can lead to dangerous system failures or unintended consequences. This is particularly true in decentralized systems, where these messages enable vehicle control and team decision making. Inadequate team control can lead to formation instability where one or multiple agents increasingly diverge from the desired behavior and risk colliding or separating from the team. Poor decision making may prevent the team from reaching consensus on a plan and remain idle without accomplishing anything or, sometimes worse, take action on an undesirable plan leading to unwanted consequences. Despite taking appropriate measures to control the communication network, transmission delays and dropouts are virtually unavoidable and may occur unexpectedly. This naturally limits the rate of information agents have available to make control decisions or formulate a team plan. Graph theoretic properties introduced in Sect. 66.3, such as the graph Laplacian \mathcal{L} and its set of eigenvalues λ_i , can provide insight into network bounds on formation stability or team consensus (Olfati-Saber et al. 2007). This section focuses on identifying these limitations, and the following two sections describe network control strategies to improve team performance and network connectivity.

66.4.1 Information Consensus

A critical component of team coordination strategies involves performing consensus, which is defined as reaching an agreement on quantities of interest that depend upon the states of all agents (Olfati-Saber et al. 2007). Most distributed planning and control approaches employ *consensus algorithms* to reach agreement on plans, situational awareness, or other desired parameters. A consensus algorithm is a set of rules, or protocol, that determines how the information is exchanged between agents to ensure that the team will convergence to an equilibrium on the parameters of interest. For example, a simple algorithm to perform consensus on a continuous parameter z can be expressed as an n th order linear system where each agent executes the following protocol:

$$\begin{aligned}\dot{x}_i(t) &= \sum_{j \in N_i} (x_j(t) - x_i(t)) \quad \forall i \\ x_i(0) &= z_i \in \mathbb{R}\end{aligned}\tag{66.12}$$

Collectively the team dynamics can be written as the linear system

$$\dot{\mathbf{x}}(t) = -\mathcal{L}\mathbf{x}(t)\tag{66.13}$$

where \mathcal{L} is the graph Laplacian as described in Sect. 66.3.3. Since Eq. (66.13) is a linear system, the spectral properties of \mathcal{L} determine the stability and convergence rate of the consensus algorithm. In particular, as mentioned in Sect. 66.3.3, for any strongly connected graph, all of the nontrivial eigenvalues of \mathcal{L} are positive, and thus the consensus algorithm is globally asymptotically stable. Furthermore, the algorithm has an exponential convergence rate determined by the algebraic connectivity λ_2 and is guaranteed to achieve a unique equilibrium $\bar{z} = 1/n \sum_i z_i$, which is the average of all the agents' initial values (Almost identical guarantees can be made for discrete representations of Eq. (66.13) as well.) (Olfati-Saber et al. 2007). Note that, in general, these convergence and stability properties are dependent upon \mathcal{L} and λ_2 , which are defined by the network structure, and not on the particular consensus algorithm used.

In realistic environments, there are several effects that complicate the transmission of messages between agents and thus impact the performance of consensus algorithms. Some examples include time delays for transmitted messages and varying network topologies where links between agents are subject to change over time. Recent research has focused on analyzing consensus convergence and stability properties in the presence of time delays and dynamic networks. It turns out that the global exponential stability guarantees can be extended to dynamic networks. As long as the graph $G(t)$ is strongly connected for all time t , the agents will asymptotically reach an average consensus with convergence rate greater than or equal to $\lambda_2^* = \min_t \lambda_2(G(t))$, where $\lambda_2(G(t))$ represents the algebraic connectivity value associated with the Laplacian for graph $G(t)$. Likewise, in time-delayed networks, where messages are received after a delay τ instead of instantaneously, the dynamics become

$$\dot{\mathbf{x}}(t) = -\mathcal{L}\mathbf{x}(t - \tau) \quad (66.14)$$

and global exponential stability to the average-consensus equilibrium can be guaranteed for delays within the range $\tau < \pi/2\lambda_n$. Note that here the last eigenvalue of the Laplacian, λ_n , provides bounds on the maximum allowable delay τ , and thus networks with lower λ_n are more robust to time delays. Recall from Sect. 66.3.3 that $\lambda_n < 2\Delta$, favoring network topologies with lower maximum degree Δ , such as random graphs and ad hoc networks (Fig. 66.2b), instead of networks with large hubs (Fig. 66.2a) (Olfati-Saber et al. 2007).

The remainder of this section describes how control and decision-making algorithms employ consensus to achieve common goals for teams of UAVs and the associated challenges and limitations. In particular, the stability and convergence properties described by the network Laplacian affect the performance of these planning and control algorithms as well, in very similar ways to the effects on consensus discussed here. As such, many multi-vehicle approaches explore strategies to directly control the network topology in order to increase mission performance (Ibrahim et al. 2007, 2009; Yan and Mostofi 2010; Michael et al. 2009; Zavlanos et al. 2011; Ponda et al. 2011). Sections 66.5 and 66.6 describe some of these methods and associated challenges in further detail.

66.4.2 Effects on Cooperative Control

The feedback control process uses sensed feedback information with a model of the system dynamics to select a control input. If feedback information is delayed or corrupted due to communication degradations, control decisions may be flawed. For instance, in military MQ-1 Predator procedures, a pilot remotely controls the UAV manually using live forward-looking video on the nose of the aircraft as reference. Delays in video feedback and control commands from link latencies have resulted in pilot-induced oscillations (PIO), an instability from poor feedback control which has resulted in numerous aircraft mishaps (Defense Research and Development Canada 2010). The same phenomenon can occur in autonomously controlled cooperative teams of UAVs.

In general, network controlled systems (NCS) require a proper balance of control and feedback update rates: too slow can prevent the system from being controlled sufficiently well, but too fast can overload the communication network (Branicky et al. 2000) or excite system dynamics resulting in instabilities (Schwager et al. 2011). The stability of the system also depends on control implementation and feedback filtering techniques, as described in detail in Fax and Murray (2004). For networked multi-agent systems, it is helpful to define the control graph G^{ctrl} , similar but separate from the communication graph G^{comm} introduced in Sect. 66.3 as G (Schwager et al. 2011). G^{ctrl} is a directed graph that defines control dependencies (Fig. 66.4). In “leader-follower” formations, each vehicle selects control inputs based on the dynamics of the vehicle(s) directly preceding it (Fig. 66.4a). Tracking errors can propagate down the formation and under certain conditions exceed control authority, leading to instability, even with no delay in information sharing (Al-Karaki and Kamal 2004). In “string” formations studied in the context of an Automated Highway System, each vehicle communicates with the vehicle directly ahead and must follow it by a prescribed safe distance (Liu et al. 2001). Agents are slotted to communicate at separate times, which propagates

Fig. 66.4 Control and communication graphs. (a) represents a “leader-follower” formation free of network delays as discussed in Al-Karaki and Kamal (2004). (b) is the configuration of the Automated Highway System in Liu et al. (2001). (c) illustrates the graph in the three UAV formation flight test in Michael et al. (2010) (Figure (c) copyright Michael et al. (2010))

an information delay down the chain. Each vehicle bases its control inputs on the dynamics of the vehicle ahead and of it and on the lead vehicle dynamics (Fig. 66.4b). In this structure, even infinitely small communication delays cause string instabilities if agents compensate for error immediately. The formation can, however, be stabilized given even greater communication delays if the vehicles delay their control response to all apply it in near unison.

In Schwager et al. (2011) and Michael et al. (2010), the effects of network delays on formation stability of a team of decentralized UAVs are explored in indoor flight testing. Vehicles can communicate only with their neighbors and are similarly slotted to broadcast knowledge of vehicle states at different times. Agents store outdated team member states x_j and update them as more recent information is relayed to them. Control inputs $u_i(t)$ in Eq. (66.15) for each UAV are based on this information:

$$\begin{aligned} u_i(t) &= \sum_{j \in N_i^{\text{ctrl}}} K_{ij} (\hat{y}_{ij}(t) - y_i(t) - \delta_{ij}) \\ \hat{y}_{ii}(t) &= C_i x_i(t) \\ \hat{y}_{ij}(t) &= C_j x_j(t - \tau_{ij}T) \end{aligned} \quad (66.15)$$

where G^{ctrl} specifies the set of neighbors N_i^{ctrl} , T is the overall time cycle of communications (for all agents to transmit once), τ_{ij} is the number of communication hops from j to i , δ_{ij} is the desired interagent distance, and K_{ij} is a control gain. To derive stability bounds on the system, the authors rewrite the system to be in continuous time at T second intervals and couple the entire system of agents as (fully defined in Schwager et al. (2011)):

$$X(t + T) = AX(t) + \Delta \quad (66.16)$$

The structure of matrix A depends on G^{ctrl} and G^{comm} , and its eigenvalues λ_i are a function of K_{ij} and T . The convergence rate of the formation is then directly related to $\alpha = |\lambda_{\max}(A)|^{1/T}$, where $\alpha \leq 1$ indicates Lyapunov stability and $\alpha < 1$ asymptotic stability. The indoor flight experiment consists of three UAVs with control and communication graphs in Fig. 66.4c and second-order control as in Eq. (66.17). Results show the following: (1) the formation is stable with small gains and converges faster with faster network cycles T , (2) at higher control gains, decreasing network cycle time may actually result in slower converge due to unstable dynamics being excited, and (3) introducing feedback cycles in G^{ctrl} can also introduce instabilities.

Communication delays can also be problematic in multi-UAV path planning for collision avoidance. In an outdoor flight test in Kopeikin et al. (2012), decentralized vehicles continuously replan the next steps of their receding horizon paths (not in formation). UAVs deconflict by not planning crossing paths to go

around each other. Short network delays and rapidly changing dynamics cause the vehicles to sometimes plan using outdated information. On occasion, two UAVs approaching each other head on may alternate in replanning deconflicting routes left or right multiple times. This phenomenon, known as “churning,” is similar to the common awkward situation where two people mutually block each other in a hallway or sidewalk, and causes delays, hazards, and system performance degradation.

66.4.3 Effects on Cooperative Decision Making

In order for multiple UAVs to cooperate in a mission, the team as a whole must plan and make decisions collectively. The objective in cooperative decision making is therefore for the networked team to reach an agreement on the tasks, plans, and actions required to execute the mission. Different strategies exist to achieve *conflict-free* plans, which require information exchange through the network. The dynamics and uncertainties of the communication network have several implications on decision-making strategies: (1) bandwidth limitations can restrict the content and frequency of planning messages, (2) even small network delays can cause agents to plan asynchronously making consensus difficult to achieve, and (3) network dropouts may prevent agents from participating in team decision making which can impact plan execution.

Because network bandwidth is a limited resource, cooperative decision-making methods need to limit the content of planning messages, efficiently select which pieces of information need to be shared with which members, and overall reach consensus with as few messages as possible to mitigate delays and conflicts. If the system operates under centralized control, every UAV needs to communicate every required bit of situational awareness information to a central leader (e.g., the base station). This strategy minimizes the number of messages required to reach consensus, but may require large amounts of low-level planning data to be communicated to the base, and can cause the system to be slow to react in a rapidly changing environment due to network delays. To overcome this, decentralized planning strategies provide individual agents with greater decision-making capability, where information can be shared more selectively and agents can locally decide on courses of action based on their own situational awareness, thus improving reaction time. Now, however, consensus on plans must be explicitly reached by exchanging messages over the network. A common distributed strategy, referred to as *implicit coordination*, consists of agents independently solving the entire centralized planning problem for all agents and carrying out actions assigned to them. This requires agents to reach consensus on individual situational awareness and planning objectives prior to planning (Ren and Beard 2005; Olfati-Saber and Murray 2004; Alighanbari et al. 2006), which may require large exchanges of data across the network, especially if inconsistencies exist (Alighanbari and How 2005). Another popular planning method

involves using *distributed auction algorithms*, where agents individually plan for themselves and consensus is reached through an auction mechanism (Sariel and Balch 2005; Ahmed et al. 2005; Atkinson 2004). A particular distributed auction approach that performs consensus on agent plans rather than on information is the Consensus-Based Bundle Algorithm (CBBA) (Choi et al. 2009). This algorithm employs a consensus protocol that explicitly specifies rules for reaching agreements on tasks, thus guaranteeing a conflict-free solution despite possible inconsistencies in situational awareness. In addition to being robust to inconsistent information, performing consensus in the task space is usually significantly faster, requiring fewer messages between the agents (Choi et al. 2009; Johnson et al. 2011).

Another challenge that affects distributed planning algorithms is that they usually rely on synchronous message passing in order to guarantee convergence. This is difficult to enforce in dynamic environments where the number of tasks or agents in the network may be changing and the network is subjected to the uncertainties and dynamics described in the previous section. When messages are asynchronous, time delays are not usually constant and messages may be received out of order, which impacts typical consensus algorithms since old information may be processed as new, thus hindering consensus. Being robust to these effects requires developing new consensus protocols or plan deconfliction rules that can recognize and process out of order messages. For instance, an asynchronous extension to CBBA addresses these issues in the decentralized task planning domain (Johnson et al. 2011), and several algorithms have been developed to perform linear asynchronous consensus in the information domain (parameter consensus) (Ren et al. 2005; Olfati-Saber et al. 2007; Blondel et al. 2005; Bemporad et al. 2010). This however remains a general problem for most multi-UAV systems of interest.

Finally, rapid link degradation or specific mission requirements (e.g., sending a reconnaissance UAV on a long duration mission at a location far from the base) may cause the network to disconnect. Most current distributed tasking algorithms, however, require continued connectivity in order to converge, and literature on limited communication environments has focused on maintaining this network connectivity through relay teams (Nguyen et al. 2003; Ibrahim et al. 2007; Ponda et al. 2011) by optimally placing vehicles (Dixon and Frew 2009) or by restricting allowable tasks. In realistic mission scenarios, where communication links are broken and created in real time and teams of agents often reconfigure themselves dynamically into different subnetwork structures, it is desirable to have distributed tasking algorithms that can ensure conflict-free solutions even when the network is disconnected. A recent study has considered distributed methods to locally adapt the task planning space within each subnetwork of agents, thus ensuring conflict-free assignments in the presence of network disconnects (Ponda et al. 2010). The approach in Ponda et al. (2010) results in assignments that would be equivalent to a mission operations center subdividing task sets among the different subnetworks, but without requiring the centralized overhead.

66.5 Motion Planning for Communications

Envisioned multi-UAV system applications involve controlling the agents to achieve a defined primary mission objective. This commonly includes maximizing area coverage, tracking a target, rendezvous in space, or formation and flocking control (Razafindralambo and Simplot-Ryl 2011; Goddemeier et al. 2011; Ghaffarkhah and Mostofi 2009; Zavlanos et al. 2011). Oftentimes, the primary objective does not specifically define connectivity objectives, but implicitly requires network communications control for the system to operate effectively. As described in the previous section, network performance depends on the quality of wireless links, the number of interconnected neighbors, and the ability to route information based on the topology. A common way to control network communications in a team of multiple UAVs is to plan the motion of the vehicles in such a way that the resulting topology supports the exchange of data required by the system. The general problem then becomes controlling a set of $N = \{1, \dots, n\}$ team members to achieve the mission objective and maintain the required state of connectivity. For mathematical simplification, vehicles are often considered to be point nodes with first-order dynamics, $\dot{x}_i(t) = u(t)$, where $u(t)$ is the control input at time t and $x_i(t)$ is the position of agent i . Some formulations go further and extend control to second-order dynamics as in Eq. (66.17) (Zavlanos et al. 2011) where v is velocity,

$$\dot{x}_i(t) = v_i(t) \quad \text{and} \quad \dot{v}_i(t) = u(t). \quad (66.17)$$

whereas others include greater detail in modeling actual vehicle kinematics (Dixon and Frew 2007). Network communication requirements vary from maintaining connectivity with a specific number of neighbors to establishing routes with sufficient throughput to send data to a base station. One of the earliest studies where motion control was employed to maintain connectivity consisted of a team of distributed robots with the task of meeting at an undefined point (rendezvous problem). The strategy involved each robot independently moving a step amount toward the geometric center of the area outlined by its perceived neighbors (Ando et al. 1999). This process was repeated iteratively until robots converged on a central location. Since, methods have expanded to include graph theoretic techniques, continuous control through potential fields, reactive control strategies, and adaptive techniques based on learning from the environment. Many of the efforts described here were focused on ground robotic systems but are relevant to aerial applications as well.

66.5.1 Graph Theoretic Methods and Potential Fields

Section 66.3 introduced the network graph G and the *algebraic connectivity* metric λ_2 , the second eigenvalue of the graph Laplacian \mathcal{L} . Several studies have formulated \mathcal{L} by assigning weights $w \in [0, 1]$ to each interagent link based on relative distance, with bounds $w_{ij} = 1$ if $d_{ij} \leq d_o$ where the link is strong and $w_{ij} = 0$ if

$d_{ij} \geq d_{\max}$ where the signal is considered too weak to connect Zavlanos et al. (2011). Connectivity objectives in multi-agent control problems often consist of meeting some threshold λ_2 or even maximizing its value. Initially, discrete methods were proposed to maximize λ_2 using iterative control inputs for each agent using greedy algorithms in both centralized (Kim and Mesbahi 2005) and decentralized frameworks (Gennaro and Jadbabaie 2006). These ensure that the team drives to connected configurations throughout the mission. Continuous control methods to maximize λ_2 using properties of \mathcal{L} were then formulated in Zavlanos and Pappas (2007) using potential fields in a centralized framework. Potential fields, which are commonly used in multi-vehicle control applications, are virtual energy fields that lead to attractive or repelling control inputs formulated as

$$u_i(t) = -k \nabla_i \phi_i - \sum_{j \neq i} \nabla_i \psi_{ij} \quad (66.18)$$

$$\psi_{ij} = \frac{1}{\|x_{ij}\|^2} + \frac{1}{d_{\max}^2 - \|x_{ij}\|^2} \quad (66.19)$$

One benefit of this formulation is that it allows multiple, sometimes competing, control objectives to be considered (Fig. 66.5). Here ψ_{ij} is designed according to the desired connectivity dynamics between i and j , as illustrated by the simple function in Eq. (66.19) which keeps the nodes within communication range and prevents them from colliding (Michael et al. 2009). ϕ_i can be any other steering function, used, for example, for obstacle avoidance or target tracking (Hsieh et al. 2008) as implemented in Fig. 66.5 (obtained from Goddemeier et al. (2011)). As the system approaches an unwanted state, such as a vehicle becoming disconnected or dangerously approaching an obstacle, that effect dominates the effective force generated by the potential field to correct the situation.

A decentralized version of this framework was proposed in Yang et al. (2010) using a power iteration algorithm for each agent to compute its local λ_2 using information from its neighbors and then estimate the global λ_2 to generate potential fields. Potential fields have also been used to control multi-vehicle systems for other connectivity requirements, using both graph theory and considering realistic channel dynamics and measurements. For instance, Ajorlou et al. (2010) and Dimarogonas and Johansson (2010) used bounded forces to minimize distance with connected neighbors for a team to rendezvous or assemble in a formation. One study considered Rician fading in wireless links to control multiple robots to track a target and maintain connectivity with the base (Ghaffarkhah and Mostofi 2009). A primal-dual optimization algorithm was used to control agents through a deployment objective while subjected to stochastic fading effects (Ny et al. 2011). Finally, in Goddemeier et al. (2011) potential fields controlled a team of eight UAVs to form a moving aerial communication network. Forces were created based on the deployment objective of maximizing area coverage over a moving point, and connectivity requirements which included maintaining a prescribed SNR over each link subject to realistic fading, and staying connected with a specified number of other UAVs.

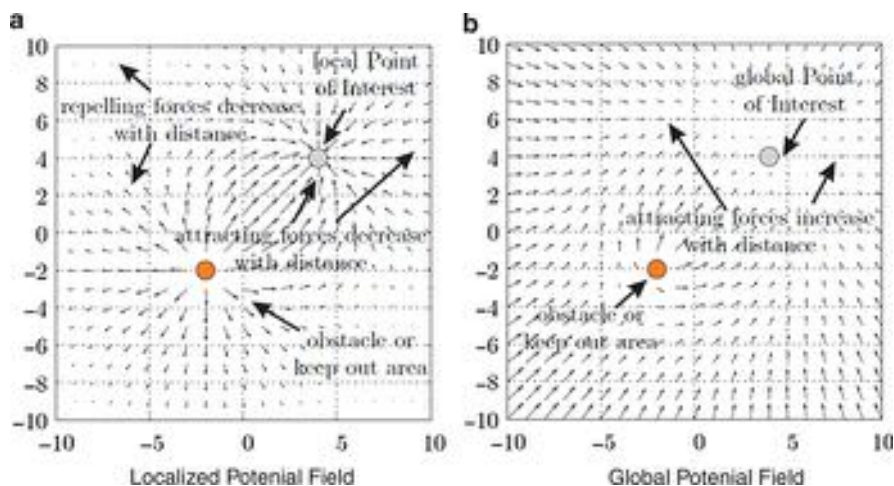

Fig. 66.5 Potential fields for motion. (a) shows a set of potential fields which dominate as vehicles approach the objects defined, and (b) represents potential fields dominating when further away to generally guide the vehicles (Figure copyright Goddemeier et al. (2011))

66.5.2 Reactive and Adaptive Techniques

Instead of controlling motion for connectivity at every time, another strategy is to allow agents to navigate freely according to mission objectives and take action only when connectivity is threatened. One method involves each robot iteratively planning how far it can travel at every step before losing connectivity with a required minimum number of neighbors (Razafindralambo and Simplot-Ryl 2011). Other studies were motivated by the difficulty of predicting wireless link performance with enough accuracy to make control decisions in a realistic environment. In these cases, each robot travels according to deployment objectives (using potential fields or random motion) until the measured signal strength with a set number k of neighbors drops below a designated threshold. At this point, the robot is commanded to halt (Reich et al. 2008) or even backtrack toward its nearest neighbor (Hsieh et al. 2008) and can only resume deployment objectives if communication requirements are again met. In these strategies, the required number of neighbors k is part of the design trade. A higher value increases network robustness to unpredicted disconnects but constrains the configuration of agents to be tighter and therefore cover less surface area (Reich et al. 2008). When warranted, the team may benefit from two agents disconnecting to add flexibility to the formation (so long as the graph does not disconnect). For such cases, the study in Zavlanos and Pappas (2008), which is explored in greater detail in the next subsection, employs a market-based algorithm for agents to come to consensus on which link to remove to meet formation objectives. Finally, certain scenarios involve agents taking on tasks beyond the reach of communications where the only option is to temporarily disconnect the network. Authors in Hollinger and Singh (2010) therefore define an implicit coordination

approach which is used to find optimal agent paths to execute the mission but reach a point of full connectivity at some specific time interval.

Many recent robotic efforts have turned to adaptive and learning techniques to adjust their behavior and overcome unpredicted changes in the environment (Leonard et al. 2010). Because it is so difficult to predict actual wireless channel performance in dynamic environments, several approaches have used measurements in the field to adapt the motion planning strategy. One basic approach is to take measurements of the environment a priori and construct a “radio map” used to plan constraints on relative node positions to stay connected (Hsieh et al. 2008). However, it may not be practical to perform this type of pre-mission survey as access to the location may be denied, and the environment may change over time due to different obstacles or other emitting devices. For this reason, several studies propose probabilistic methods based on the spatial correlation of channel fading to select locations to transmit. For instance, in Lindhe and Johansson (2010) a single mobile agent tracks a moving target and must send collected data to a fixed base. Current measures of the SNR are used with link dynamics previously described to adaptively schedule stops where the channel is predicted to be strong to transmit information rather than waste energy transmitting during fades. Bounds on the dynamics are derived to ensure system stability and prevent the agent from falling behind the target. In a similar scenario, a single agent must repeatedly visit multiple areas and send information to the base. Here the planner sequentially solves for the optimal visit path using a Mixed-Integer Linear Program (MILP) and budgets the power needed to transmit given the environment throughout and the path using a nonlinear program (Ghaffarkhah et al. 2011) for energy conservation. Finally in Mostofi (2009), a team of multiple UAVs learn link dynamics online to plan motion cooperatively and track a target. At each step, the vehicles seek to gain information $\mathcal{I}_i[k]$:

$$\mathcal{I}_i[k] = \mathcal{I}_i^s[k] + \sum_{j \neq i} \mathcal{I}_j^c[k], \quad (66.20)$$

about the target either through direct sensing $\mathcal{I}_i^s[k]$ (which degrades with distance) or by exchanging information with other agents $\mathcal{I}_j^c[k]$ (which degrades with poor communications). The measured SNR is used to learn the communication environment and properly balance sensing and communication objectives. Furthermore, channel fades correlated over multiple steps are used to identify areas of shadowing, and adapt the motion strategy to improve communications.

66.5.3 Implementation Examples

Motion planning to control network communications is a relatively new research topic in robotics, and as such, there have only been a few implementations of these principles using actual vehicles. Most of the studies described previously in this section were conducted in simulation. The following discusses two experiments that are particularly relevant because they incorporate several of the motion planning methods discussed previously.

In Reich et al. (2008), four UGVs are each tasked to a designated location, and the mission objective is to transmit imagery back to the base, using multiple hops if needed. A radio map is constructed by measuring the signal strength between many pairs of locations in the area, and it is employed in assigning tasks to the robots so that a connected multi-hop path exists to the base. During the deployment, a centralized scheme uses potential fields to navigate the robots to their targets. A reactive controller based on signal strength and throughput measurements halts individual robots if connectivity thresholds are violated. The experiment successfully shows the ability to control robots using the scheme. It also highlights that signal strengths and throughputs vary significantly during the mission with previous static measurements due to fading and multi-user interference. Results support the choice to implement a reactive controller.

In Michael et al. (2009), potential fields are implemented in a decentralized framework on a team of seven UGVs (Fig. 66.6). The objective is for each robot to maintain distance-based connectivity with k neighbors while a leader robot is given navigation commands. When flexibility is needed in the formation, links are switched off from the potential field using a market-based consensus algorithm. In this process, robots place bids on their link most at risk with bid value based on their number of neighbors. The bids are propagated through the network, and the highest bid link is allowed to be deleted. The framework only allows one link to be deleted at a time to ensure that the graph stays connected, and the approach introduces methods to handle asynchronous planning issues (see Sect. 66.4). In this effort, robots compute their own local estimate of the network and exchange position and bid information using Transmission Control Protocol (TCP) messages only with their neighbors.

Fig. 66.6 Experiment with seven UGVs maintaining connectivity through motion control. Each *colored line* in the visualization depicts the current connectivity graph estimate for a particular robot (Figure and caption copyright Michael et al. (2009))

66.6 Communication Relays for Network Support

Because of their rapid and flexible deployment capabilities, persistence, ability to fly above obstacles, and relative low cost, UAVs have generated significant interest to serve as communication relays. Relays can be used to extend the range of a network, add capacity for increased throughput, and increase the robustness of the system to failure. Large-scale military UAVs are already delivering wide-area communication connectivity to ground troops in mountainous areas (Jonson et al. 2008), and similar smaller tactical concepts have been proposed for disaster area recovery (Federal Communications Commission 2011), and wild land fire fighting (Zajkowski et al. 2006) and to connect scattered wireless sensors and mobile ad hoc networks (Palat et al. 2005). When deploying UAVs to serve as communication relays, their primary mission objective is to maximize connectivity. Many of the communication control methods described in the previous section apply to this problem, but here the underlying network to be supported cannot usually be controlled and may be dynamic. Control objectives typically involve guiding relay agents to optimized locations to support data exchange requirements at the lowest resource cost possible. Two classes of problems are provided in this section. First, methods are investigated to optimize the control of a chain of relays linking two mobile end nodes. Second, the problem of optimal relay deployment to support a larger, typically fixed network is considered. In all cases, controlling the communication network involves considering the dynamics of wireless links, the topology, and information routing options.

66.6.1 Controlling Relay Chains

Several applications have called for a chain of relay nodes to extend communications through multiple hops from one end of the chain to the other. In this case, once the chain forms, the relationship between pairs of nodes remains constant (same two neighbors), and information routing is known since it simply follows the nodes in the chain by default. A common application under which this is studied involves maintaining communications between a moving agent and its base station. This problem has been examined in complex obstructed environments where the objective is to optimally navigate and position N relays to establish multi-hop line of sight with the base. Optimal deployment paths can be generated in a centralized framework using a Mixed-Integer Linear Program (Schouwenaars et al. 2006) or a Gauss pseudospectral solver initialized using a rapidly-exploring random tree (RRT) solution (Kulling 2009). A suboptimal decentralized receding horizon planner can also be used to provide faster real-time control to repeatedly “redeploy” relays as the mission progresses (Kulling 2009). In a similar problem, a chain of UGV relays must connect a mobile node to a base and optimize their formation to minimize the end-to-end *bit error rate* (BER) (see Sect. 66.3 and Eq. (66.7)). Here, wireless links are subjected to path loss, shadowing, and multipath fading

(Yan and Mostofi 2010; Bezzo and Fierro 2011). The resulting optimization can be written as

$$\max \mathcal{J}(x) = \sum_{i=2}^N \ln(1 - \text{BER}_{i-1,i}) \quad (66.21)$$

which is reformulated as a set of decentralized potential fields used for vehicle control as in Eq. (66.19). In Yan and Mostofi (2010), the formulation does not assume deterministic link dynamics, since actual channel qualities can vary significantly with predicted models. It instead employs a probabilistic framework with least squares regression to estimate the value of the path loss exponent α in Eq. (66.2) and shadowing variance and correlation in Eq. (66.4) from several SNR measurements. These estimates are constantly updated to plan motion to optimize the chain BER. Since multipath fading is assumed to be spatially uncorrelated and varies quickly over small distances, once the relay reaches its destination, it “jitters” around its position to further reduce the quantity $\text{BER}_{i-1,i}$. With a slight modification to the problem formulation, the objective is changed to provide a chain configuration which meets a threshold end-to-end BER but minimizes relay energy costs. This allows motion cost and transmission costs (through variable power transmission) to be traded off in the optimization, with tunable weights associated with each to favor one over the other (Yan and Mostofi 2010).

Again, due to the recency of these studies, most of the above efforts were conducted in simulation or controlled hardware experiments with simplifying assumptions. However, authors in Dixon and Frew (2007) and Dixon (2010) tackle the problem of forming a chain of relays using actual fixed wing UAVs flying over a mountainous terrain. In this study, the objective is to maximize the end-to-end *capacity* c of the chain found from Eq. (66.6) or in other words maximize the minimum link capacity in the chain (Fig. 66.7). Two complicating but realistic factors in this work include: (1) fixed wing aircraft have velocity limits $0 < v_{\min} < v < v_{\max}$ and must loiter in orbits also constrained by ϕ_{\max} bank angle, and (2) the authors chose to control the chain based on SINR signal strength measurements only and avoid using channel models deemed inaccurate in dynamic environments. Because of the first challenge, vehicle dynamics are modeled as being nonholonomic with bicycle kinematics:

$$\dot{x}_i = v_i \cos \psi_i, \quad \dot{y}_i = v_i \sin \psi_i, \quad \text{and} \quad \dot{\psi}_i = v_i s_i \quad (66.22)$$

where $s_i = \frac{g \tan \phi}{v_i^2}$ is the path curvature and ψ_i is the heading angle. Consequently control inputs take on the form $u_i = v_i s_i$. Since each relay is controlled based on its SINR measurements only, an extremal seeking algorithm is implemented where each UAV hones in on the heading which maximizes γ with its neighbors using

$$\theta^*(t) = \operatorname{argmax} \left(\frac{1}{\min\{\gamma_{i,i-1}, \gamma_{i-1,i}, \gamma_{i,i+1}, \gamma_{i+1,i}\}} \right). \quad (66.23)$$

Fig. 66.7 Flight testing a chain of UAV relays. The evolution of a simulation with two UAV relays (*left*) and the type of fixed wing aircraft used in the experiment (*right*) (Figure copyright Dixon (2010))

This framework does not assume equal interference levels for neighboring UAVs, and as such, the SINR measurements are asymmetric on each side of the link. The optimization therefore maximizes the minimum link capacity on either side of each link. Then, a Lyapunov Guidance Vector Field (LGVF) (Dixon and Frew 2007) drives the UAVs to an orbital pattern about a center point θ_i , and a consensus algorithm is used to synchronize the UAVs on a common orbiting phase angle. Flight test results demonstrate the ability to control an aircraft to climb the SINR gradient and improve capacity using signal strength measurements only. However, RF fluctuations encountered are detrimental to the chaining algorithm and at times cause the measured γ to actually increase while flying away from a neighbor. This exemplifies the complexity in controlling the communication network with operational dynamics using feedback measurements alone.

66.6.2 Deploying Relays to Support a Network

So far this section has explored problems involving the control of a chain of relays between two designated points. In a number of other applications, however, UAVs (or other mobile agents) serving as relays can be deployed to provide general connectivity support to an existing network consisting of many nodes. The problem here is to determine how best to deploy each relay and which nodes they should form links with to satisfy the data requirements of the network. Objectives here include maximizing the performance of the supported network or minimizing the number of relays deployed to meet communication thresholds. These problems are often studied in the context of UAVs relaying information from poorly connected ground nodes or for wireless sensor network (WSN) nodes with connectivity and energy limitations sending data to a base station.

Network graph theoretic processes described in Sect. 66.3 have also been explored in these problems. One example consists of maximizing the lifetime of a fixed WSN collecting data which depletes its battery over time as the energy is used to transmit information (Ibrahim et al. 2007, 2009). Here K relays are available to be deployed and redeployed to support the network. The graph Laplacian \mathcal{L} in Eq. (66.8) is composed of weights w_{ij} in its adjacency matrix A based on the transmitter power needed to maintain a threshold BER across the link. This formulation assumes all starting nodes have equal battery life, and therefore the algebraic connectivity of the graph λ_2 can be used as a metric of remaining network life. A centralized semi-definite programming (SDP) algorithm optimizes the placement of the K relays to maximize λ_2 over the network. It discretizes the area into cells, finds the best combination of placements for the K relays at the center of these cells, and then rediscrretizes selected cells to refine relay placement over several iterations. From there, a minimum cost path routing algorithm (see Sect. 66.3) is implemented where relays are encoded with reduced cost to incentivize their use. The deployment process is repeated as needed as other nodes deplete. The formulation is also modified to solve for the minimum number of additional relays required to support the network at a threshold level (Ibrahim et al. 2009).

In a similar problem, WSN nodes compute their k -redundancy in a distributed framework using neighbor discovery messages (Atay and Bayazit 2008). The k_i^{red} is the number of links that need to be removed to disconnect any two neighbors of i and is a measure of the importance of that node in global connectivity. Here if any k_i^{red} falls below some threshold because of a change in topology, the network requests a relay which is positioned using several different optimization schemes to meet connectivity requirements. Finally, the study in Zhu et al. (2009) discusses how the deployment strategy changes for one UAV relay to support an ad hoc network according to different connectivity objectives. Optimization methods are presented to maximize (1) global and (2) worst-case connectivity based on properties of the minimum spanning tree (MST) graph (Bertsimas and Tsitsiklis 1997) or (3) minimize network bisection probability and (4) maximize the Fiedler value using graph Laplacian \mathcal{L} . Each objective results in a different UAV relay deployment plan.

In the previous three examples, the deployed relays essentially became nodes in the supported ad hoc network, thus changing the topology and information routing options. However, another strategy is to assume that relays are similar to gateways and have a separate strong communication network to connect to other relays and the rest of the world. These can then be used as a communication backbone to support a disconnected ad hoc network (as illustrated with the “UAV Comm. Relay” in Fig. 66.1). The network then takes on a form more consistent with a cellular network architecture, where relays serve as mobile base stations and connect to nodes in their area of responsibility. This is how current military large-scale UAV communication relays operate (Jonson et al. 2008). Mobile backbone network (MBN) optimization seeks to simultaneously position and assign K MBN relays over a network in order to (1) maximize the minimum throughput in the network (Srinivas and Modiano 2008), (2) maximize the aggregate network throughput

(Srinivas and Modiano 2008), (3) maximize the number of nodes meeting a threshold throughput (Craparo and How 2010), and (4) optimize relay deployment and node positioning (if those nodes can be controlled) for objective (3) (Craparo and How 2010). In objectives (3) and (4), the optimization is solved using a Mixed-Integer Linear Program (MILP) for a network optimization formulation (Bertsimas and Tsitsiklis 1997). Similar to other previous studies, the optimal solver scales poorly with increasing numbers of nodes and relays, and a suboptimal greedy solution based on solving the Max-Flow problem (Bertsimas and Tsitsiklis 1997) is provided in parallel for fast and provably good solutions.

66.6.3 Controlling Communications Through Task Allocation

A similar, yet distinct method to control network communications in a team of UAVs is through task allocation. Here, the system consists of a multi-agent team with a set of objectives, and similar to motion planning problems discussed in Sect. 66.5, connectivity is an implicitly derived requirement. The framework can use task allocation to ensure agents only take on tasks which result in a suitable network topology, or better yet, allocate additional tasks to certain agents to serve as communication relays as needed (Ponda et al. 2011). The challenges now include: (1) determining which tasks should be assigned to which agents, (2) identifying when the network topology will not support the assignment, (3) designating which agents to take away from executing mission tasks to assign as relays and where to position them, and (4) adapting to dynamic scenarios and uncertainty. These frameworks follow the same general principles of multi-UAV mission planning methods addressed in chapter ▶[Cooperative Mission Planning for Multi-UAV Teams](#).

The authors in Tardioli et al. (2010) discuss a task allocation-based network control mechanism. A set of N UGVs have a set of \mathcal{J} possible tasks to accomplish and must maintain a threshold receive signal strength (RSS), through multiple hops if needed, to a base. A centralized task allocation planner initializes by dividing the team of robots into subset clusters. Each cluster is assigned a common task to accomplish. Then, motion planning potential fields similar to Eq. (66.19) are used to attract the cluster to the goal, to the base, and to maintain connectivity within the cluster while accomplishing the task. If the cluster cannot achieve the goal and stay connected, it is merged with a neighboring cluster to expand the multi-hop capability. Clusters can monotonically grow in size until the entire team is included in one large cluster. Unachievable tasks are then discarded. At every planning cycle, clusters are reset to their original size to again allow more flexibility in task assignment. Different optimization strategies can be implemented to select which task gets assigned to each cluster at every step (Tardioli et al. 2010). The framework is implemented in an outdoor hardware system experiment with three small UGVs. Results, while successful, again highlight the difficulty in predicting link quality due to rapid variations and uncertainty in the dynamics.

Fig. 66.8 Flight testing a task allocation framework which maintains connectivity. On the *left*, UAV2 relays UAV3 as it executes a task, and both plan to implement a similar strategy for UAV3 to accomplish the task in *red* at the top of the image

A different task allocation strategy is proposed in Ponda et al. (2011) and Kopeikin et al. (2011). A decentralized task allocation planner is used to coordinate a team of N UAVs in maximizing reward in the mission by taking on high-value tasks while maintaining distance-based connectivity requirements. The scenario is dynamic, similar to realistic operations, and tasks are created at random times and locations throughout the mission and have a limited time window of validity. Because the assignment problem is combinatorial and difficult to solve optimally, an auction-based multi-agent multi-task assignment algorithm (Consensus-Based Bundle Algorithm) allows agents to place bids on each task (Choi et al. 2009). Bids are based on task values, agent capabilities, and availability for execution. Agents then share bids, assign winners, and iterate through the algorithm to reach consensus on a conflict-free plan. The framework then predicts the network topology for the execution of each task assigned, identifies disconnected configurations, and creates new relay tasks to repair the network. Underutilized UAVs can then bid on these relay tasks similar to any other. Two challenges in this planning framework discussed in Ponda et al. (2011) involve (1) properly incentivizing agents to take on the relay tasks which by themselves add no reward to the mission and (2) ensuring the algorithm converges quickly to mitigate planning delays. This strategy does not plan for connectivity through motion as UAVs travel to and from tasks, and instead ensures the network is connected during task execution only. The system was implemented in an outdoor flight test with a team of three UAVs to demonstrate initial functionality (Fig. 66.8) and is being modified to account for more complex wireless connectivity models (Kopeikin et al. 2011).

66.7 Concluding Remarks and Remaining Challenges

Teams of multiple UAVs show tremendous potential in a growing number of military, first response, exploration, and other applications. As technology advances, these cooperative systems will make their way to the operational domain. To realize

this, the research community is involved in a wide range of studies including aircraft design, control, cooperative mission planning, sensing, and exploitation, among many others. Effective and robust control of the communication network will be a near universal requirement for these systems.

This chapter presented several topics on controlling the network for a team of UAVs to ensure command and control messages are exchanged properly, and remotely sensed data is transmitted back to desired locations. Control methods discussed include motion planning to create an effective network topology, transmitter power regulation, deployment and control of mobile communication relay nodes, and task allocation algorithms to ensure connectivity. While progress is ongoing in all of these areas, there are nevertheless several high-level challenges which need to be considered:

1. *Robustness to uncertainty*: Because of the recent surge in wireless devices for every day applications, the electromagnetic spectrum is becoming more crowded and communication systems are competing for bandwidth. Furthermore, as described earlier, it is often difficult to accurately predict wireless channel performance in dynamic environments. The need to control and implement multi-vehicle systems to be robust to uncertainties and interference, and degrade gracefully when the network underperforms, is critical (Goldsmith 2005).
2. *Limiting bandwidth usage*: Each bit transmitted costs valuable resources in both bandwidth and energy. In order to maximize resources, all sensing and control functions must minimize the amount of information to transmit. Consensus in cooperative control and decision making must converge accurately across team members with as few messages as possible. Methods to process and sort sensed data onboard the UAV to minimize transfer requirements for analysis is also paramount.
3. *Ad hoc networking protocols*: Researchers in the cooperative control and ad hoc networking communities need to partner to jointly optimize control and routing strategies to maximize resources. Network protocols need to quickly adapt to the dynamics of multi-UAV networks, be flexible enough for the wide scope of envisioned applications, and ensure that the network is secure from unwanted users.

The communication network is one of many critical components of a multi-UAV system. Many of the methods presented in this chapter require a more in-depth understanding of other focused disciplines. Interested readers are encouraged to read other chapters in this handbook describing ►Multi-UAV Cooperative Mission Planning, ►Aircraft Flight Control, ►Trajectory Planning, and ►Advanced UAV Communication Systems. In addition, the references listed in this chapter contain detailed information on all of the topics covered. The following references are recommended for readers interested in specific topics: wireless communications and modeling (Goldsmith 2005; Mostofi et al. 2009), ad hoc topology control (Santi 2005), mesh networking standards (Hiertz et al. 2010), consensus in network graphs (Olfati-Saber et al. 2007), and graph theoretic vehicle control (Zavlanos et al. 2011).

Abstract

An information-theoretic path planning for exploration mission in unknown environment is proposed. Instead of using traditional grid-based occupancy maps, the Gaussian process (GP) is used to build an environmental map. The GP map performs inference directly on the collected sensor datasets which allows it to infer the probability of collision for any query point in continuous 3D space, removing the need for maintaining a full discrete map. This GP map is fused with the Rapidly exploring random tree (RRT) path planner to plan a safe path and acquire information about the unknown environments. Using mutual information as an information measure, the most informative path is chosen as the path for exploration. Simulation results show that GP map combined with RRT planner achieves exploration task successfully in unknown complex environment and present their potential implementation in unmanned aerial vehicle (UAV) missions.

67.1 Introduction

Autonomous navigation in unknown cluttered environments is a challenging problem. To achieve this task the vehicle must have the ability to build an environment representation, generate a safe and feasible path, and execute the plan reliably. A path planner plans a path based on its understanding about the environment. In a global collision-free path planning problem, the environment is represented by an occupancy map that contains the joint sensory information about the robot operation space (Scherer et al. 2008). The most straightforward approach is to discretize the operational area into a predefined uniform grid where each grid cell holds the probability of occupancy within the cell (LaValle 2006). This grid based path planning approach has been widely used and successfully demonstrated for real-time applications, especially well suited for robots that operate in two-dimensional planar domains (Ferguson and Stentz 2006; Grabowski et al. 2006; Montemerlo et al. 2008). However, in three-dimensional applications, the grid-based approach suffers greatly from the curse of dimensionality because the grid density required to reasonably represent the 3D operational environment to a certain resolution exponentially increases. Furthermore, the flexibility of the path planner is restricted by the resolution and orientation of the grid.

In this research, the traditional grid-based occupancy map approach is replaced with a Gaussian process (GP) occupancy map for path planning. The GP map operates directly on the collected environment data, which eliminates the grid-based map and the concerns with grid size, grid shape, obstacle shape, and map resolution. There is no need to associate the data to discrete cells, and thus no information is lost. The GP map outputs the probability of occupancy given any selected query point in the continuous space. This grants it the potential to explore all possible paths in the full space when used in conjunction with a continuous path planner. Furthermore, a path planned with a GP map is embedded with the probability of collision along the path. This valuable information is not available in other grid- or graph-based frameworks.

In this research, a Rapidly exploring random tree (RRT) path planner is used for the planning algorithm. The GP map is well matched with the RRT framework since it works as collision detection module that implicitly represents free space. The RRT expands its network as part of the exploration mission to get information of the unknown cluttered environment. Autonomous vehicles with sensing capabilities can actively take advantage of their mobility to get information about the environment. A key component of active environment sensing systems is the dependence of information gathering on robot motion, and the ability to predict in advance the effect of robot motion on the quality of information that is collected (Frew 2007a). Information-theoretic approaches, which use information measures, such as entropy, Fisher information, and mutual information as an objective functionality, have been actively investigated (Bourgault et al. 2002; Stachniss et al. 2005; Ryan et al. 2007; Frew 2007b). An appropriate selection of the information criteria is important because each information measure has a different way of characterizing the uncertainty. Mutual information is used as an information measure because it provides a pre-observation measure of the usefulness of obtaining information about the value of the sensor measurement (Grocholsky 2002).

The role of the planner in the exploration mission is to generate a path that maximizes the information of the environment. Therefore, it is important to evaluate properly the uncertainty of the environment based on the accumulated environment data, because the quality of path is quantified by this evaluation. GP is an excellent method to evaluate the uncertainty because it has an inference capability in occluded areas. The exploration problem, which aims to minimize the uncertainty in the environment, is similar to the sensor management problem. The main difference between mobile robotic networks and sensor management is that there is no restriction to the deployment of sensors in sensor networks (Singh et al. 2010; Krause et al. 2008), but there are severe constraints in a mobile robot such as a UAV: kinematic and dynamic constraints which restrict the evolution of the vehicle states. In addition to the differential constraint of the vehicle, there are other constraints which makes the exploration task challenging. The observation is also constrained by the limited sensor field of view, and the difficulties are compounded by the occlusion due to obstacles. Finally, the vehicle must satisfy the safety condition which ensures no collision with obstacles. All of these constraints complicate the planning problem. In this research, an information-theoretic path planning algorithm is proposed for the exploration mission which takes into account these constraints within the RRT framework. Simulation results show that GP map combined with RRT planner achieves exploration task successfully in unknown complex environment and present their potential implementation in unmanned aerial vehicle (UAV) missions.

The rest of the chapter is organized as follows: Sect. 67.2 presents a brief background of the Gaussian process and how it can be used as a tool to generate a continuous occupancy map. Section 67.3 addresses information-theoretic exploration in cluttered environments. Section 67.4 presents simulation results of a UAV performing a navigation and exploration task, and the conclusions are presented thereafter.

67.2 3D Gaussian Process Occupancy Map

67.2.1 Foundations of Gaussian Processes

Gaussian processes is a powerful nonparametric tool for regression based on locally available datasets. It represents a family of distributions over functions and inference takes place directly in the function space (Rasmussen and Williams 2006). It is particularly useful to infer the most likely function value f_* and its corresponding variance for a given test input \mathbf{x}_* when exact observation on \mathbf{x}_* is not available. Especially for the case when there is no information about the underlying function, inference with GP can be achieved by placing a multivariate Gaussian distribution across the function space.

Consider $\chi = \{(\mathbf{x}_i, y_i) | i = 1, \dots, n\}$ as a collection of N datasets, where $\mathbf{x}_i \in \mathbb{R}^D$ represents a D dimensional training input and $y_i \in \mathbb{R}$ the corresponding scalar training output (in this research, y_i is +1 or -1 for occupied and non-occupied, respectively). Condition on χ , for any selected testing input \mathbf{x}_* , the predictive distribution of the function output becomes

$$f_* | \mathbf{x}_*, \chi \sim N(\mu_*, \sigma_*^2) \quad (67.1)$$

with mean

$$\mu_* = k(\mathbf{x}_*, \mathbf{x}) [k(\mathbf{x}, \mathbf{x}) + \sigma_n^2 I]^{-1} \mathbf{y} \quad (67.2)$$

and variance

$$\sigma_*^2 = k(\mathbf{x}_*, \mathbf{x}_*) - k(\mathbf{x}_*, \mathbf{x}) [k(\mathbf{x}, \mathbf{x}) + \sigma_n^2 I]^{-1} k(\mathbf{x}, \mathbf{x}_*) \quad (67.3)$$

Here, $k(\mathbf{x}, \mathbf{x}')$ is the GP covariance or kernel function, which effectively sets the correlation between the output of \mathbf{x} and \mathbf{x}' based on trained kernel hyperparameters.

Selection of the appropriate covariance function highly depends on the application. A commonly used kernel is the stationary squared exponential(SE) kernel:

$$k(\mathbf{x}, \mathbf{x}') = \sigma_f^2 \exp\left(-\frac{1}{2}(\mathbf{x} - \mathbf{x}')^T \mathbf{M}(\mathbf{x} - \mathbf{x}')\right) \quad (67.4)$$

where σ_f^2 is the signal strength, σ_n^2 the Gaussian noise variance, and $\mathbf{M} = \text{diag}[1/l_1^2, \dots, 1/l_D^2]$, where l_i is the length scale that sets the kernel smoothness characteristic in different dimensions. There exist other covariance functions that outperform squared exponential in terms of modeling noncontinuous spatial functions, such as the neural-network demonstrated in OCallaghan et al. (2009). Nevertheless, the squared exponential is by far the most computationally efficient kernel that suits in this application.

67.2.2 Probabilistic Least Square Classification

The aim here is to estimate the probability of collision for any chosen location in 3D workspace for collision-free path planning. There are various classification algorithms available, but, as described by Rasmussen and Williams (2006) and implemented by OCallaghan et al. (2009), one simple yet efficient method is to treat the classification as a GP regression problem and then further squash the GP predictions through a cumulative Gaussian sigmoid function to obtain a valid probability

$$p(y_i | \mathbf{x}, \mathbf{y}_{-i}, \theta) = \Phi \left(\frac{y_i (\alpha \mu_i + \beta)}{\sqrt{1 + \alpha^2 \sigma_i^2}} \right) \quad (67.5)$$

where Φ is a cumulative unit Gaussian which is defined as $\Phi = (2\pi)^{-1/2} \int_{-\infty}^z \exp(-t^2/2) dt$, θ denotes the hyperparameters of the covariance function, α and β are the classifier hyperparameters that can be trained using the leave-one-out cross-validation procedure as described in Sect. 67.2.4. The full method is called probabilistic least square classification (PLSC).

67.2.3 3D Laser Sensor Model

A rotary UAV (RUAV) is considered in this research. It is assumed that the RUAV platform is equipped with a sparse 3D laser range finder, capable of scanning n_b beams every instant the sensor is activated, as depicted in Fig. 67.1a. Each time the sensor scans the environment, the following information is stored for each beam segment $\Lambda^k = \{(\mathbf{s}_i, \mathbf{u}_i, b_i) | i = 1 : n_b\}^k$ where \mathbf{s}_i , \mathbf{u}_i and b_i are, respectively, the sensor position, beam vector from sensor to return position, and a boolean indicating either 1 if the beam hits an obstacle and 0 otherwise.

67.2.4 Training GP and Classifier Hyperparameters

Training datasets can be obtained by firstly flying the RUAV platform around an obstacle in a simulated environment, like one in Fig. 67.1a, collecting laser beam data. The collected laser beam segments are then divided into discrete points where each point is described by its 3D location \mathbf{x} and corresponding label y , used for the hyperparameter training described below.

Training the GP hyperparameters is effectively setting the appropriate properties for the covariance function. A common method is based on maximization of the log of the marginal likelihood:

$$\theta_{\text{opt}} = \arg \max [\ln p(\mathbf{y} | \mathbf{x}, \theta)] \quad (67.6)$$

Fig. 67.1 Gaussian process occupancy map construction: (a) shows the instant where an obstacle is detected within the FOV of the 3D laser range finder. The notation used in Algorithm 1 for extracting training data from a single laser beam is illustrated in (b). Diagram (c) illustrates the high resolution horizontal plane GP map at the height of the sensor with the *color* indicating the probability of obstacle. The modifications made to suit path planning are shown in (d) where a safety boundary parameter d_{safety} of 5 m is used. Note that (c) and (d) are for visualization purposes. There is no need to construct the full map for online path planning applications

where

$$\ln p(\mathbf{y}|\mathbf{x}, \theta) = -\frac{1}{2}\mathbf{y}^T K_y \mathbf{y} - \frac{1}{2} \ln |K_y| - \frac{n}{2} \ln 2\pi \quad (67.7)$$

and $K_y = k(\mathbf{x}, \mathbf{x}) + \sigma_n^2 I$. The optimal solution of this method produces a model that balances between model complexity and data fitness, which is known as the Occam's razor principle.

Having trained the GP hyperparameters, the classifier hyperparameters can then be trained using the cross validation approach, based on maximizing the sum of the log leave-one-out (LOO) probability:

$$\{\alpha, \beta\}_{\text{opt}} = \arg \max \left[\sum_{i=1}^N \ln p(y_i | \mathbf{x}, \mathbf{y}_{-i}, \theta, \alpha, \beta) \right] \quad (67.8)$$

where

$$\ln p(y_i | \mathbf{x}, \mathbf{y}_{-i}, \theta) = -\frac{1}{2} \ln \sigma_i^2 - \frac{(y_i - \mu_i)^2}{2\sigma_i^2} - \frac{1}{2} \ln 2\pi \quad (67.9)$$

and

$$\mu_i | \theta = \mathbf{y}_i - \left[k(\mathbf{x}, \mathbf{x})^{-1} \mathbf{y} \right]_i / \left[k(\mathbf{x}, \mathbf{x})^{-1} \right]_{ii} \quad (67.10)$$

$$\sigma_i^2 | \theta = 1 / \left[K(\mathbf{x}, \mathbf{x})^{-1} \right]_{ii} \quad (67.11)$$

are the mean and variance after leaving out the training dataset y_i . Note that these hyperparameters are fixed once they are trained in this application.

67.2.5 Sparse Training Data Extraction

Λ is a database of collected continuous beam segments representing the true occupancy information about the environment. When the occupancy hypothesis of a point \mathbf{x}_* is queried, a series of sparse spatial training data is to be extracted from its local neighborhood database subset $\Lambda_{\mathbf{x}_*} = \{\Lambda_{j, \mathbf{x}_*} | j = 1 : n_s\}$ where n_s is the number of the nearest beam segment. Among $\Lambda_{\mathbf{x}_*}$, training input \mathbf{x} and its corresponding label \mathbf{y} can thus be extracted using Algorithm 1. Lines 1 and 2 determine the distance d and location of the point that is projected orthogonally from \mathbf{x}_* onto the beam segment \mathbf{u} (note that $\hat{\mathbf{u}}$ is the unit vector of \mathbf{u}). Line 3 extracts the end of the beam segment. Lines 4–10 simply infer the conditions when the point \mathbf{x}_\perp lies outside of the beam segment. Lines 11–13 use a simple logic to set a safety boundary around obstacles for the path planning purpose that will be further described in the following section.

67.2.6 Safety Boundary Construction

Setting a safety region around obstacles is crucial for an airborne platform as flying close to obstacles significantly increases the risk of collision. A simple yet efficient way is to include this feature in the GP Map framework, appearing in lines 11–13 in Algorithm 1.

The aim is to enforce maximum correlation between the output of \mathbf{x}_{end} and \mathbf{x}_* , for \mathbf{x}_{end} that is extracted from an obstacle beam, when the distance between them is less than the safety distance d_{safety} . The simplest way to achieve this without modifying the GP framework is to simply set \mathbf{x} to be the same as \mathbf{x}_* , which, referring to (Eq. 67.4), effectively sets $k(\mathbf{x}, \mathbf{x}')$ to the maximum value of the covariance function. This method directly embeds the safety boundary feature in the training dataset extraction process, flexibly controlled by the single parameter d_{safety} with no induced cost while transitioning from 2D to 3D workspace.

Algorithm 1 Sparse training data extraction

Require: Λ_{x_*}, x_*

```

1:  $d \leftarrow a \cdot \hat{u}$ 
2:  $x_{\perp} \leftarrow s + d \hat{u}$ 
3:  $x_{end} \leftarrow s + u$ 
4: if  $d \leq 0$  then
5:    $x \leftarrow s, y \leftarrow -1$ 
6: else if  $d \geq |u|$  then
7:    $x \leftarrow x_{end}, y \leftarrow 2b - 1$ 
8: else
9:    $x \leftarrow x_{\perp}, y \leftarrow -1$ 
10: end if
11: if  $b = 1$  &  $|x_{end} - x_*| \leq d_{safety}$  then
12:    $x \leftarrow x_*, y \leftarrow 1$ 
13: end if

```

67.3 Information-Theoretic Path Planning for Exploration Mission

If a perfect information about an environment is known a priori, it is possible to plan a path before the mission. In real applications, however, this is rarely the case. The vehicle must sense the environment using onboard sensors, plan the path using the latest information on the environment and vehicle, and execute this plan.

A key component of active environment sensing systems is the dependence of information gathering on robot motion, and the ability to predict in advance the effect of robot motion on the quality of information that is collected (Frew 2007a). Information-theoretic approaches, which use information measures, such as entropy, Fisher information, and mutual information as an objective functionality, are actively investigated (Bourgault et al. 2002; Stachniss et al. 2005; Ryan et al. 2007; Frew 2007b). Here, appropriate selection of the information criteria is important because each information measure has a different way of characterizing the uncertainty.

67.3.1 Information Measures

The purpose of exploration is to reduce the uncertainty of the environment. Information measures can be used to quantify the level of uncertainty of the environment. Several different information measures are described in the following subsections from which the best measure for this application will be chosen.

67.3.1.1 Shannon Information

The Shannon information, a.k.a entropy, associated with a probability distribution of $P(\mathbf{x})$ is defined as the expected value of a negative log-likelihood:

$$H(\mathbf{x}) \triangleq -E[\log P(\mathbf{x})] = - \int_{-\infty}^{\infty} P(\mathbf{x}) \log P(\mathbf{x}) d\mathbf{x} \quad (67.12)$$

where $H(\mathbf{x})$ denotes entropy associated with the variable \mathbf{x} .

If $P(\mathbf{x})$ is a probability distribution function for an n -dimensional Gaussian, the entropy for this distribution is obtained as follows:

$$H(\mathbf{x}) = -\frac{1}{2} \log[(2\pi e)^n |\mathbf{K}|] \quad (67.13)$$

where \mathbf{K} is a covariance matrix of the probability distribution and $|\cdot|$ is a determinant.

Entropy provides a compactness to the probability distribution because the determinant of a matrix is a volume measure.

67.3.1.2 Fisher Information

The Fisher information associated with a probability distribution of $P(\mathbf{x})$ is defined as the second derivative of the log-likelihood:

$$J(\mathbf{x}) \triangleq \frac{\partial^2}{\partial \mathbf{x}^2} \log P(\mathbf{x}) \quad (67.14)$$

If $P(\mathbf{x})$ is a probability distribution function for an n -dimensional Gaussian, the Fisher information for this distribution is obtained as follows:

$$J(\mathbf{x}) = \mathbf{K}^{-1} \quad (67.15)$$

From (Eq. 67.15), it can be seen that the Fisher information of a multivariate Gaussian distribution is simply the inverse of the covariance.

Fisher information is inversely related to the surface area of the probability distribution.

67.3.1.3 Mutual Information

The mutual information is defined as a negative expectation of the conditional log-likelihood:

$$I(\mathbf{x}, \mathbf{z}) \triangleq -E \log[P(\mathbf{x}|\mathbf{z})] = -E \left[\log \left\{ \frac{P(\mathbf{z}|\mathbf{x})}{P(\mathbf{z})} \right\} \right] = H(\mathbf{z}) - H(\mathbf{z}|\mathbf{x}) \quad (67.16)$$

Mutual information measures the amount of information about one variable contained in another. If \mathbf{x} is a state and \mathbf{z} is an observation, then mutual information represents an a priori measure of the information to be gained through observation. It is a function of the ratio of the density $P(\mathbf{x}|\mathbf{z})$ following an observation to the

prior density $P(\mathbf{x})$. The expectation is taken over \mathbf{z} and \mathbf{x} , so the mutual information gives an average measure of the gain to be expected before making the observation (Grocholsky 2002).

67.3.2 Decision of the Appropriate Information Measure

The objective of path planning for an exploration mission is to compute a path towards the most informative area. In order to judge the quality of the path, it is necessary to establish the notion of *informativeness*. Several information measures were introduced in the previous section. Each class of information measure results in a different output. The existence of different information measures naturally raises the question of deciding upon the most appropriate measure.

The Fisher information is a useful information measure for Gaussian representations because it is simply the information matrix (Eq. 67.15). However, it is not scalar, and so cannot be used explicitly for preference ordering of posteriors as a measure of information gain (Cole 2009).

Shannon information is a good measure for making a decision on which observations are the most uncertain. Though Shannon information is a proper measure to evaluate the absolute amount of information, it cannot capture the objective of the exploration task. What is important in the exploration mission is the amount of uncertainty reduction after the observation is made instead of the absolute magnitude of the information itself.

Mutual information provides an average measure of how much more information can be obtained if the observations are made. Most importantly, mutual information provides a preexperimental measure of the usefulness of obtaining information (through observation) about the value of \mathbf{z} (Grocholsky 2002). In that sense, mutual information is a more useful measure than entropy. The mutual information is chosen as a measure of evaluation of the information.

67.3.3 Evaluation of Uncertainty of the Environment

Consider Λ is a database of collected continuous beam segments. When a point \mathbf{x}_* is queried for the evaluation of information at this point, a series of sparse spatial training data are to be extracted from its local neighborhood database subset $\Lambda_{\mathbf{x}_*} = \{\Lambda_{j,\mathbf{x}_*} | j = 1 : n\}$, where n is the number of the nearest beam segment. Using the *Sparse Training Data Extraction* algorithm in Sect. 67.2, n number of orthogonal points are obtained from $\Lambda_{\mathbf{x}_*}$. Let $\mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$ be the extracted orthogonal points. Then the covariance at this testing point \mathbf{x}_* is calculated using (Eq. 67.17) which comes from (Eq. 67.3):

$$\sigma_*^2 = k(\mathbf{x}_*, \mathbf{x}_*) - k(\mathbf{x}_*, \mathbf{x}) k(\mathbf{x}, \mathbf{x})^{-1} k(\mathbf{x}, \mathbf{x}_*) \quad (67.17)$$

Fig. 67.2 Laser beam data and covariance map: *Blue rays* in **(a)** show laser beam data and *red circles* represent laser beam hit locations with obstacles. **(b)** shows the covariance map of the environment based on the laser beam data collected by the vehicle. The uncertainty of the occluded area is smaller than the unexplored area though there is no laser beam data behind obstacles

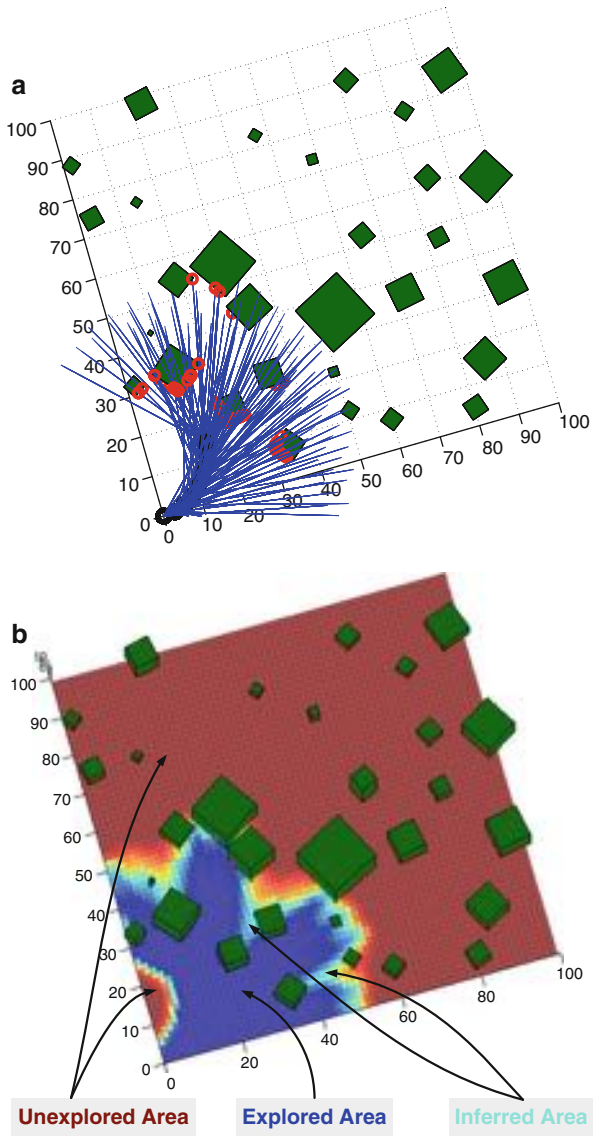

Figure 67.2 shows the laser beam data and the covariance map of the environment. Blue rays in Fig. 67.2a show laser beam data ($\mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$), and red circles represent laser beam hit locations on obstacles, and squares are obstacles. The environment is discretized to evaluate the covariance map of the environment. The purpose of this discretization is only intended for visualization of the covariance. In practice, this discretization is not required. The result of the covariance evaluation of the environment is shown in Fig. 67.2b.

The advantage of GP is that it has an ability to infer into an area occluded by obstacles. Figure 67.2b shows this property. Purple denotes a highly uncertain area and blue denotes a certain area; the color between purple and blue denotes the level of inference of uncertainty. If there is laser beam data surrounding a testing point, the GP function generates a small covariance value which is represented as a blue color. However, if there is no laser beam data around a testing point, it outputs a high covariance value which is represented as a purple color. Though there is no laser beam data near the testing point, the GP can infer the uncertainty based on neighboring laser beam data. The ability to extract information from an unexplored area is a strength of the GP.

67.3.4 Information-Theoretic Path Planning Algorithm

The objective of exploration is to get as much information as possible on the environment in a cost effective way.

Algorithm 2 shows the proposed information-theoretic path planning algorithm. There are four functions in this algorithm. First, the **Candidate Path Generation** function generates several candidate paths as shown in Fig. 67.3. Second, the **Sensor Emulation** function simulates laser beams along the path. Thirdly, the **Information Evaluation** function calculates the mutual information of each path. Finally, the **Informative Path Selection** function compares the information gain of each path and chooses the most informative path.

67.3.4.1 Candidate Path Generation

The role of the **Candidate Path Generation** function is to generate several candidate paths which satisfy the feasibility and safety conditions using GP map.

Fig. 67.3 The difficulties of an exploration mission: The planner must satisfy the differential constraints of the vehicle, and generate a collision-free path, overcoming a limited sensor field of view and occlusion due to obstacles

Algorithm 2 Information-theoretic path planning algorithm

- 1: Candidate Path Generation
- 2: Sensor Emulation
- 3: Information Evaluation
- 4: Informative Path Selection

Figure 67.4 shows the generated paths at the current vehicle position in Fig. 67.2a. All paths satisfy the nonholonomic constraints of the vehicle. There are no collisions between obstacles near the starting point, but there are collisions where there is little information about the environment. When a path is planned, the uncertain area is regarded as free space. If the uncertain area is considered an obstacle, the planner cannot generate a path outside of the certain area. This assumption does not affect the safety of the vehicle because as the vehicle receives information about the environment, the obstacles are identified. If any potential collisions are detected along the path, the planner triggers replanning of the path to generate a new collision-free path.

67.3.4.2 Sensor Emulation

To evaluate the information of the path, it is necessary to emulate the laser beam along the path. Firstly, the sensor emulation points are decided, and then laser beam data are radiated at these points.

Figure 67.5 shows the laser beam data. Blue rays in Fig. 67.5a represent accumulated real laser beam data (Λ^r), red rays in Fig. 67.5b represent simulated

Fig. 67.4 Candidate path generation satisfying the feasibility requirement and safety condition: The *square* is a starting point of the planning, the *red dashed line* is the flight path of the vehicle, and the *cyan square* are generated candidate paths

Fig. 67.5 Laser beam data: (a) shows 3D accumulated real laser beam data. (b) Red rays represent simulated laser beam data. (c) and (d) are the 2D representations of the laser beams of (a) and (b)

laser beam data (Λ^s), and Λ^c represents combined blue and red laser beams in Fig. 67.5b. Figure 67.5c, d are 2D representations of Fig. 67.5a, b.

67.3.4.3 Information Evaluation

The quality of the path can be determined by measuring the amount of reduction in the uncertainty of the environment. The goal of information evaluation is to select a path with the least uncertainty after observations are made. Mutual information is the fittest measure to quantify the variance of information about the unsensed area. Mutual information can be obtained by comparing the covariance of the environment using the real accumulated laser data with the combined laser data.

Consider Λ^r as the accumulated real laser beam data, Λ^s as the simulated laser beam data at points obtained from the *Sensor Emulation* algorithm, and $\Lambda^c = \Lambda^r \cup \Lambda^s$ as the combined data of both laser beams. There are N testing points $\mathcal{X}^t = \{\mathbf{x}_1^t, \mathbf{x}_2^t, \dots, \mathbf{x}_N^t\}$ in the environment for the evaluation of the information.

Using the *Sparse Training Data Extraction* algorithm in Sect. 67.2, n number of orthogonal points are obtained. Let $\mathcal{X}^r = \{\mathbf{x}_1^r, \mathbf{x}_2^r, \dots, \mathbf{x}_n^r\}$ be the extracted orthogonal points from accumulated real laser beam data (Λ_r), and $\mathcal{X}_i^c = \{\mathbf{x}_1^c, \mathbf{x}_2^c, \dots, \mathbf{x}_n^c\}$ be the extracted orthogonal points from i th combined laser beam data (Λ_i^c).

Condition on \mathcal{X}^r and \mathcal{X}_i^c , the covariance at testing input \mathcal{X}^t becomes

$$\mathbf{K}^r = k(\mathbf{x}^t, \mathbf{x}^t) - k(\mathbf{x}^t, \mathbf{x}^r) k(\mathbf{x}^r, \mathbf{x}^r)^{-1} k(\mathbf{x}^r, \mathbf{x}^t) \quad (67.18)$$

$$\mathbf{K}_i^c = k(\mathbf{x}^t, \mathbf{x}^t) - k(\mathbf{x}^t, \mathbf{x}^c) k(\mathbf{x}^c, \mathbf{x}^c)^{-1} k(\mathbf{x}^c, \mathbf{x}^t) \quad (67.19)$$

where \mathbf{K}^r is a covariance obtained from accumulated real laser beam data and \mathbf{K}_i^c is a predicted covariance of i th path.

Then, the mutual information in i th candidate path can be obtained:

$$I_i = \log |\mathbf{K}^r| - \log |\mathbf{K}_i^c| \quad (67.20)$$

where $\log |\mathbf{K}^r|$ is an entropy of the environment before sensor observation, and $\log |\mathbf{K}_i^c|$ is an entropy of the environment after sensor observation of i th path is made.

67.3.4.4 Informative Path Selection

Mutual information explicitly presents the amount of the uncertainty reduction. Therefore, a path which outputs maximum mutual information can offer more information about the environment. After evaluating the mutual information of all candidate paths, a path which gets the largest mutual information is chosen as the most informative path.

67.4 Simulation Experiments

Simulations were conducted of an exploration mission of an unknown environment. The objective of exploration is to maximize information about the environment. The environment is filled with obstacles of which the locations and size are randomly generated. The environment is discretized (1.5×1.5 m) for the covariance evaluation of the environment. In practice, this process is not required during the planning, but it is discretized here only for visualization purposes.

Figures 67.6 and 67.7 show the first exploration results. The candidate path number is set to 10. Figure 67.6a shows the environment to explore. Initially, the planner has no information about the environment. Figure 67.6b shows ten candidate paths and a covariance map of the environment. Purple denotes a highly uncertain areas and the blue denotes certain areas; the color between the purple and blue denotes the level of inference of uncertainty. The magenta asterisks represent laser beam hits to obstacles. The red curve denotes the selected best informative path, the black curve is the previous best path, the cyan curves represents the other

Fig. 67.6 Information-theoretic exploration case I

Fig. 67.7 Information-theoretic exploration case I (continue)

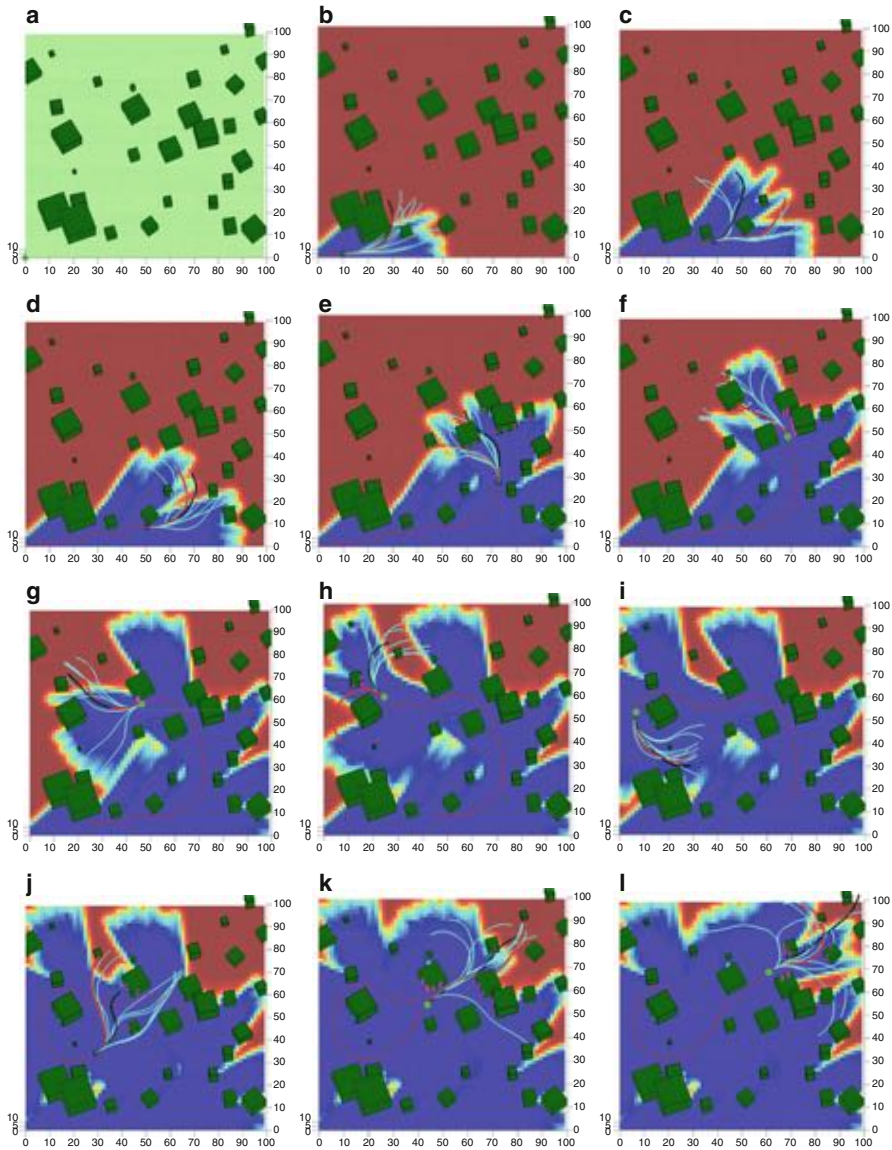

Fig. 67.8 Information-theoretic exploration case II

candidate paths, and the dotted red line is the flight path of the UAV. There are severe occlusions due to obstacles as can be seen in Fig. 67.6b–l. However, even though there are no laser beam data within the occluded area, GP can infer the information about these areas. With this inference ability, the planner can choose the most informative path. The planner selects the most right-side candidate path

Fig. 67.9 Information-theoretic exploration case II (continue)

as a best informative path because this path can offer more information about the environment as shown in Fig. 67.6b. On the contrary, the planner selects the left-side as a best informative path because the UAV already acquire more information about the right direction area than that of the left as shown in Fig. 67.6c. In this way, the UAV selects the path which expands toward unexplored area as can be seen

in Fig. 67.6. As can be expected, the mutual information measure selects the most informative path which maximally reduces the uncertainty of the environment.

Figure 67.7 shows the progress of the exploration mission of Fig. 67.6. Gradually the uncertainty of the environment is reduced. Figure 67.71 shows that the planner generates a path toward the left-bottom corner of the environment because this area is the most uncertain region in the environment.

Figures 67.8 and 67.9 show the second exploration results. The first exploration results are plotted from the top view to clearly visualize the paths and uncertainty in the environment. On the contrary, the second exploration results are plotted in 3D view. Similar to the first example, there are many occlusions due to the densely populated obstacles as shown in Fig. 67.8. However, the RRT planner incorporating the mutual information measure generates an informative collision-free feasible path which maximizes the information of the environment.

Figure 67.9 shows the progress of the exploration mission of Fig. 67.8. There are several uncertain areas in the environment, but the RRT planner gradually reduces the uncertainty. At the end of simulation, a small portion of the environment on the right edge is not observed. Figure 67.9 shows that the planner computes a path to explore the last unvisited areas.

67.5 Conclusions

A new framework which adopts a Rapidly exploring random tree path planner with a Gaussian Process occupancy map is developed for the exploration of an unknown but cluttered environment. The GP map outputs the probability of occupancy given any selected query point in the continuous space and thus makes it possible to explore the full space when used in conjunction with a continuous path planner. Furthermore, the GP map-generated path is embedded with the probability of collision along the path which lends itself to obstacle avoidance. Using mutual information as an information-theoretic measure, an informative path which reduces the uncertainty of the environment is generated. Simulation results show that GP map combined with RRT planner can achieve the 3D navigation and exploration task successfully in unknown and complex environments.

Abstract

A well-known path-planning technique for mobile robots or planar aerial vehicles is to use Dubins paths, which are minimum-distance paths between two configurations subject to the constraints of the Dubins car model. An extension of this method to a three-dimensional Dubins airplane model has recently been proposed. This chapter builds on that work showing a complete architecture for implementing Dubins airplane paths on small fixed-wing UAVs. The existing Dubins airplane model is modified to be more consistent with the kinematics of a fixed-wing aircraft. The chapter then shows how a recently proposed vector-field method can be used to design a guidance law that causes the Dubins airplane model to follow straight-line and helical paths. Dubins airplane paths are more complicated than Dubins car paths because of the altitude component. Based on the difference between the altitude of the start and end configurations, Dubins airplane paths can be classified as low, medium, or high altitude gain. While for medium and high altitude gain there are many different Dubins airplane paths, this chapter proposes selecting the path that maximizes the average altitude throughout the maneuver. The proposed architecture is implemented on a six degree-of-freedom Matlab/Simulink simulation of an Aerosonde UAV, and results from this simulation demonstrate the effectiveness of the technique.

68.1 Introduction

Unmanned aerial vehicles (UAVs) are used for a wide variety of tasks that require the UAV to be flown from one particular pose (position and attitude) to another. Most commonly, UAVs are flown from their current position and heading angle to a new desired position and heading angle. The ability to fly from one pose (or waypoint) to another is the fundamental building block upon which more sophisticated UAV navigation capabilities are built. For UAV missions involving sensors, the ability to position and orient the sensor over time is critically important. Example applications include wildlife observation and tracking, infrastructure monitoring (Rathinam et al. 2005; Frew et al. 2004; Egbert and Beard 2011), communication relays (Frew et al. 2009), meteorological measurements (Elston et al. 2010), and aerial surveillance (Rahmani et al. 2010; Elston and Frew 2008; Spry et al. 2005). Positioning and orienting the sensor is accomplished in part by planning and following paths through or above the sensing domain. Two-dimensional (2D) path planning and following at a constant altitude through unobstructed airspace is common, but as mission scenarios become increasingly sophisticated by requiring flight in three-dimensional (3D) terrain, the need for full 3D planning and guidance algorithms is becoming increasingly important.

For a vehicle that moves in a 2D plane at constant forward speed with a finite turn-rate constraint, the minimum-distance path between two configurations is termed a Dubins path. The initial and final configurations are defined by a 2D position in the plane of motion and an orientation. It has been shown that the optimal Dubins path in the absence of wind is composed of a constant radius turn, followed by a straight-line path, followed by another constant radius

turn (Dubins 1957). A vehicle that follows Dubins paths is often termed a Dubins car. There have been a wide variety of path-planning techniques proposed for mobile robots based on the Dubins car model (e.g., Hanson et al. 2011; Balluchi et al. 1996; Anderson and Milutinovic 2011; Karaman and Frazzoli 2011; Cowlagi and Tsiotras 2009; Yong and Barth 2006). The Dubins car model has also been used extensively for UAV applications by constraining the air vehicle to fly at a constant altitude (e.g., Yu and Beard 2013; Sujit et al. 2007; Yang and Kapila 2002; Shima et al. 2007).

The Dubins car model was recently extended to three dimensions to create the Dubins airplane model, where in addition to turn-rate constraints, a climb-rate constraint was added (Hosak and Ghose 2010; Chitsaz and LaValle 2007; Rahmani et al. 2010). Minimum-distance paths for the Dubins airplane were also derived in Chitsaz and LaValle (2007), using the Pontryagin minimum principle (Lewis 1986). However, in Chitsaz and LaValle (2007) some practical issues were not considered, leaving a gap between the theory and implementation on actual UAVs. The purpose of this chapter is to fill that gap. In particular, alternative equations of motion for the Dubins airplane model that include airspeed, flight-path angle, and bank angle are given. The kinematic equations of motion presented in this chapter are standard in the aerospace literature. The chapter also describes how to implement Dubins airplane paths using low-level autopilot loops, vector-field guidance laws for following straight lines and helices, and mode switching between the guidance laws.

In addition to the complexity of a third dimension of motion, Dubins airplane paths are more complicated than Dubins car paths. In particular, when the altitude component of the path falls within a specific range, there are an infinite number of paths that satisfy the minimum-distance objective. This chapter also proposes specific choices for paths that make practical sense for many UAV mission scenarios. Specifically, the path that also maximizes the average altitude of the path is selected.

The software architecture proposed in this chapter is similar to that discussed in Beard and McLain (2012) and is shown in Fig. 68.1. At the lowest level is the fixed-wing UAV. A state estimator processes sensors and produces the estimates of the state required for each of the higher levels. A low-level autopilot accepts airspeed, flight-path angle, and bank angle commands. The commands for the low-level autopilot are produced by a vector-field guidance law for following either straight-line paths or helical paths. The minimum-distance Dubins airplane path between two configurations is computed by the path manager, which also switches between commanding straight-line paths and helical paths.

This chapter will not discuss state estimation using the available sensors, but the interested reader is referred to Beard and McLain (2012) and other publications on state estimation for UAVs (see, e.g., Mahony et al. 2008; Misawa and Hedrick 1989; Brunke and Campbell 2004). Section 68.2 briefly describes assumptions on the unmanned aircraft and how the low-level autopilot is configured to produce the Dubins airplane kinematic model. Section 68.3 describes the vector-field guidance strategy used in this chapter for following both straight lines and helices. The Dubins airplane paths and the path manager used to follow them are discussed in Sect. 68.4. Section 68.5 offers concluding remarks.

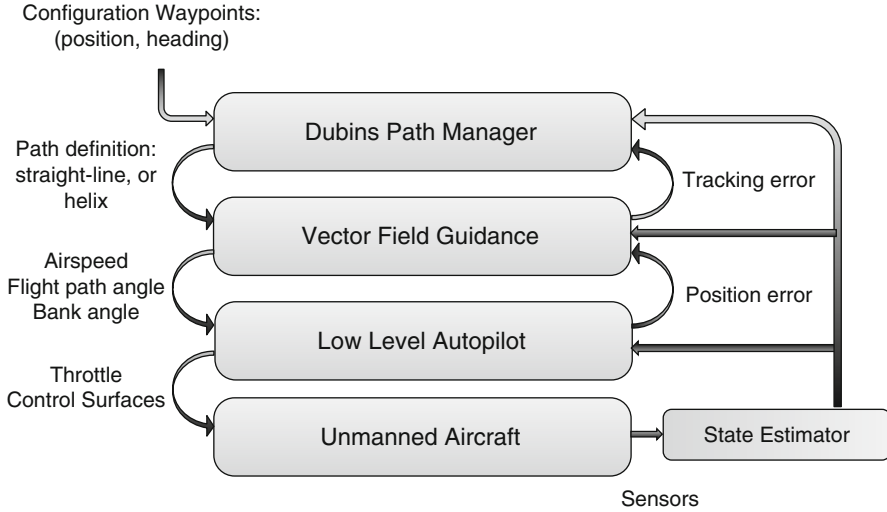

Fig. 68.1 Flight control architecture proposed in this chapter

68.2 Equations of Motion for the Dubins Airplane

Unmanned aircraft, particularly smaller systems, fly at relatively low airspeeds causing wind to have a significant effect on their performance. Since wind effects are not known prior to the moment they act on an aircraft, they are typically treated as a disturbance to be rejected in real time by the flight control system, rather than being considered during the path planning. It has been shown that vector-field-based path following methods, such as those employed in this chapter, are particularly effective at rejecting wind disturbances (Nelson et al. 2007). Treating wind as a disturbance also allows paths to be planned relative to the inertial environment, which is important as UAVs are flown in complex 3D terrain. Accordingly, when the Dubins airplane model is used for path planning, the effects of wind are not accounted for when formulating the equations of motion. In this case, the airspeed V is the same as the groundspeed, the heading angle ψ is the same as the course angle (assuming zero sideslip angle), and the flight-path angle γ is the same as the air-mass-referenced flight-path angle (Beard and McLain 2012).

Figure 68.2 depicts a UAV flying with airspeed V , heading angle ψ , and flight-path angle γ . Denoting the inertial position of the UAV as $(r_n, r_e, r_d)^T$, the kinematic relationship between the inertial velocity, $\mathbf{v} = (\dot{r}_n, \dot{r}_e, \dot{r}_d)^T$, and the airspeed, heading angle, and flight-path angle can be easily visualized as

$$\begin{pmatrix} \dot{r}_n \\ \dot{r}_e \\ \dot{r}_d \end{pmatrix} = \begin{pmatrix} V \cos \psi \cos \gamma \\ V \sin \psi \cos \gamma \\ -V \sin \gamma \end{pmatrix},$$

where $V = \|\mathbf{v}\|$.

Fig. 68.2 Graphical representation of aircraft kinematic model

This chapter assumes that a low-level autopilot regulates the airspeed V to a constant commanded value V^c , the flight-path angle γ to the commanded flight-path angle γ^c , and the bank angle ϕ to the commanded bank angle ϕ^c . In addition, the dynamics of the flight-path angle and bank angle loops are assumed to be sufficiently fast that they can be ignored for the purpose of path following. The relationship between the heading angle ψ and the bank angle ϕ is given by the coordinated turn condition (Beard and McLain 2012)

$$\dot{\psi} = \frac{g}{V} \tan \phi,$$

where g is the acceleration due to gravity.

Under the assumption that the autopilot is well tuned and the airspeed, flight-path angle, and bank angle states converge with the desired response to their commanded values, then the following kinematic model is a good description of the UAV motion:

$$\begin{aligned}
\dot{r}_n &= V \cos \psi \cos \gamma^c \\
\dot{r}_e &= V \sin \psi \cos \gamma^c \\
\dot{r}_d &= -V \sin \gamma^c \\
\dot{\psi} &= \frac{g}{V} \tan \phi^c.
\end{aligned} \tag{68.1}$$

Physical capabilities of the aircraft place limits on the achievable bank and flight-path angles that can be commanded. These physical limits on the aircraft are represented by the following constraints:

$$|\phi^c| \leq \bar{\phi} \tag{68.2}$$

$$|\gamma^c| \leq \bar{\gamma}. \tag{68.3}$$

The kinematic model given by (68.1) with the input constraints (68.2) and (68.3) will be referred to as the Dubins airplane. This model builds upon the model originally proposed for the Dubins airplane in Chitsaz and LaValle (2007), which is given by

$$\begin{aligned}
\dot{r}_n &= V \cos \psi \\
\dot{r}_e &= V \sin \psi \\
\dot{r}_d &= u_1 \quad |u_1| \leq 1 \\
\dot{\psi} &= u_2 \quad |u_2| \leq 1.
\end{aligned} \tag{68.4}$$

Although (68.1) is similar to (68.4), it captures the aircraft kinematics with greater accuracy and provides greater insight into the aircraft behavior and is more consistent with commonly used aircraft guidance models. Note, however, that (68.1) is only a kinematic model that does not include aerodynamics, wind effects, or engine/thrust limits. While it is not sufficiently accurate for low-level autopilot design, it is well suited for high-level path-planning and path-following control design. In-depth discussions of aircraft dynamic models can be found in Phillips (2010), Stevens and Lewis (2003), Nelson (1998) and Yechout et al. (2003).

68.3 3D Vector-Field Path Following

This section shows how to develop guidance laws to ensure that the kinematic model (68.1) follows straight-line and helical paths. Section 68.4 shows how straight-line and helical paths are combined to produce minimum-distance paths between start and end configurations.

68.3.1 Vector-Field Methodology

The guidance strategy will use the vector-field methodology proposed in Gonçalves et al. (2010), and this section provides a brief overview. The path to be followed in \mathbb{R}^3 is specified as the intersection of two two-dimensional manifolds given by $\alpha_1(\mathbf{r}) = 0$ and $\alpha_2(\mathbf{r}) = 0$ where α_1 and α_2 have bounded second partial derivatives, and where $\mathbf{r} \in \mathbb{R}^3$. An underlying assumption is that the path given by the intersection is connected and one-dimensional. Defining the function

$$V(\mathbf{r}) = \frac{1}{2}\alpha_1^2(\mathbf{r}) + \frac{1}{2}\alpha_2^2(\mathbf{r})$$

gives

$$\frac{\partial V}{\partial \mathbf{r}} = \alpha_1(\mathbf{r}) \frac{\partial \alpha_1}{\partial \mathbf{r}}(\mathbf{r}) + \alpha_2(\mathbf{r}) \frac{\partial \alpha_2}{\partial \mathbf{r}}(\mathbf{r}).$$

Note that $-\frac{\partial V}{\partial \mathbf{r}}$ is a vector that points toward the path. Therefore following $-\frac{\partial V}{\partial \mathbf{r}}$ will transition the Dubins airplane onto the path. However, simply following $-\frac{\partial V}{\partial \mathbf{r}}$ is insufficient since the gradient is zero on the path. When the Dubins airplane is on the path, its direction of motion should be perpendicular to both $\frac{\partial \alpha_1}{\partial \mathbf{r}}$ and $\frac{\partial \alpha_2}{\partial \mathbf{r}}$. Following Gonçalves et al. (2010) the desired velocity vector $\mathbf{u}' \in \mathbb{R}^3$ can be chosen as

$$\mathbf{u}' = -K_1 \frac{\partial V}{\partial \mathbf{r}} + K_2 \frac{\partial \alpha_1}{\partial \mathbf{r}} \times \frac{\partial \alpha_2}{\partial \mathbf{r}}, \quad (68.5)$$

where K_1 and K_2 are symmetric tuning matrices. It is shown in Gonçalves et al. (2010) that the dynamics $\dot{\mathbf{r}} = \mathbf{u}'$, where \mathbf{u}' is given by Eq. (68.5), results in \mathbf{r} asymptotically converging to a trajectory that follows the intersection of α_1 and α_2 if K_1 is positive definite, and where the definiteness of K_2 determines the direction of travel along the trajectory.

The problem with Eq. (68.5) is that the magnitude of the desired velocity \mathbf{u}' may not equal V , the velocity of the Dubins airplane. Therefore \mathbf{u}' is normalized as

$$\mathbf{u} = V \frac{\mathbf{u}'}{\|\mathbf{u}'\|}. \quad (68.6)$$

Fortunately, the stability proof in Gonçalves et al. (2010) is still valid when \mathbf{u}' is normalized as in Eq. (68.6).

Setting the NED components of the velocity of the Dubins airplane model given in Eq. (68.1) to $\mathbf{u} = (u_1, u_2, u_3)^\top$ gives

$$V \cos \psi^d \cos \gamma^c = u_1$$

$$V \sin \psi^d \cos \gamma^c = u_2$$

$$-V \sin \gamma^c = u_3.$$

Solving for the commanded flight-path angle γ^c and the desired heading angle ψ^d results in the expressions

$$\begin{aligned}\gamma^c &= -\text{sat}_{\bar{\gamma}} \left[\sin^{-1} \left(\frac{u_3}{V} \right) \right] \\ \psi^d &= \text{atan2}(u_2, u_1),\end{aligned}\tag{68.7}$$

where atan2 is the four quadrant inverse tangent and where the saturation function is defined as

$$\text{sat}_a[x] = \begin{cases} a & \text{if } x \geq a \\ -a & \text{if } x \leq -a \\ x & \text{otherwise} \end{cases}.$$

Assuming the inner-loop lateral-directional dynamics are accurately modeled by the coordinated-turn equation, roll-angle commands yielding desirable turn performance can be obtained from the expression

$$\phi^c = \text{sat}_{\bar{\phi}} [k_{\phi}(\psi^d - \psi)],\tag{68.8}$$

where k_{ϕ} is a positive constant.

Sections 68.3.2 and 68.3.3 apply the framework described in this section to straight-line following and helix following, respectively.

68.3.2 Straight-Line Paths

A straight-line path is described by the direction of the line and a point on the line. Let $\mathbf{c}_{\ell} = (c_n, c_e, c_d)^{\top}$ be an arbitrary point on the line, and let the direction of the line be given by the desired heading angle from north ψ_{ℓ} and the desired flight-path angle γ_{ℓ} measured from the inertial north-east plane. Therefore,

$$\mathbf{q}_{\ell} = \begin{pmatrix} q_n \\ q_e \\ q_d \end{pmatrix} \triangleq \begin{pmatrix} \cos \psi_{\ell} \cos \gamma_{\ell} \\ \sin \psi_{\ell} \cos \gamma_{\ell} \\ -\sin \gamma_{\ell} \end{pmatrix}$$

is a unit vector that points in the direction of the desired line. The straight-line path is given by

$$\mathcal{P}_{\text{line}}(\mathbf{c}_{\ell}, \psi_{\ell}, \gamma_{\ell}) = \{\mathbf{r} \in \mathbb{R}^3 : \mathbf{r} = \mathbf{c}_{\ell} + \sigma \mathbf{q}_{\ell}, \sigma \in \mathbb{R}\}.\tag{68.9}$$

A unit vector that is perpendicular to the longitudinal plane defined by \mathbf{q}_{ℓ} is given by

Fig. 68.3 This figure shows how the straight-line path $\mathcal{P}_{\text{line}}(\mathbf{c}_\ell, \psi_\ell, \gamma_\ell)$ is defined by the intersection of the two surfaces given by $\alpha_{\text{lon}}(\mathbf{r}) = 0$ and $\alpha_{\text{lat}}(\mathbf{r}) = 0$

$$\mathbf{n}_{\text{lon}} \triangleq \begin{pmatrix} -\sin \psi_\ell \\ \cos \psi_\ell \\ 0 \end{pmatrix}.$$

Similarly, a unit vector that is perpendicular to the lateral plane defined by \mathbf{q}_ℓ is given by

$$\mathbf{n}_{\text{lat}} \triangleq \mathbf{n}_{\text{lon}} \times \mathbf{q}_\ell = \begin{pmatrix} -\cos \psi_\ell \sin \gamma_\ell \\ -\sin \psi_\ell \sin \gamma_\ell \\ -\cos \gamma_\ell \end{pmatrix}.$$

It follows that $\mathcal{P}_{\text{line}}$ is given by the intersection of the surfaces defined by

$$\alpha_{\text{lon}}(\mathbf{r}) \triangleq \mathbf{n}_{\text{lon}}^\top (\mathbf{r} - \mathbf{c}_\ell) = 0 \quad (68.10)$$

$$\alpha_{\text{lat}}(\mathbf{r}) \triangleq \mathbf{n}_{\text{lat}}^\top (\mathbf{r} - \mathbf{c}_\ell) = 0. \quad (68.11)$$

Figure 68.3 shows \mathbf{q}_ℓ , \mathbf{c}_ℓ , and the surfaces defined by $\alpha_{\text{lon}}(\mathbf{r}) = 0$ and $\alpha_{\text{lat}}(\mathbf{r}) = 0$.

The gradients of α_{lon} and α_{lat} are given by

$$\begin{aligned} \frac{\partial \alpha_{\text{lon}}}{\partial \mathbf{r}} &= \mathbf{n}_{\text{lon}} \\ \frac{\partial \alpha_{\text{lat}}}{\partial \mathbf{r}} &= \mathbf{n}_{\text{lat}}. \end{aligned}$$

Therefore, before normalization, the desired velocity vector is given by

$$\mathbf{u}'_{\text{line}} = K_1 (\mathbf{n}_{\text{lon}} \mathbf{n}_{\text{lon}}^\top + \mathbf{n}_{\text{lat}} \mathbf{n}_{\text{lat}}^\top) (\mathbf{r} - \mathbf{c}_\ell) + K_2 (\mathbf{n}_{\text{lon}} \times \mathbf{n}_{\text{lat}}). \quad (68.12)$$

68.3.3 Helical Paths

A time-parameterized helical path is given by

$$\mathbf{r}(t) = \mathbf{c}_h + \begin{pmatrix} R_h \cos(\lambda_h t + \psi_h) \\ R_h \sin(\lambda_h t + \psi_h) \\ -t R_h \tan \gamma_h \end{pmatrix}, \quad (68.13)$$

where $\mathbf{r}(t) = \begin{pmatrix} r_n \\ r_e \\ r_d \end{pmatrix}(t)$ is the position along the path, $\mathbf{c}_h = (c_n, c_e, c_d)^\top$ is the center of the helix, and the initial position of the helix is

$$\mathbf{r}(0) = \mathbf{c}_h + \begin{pmatrix} R_h \cos \psi_h \\ R_h \sin \psi_h \\ 0 \end{pmatrix}$$

and where R_h is the radius, $\lambda_h = +1$ denotes a clockwise helix ($N \rightarrow E \rightarrow S \rightarrow W$), and $\lambda_h = -1$ denotes a counterclockwise helix ($N \rightarrow W \rightarrow S \rightarrow E$), and where γ_h is the desired flight-path angle along the helix.

To find two surfaces that define the helical path, the time parameterization in (68.13) needs to be eliminated. Equation (68.13) gives

$$(r_n - c_n)^2 + (r_e - c_e)^2 = R_h^2.$$

In addition, divide the east component of $\mathbf{r} - \mathbf{c}_h$ by the north component to get

$$\tan(\lambda_h t + \psi_h) = \frac{r_e - c_e}{r_n - c_n}$$

Solving for t and plugging into the third component of (68.13) gives

$$r_d - c_d = -\frac{R_h \tan \gamma_h}{\lambda_h} \left(\tan^{-1} \left(\frac{r_e - c_e}{r_n - c_n} \right) - \psi_h \right).$$

Therefore, normalizing these equations by R_h results in

$$\begin{aligned} \alpha_{\text{cyl}}(\mathbf{r}) &= \left(\frac{r_n - c_n}{R_h} \right)^2 + \left(\frac{r_e - c_e}{R_h} \right)^2 - 1 \\ \alpha_{\text{pl}}(\mathbf{r}) &= \left(\frac{r_d - c_d}{R_h} \right) + \frac{\tan \gamma_h}{\lambda_h} \left(\tan^{-1} \left(\frac{r_e - c_e}{r_n - c_n} \right) - \psi_h \right). \end{aligned}$$

Normalization by R_h makes the gains on the resulting control strategy invariant to the size of the orbit.

Fig. 68.4 A helical path for parameters $\mathbf{c}_h = (0, 0, 0)^\top$, $R_h = 30$ m, $\gamma_h = \frac{15\pi}{180}$ rad, and $\lambda_h = +1$

A helical path is then defined as

$$\mathcal{P}_{\text{helix}}(\mathbf{c}_h, \psi_h, \lambda_h, R_h, \gamma_h) = \{\mathbf{r} \in \mathbb{R}^3 : \alpha_{\text{cyl}}(\mathbf{r}) = 0 \text{ and } \alpha_{\text{pl}}(\mathbf{r}) = 0\}. \quad (68.14)$$

The two surfaces $\alpha_{\text{cyl}}(\mathbf{r}) = 0$ and $\alpha_{\text{pl}}(\mathbf{r}) = 0$ are shown in Fig. 68.4 for parameters $\mathbf{c}_h = (0, 0, 0)^\top$, $R_h = 30$ m, $\gamma_h = \frac{15\pi}{180}$ rad, and $\lambda_h = +1$. The associated helical path is the intersection of the two surfaces.

The gradients of α_{cyl} and α_{pl} are given by

$$\begin{aligned} \frac{\partial \alpha_{\text{cyl}}}{\partial \mathbf{r}} &= \left(2 \frac{r_n - c_n}{R_h}, 2 \frac{r_e - c_e}{R_h}, 0 \right)^\top \\ \frac{\partial \alpha_{\text{pl}}}{\partial \mathbf{r}} &= \left(\frac{\tan \gamma_h}{\lambda_h} \frac{-(r_e - c_e)}{(r_n - c_n)^2 + (r_e - c_e)^2}, \frac{\tan \gamma_h}{\lambda_h} \frac{(r_n - c_n)}{(r_n - c_n)^2 + (r_e - c_e)^2}, \frac{1}{R_h} \right)^\top. \end{aligned}$$

Before normalization, the desired velocity vector is given by

$$\mathbf{u}'_{\text{helix}} = K_1 \left(\alpha_{\text{cyl}} \frac{\partial \alpha_{\text{cyl}}}{\partial \mathbf{r}} + \alpha_{\text{pl}} \frac{\partial \alpha_{\text{pl}}}{\partial \mathbf{r}} \right) + \lambda K_2 \left(\frac{\partial \alpha_{\text{cyl}}}{\partial \mathbf{r}} \times \frac{\partial \alpha_{\text{pl}}}{\partial \mathbf{r}} \right), \quad (68.15)$$

where

$$\frac{\partial \alpha_{\text{cyl}}}{\partial \mathbf{r}} \times \frac{\partial \alpha_{\text{pl}}}{\partial \mathbf{r}} = \frac{2}{R_h} \left(\frac{r_e - c_e}{R_h}, -\frac{r_n - c_n}{R_h}, \lambda_h \tan \gamma_h \right)^\top.$$

68.4 Minimum-Distance Airplane Paths

This section describes how to concatenate straight-line and helix paths to produce minimum-distance paths between two configurations for the Dubins airplane model. A configuration is defined as the tuple (z_n, z_e, z_d, ψ) , where $(z_n, z_e, z_d)^\top$ is a

north-east-down position referenced to an inertial frame, and ψ is a heading angle measured from north. Given the kinematic model (68.1) subject to the constraints (68.2) and (68.3), a Dubins airplane path refers to a minimum-distance path between a start configuration $(z_{ns}, z_{es}, z_{ds}, \psi_s)$ and an end configuration $(z_{ne}, z_{ee}, z_{de}, \psi_e)$. Minimum-distance paths for the Dubins airplane are derived in Chitsaz and LaValle (2007) using the Pontryagin Maximum Principle for the dynamics given in (68.4) with constraints $\bar{\gamma} = 1$ and $\bar{\phi} = 1$. This section recasts the results from Chitsaz and LaValle (2007) using the standard aircraft kinematic model given in (68.1) using the constraints (68.2) and (68.3).

68.4.1 Dubins Car Paths

Minimum-distance paths for the Dubins airplane are closely related to minimum-distance paths for the Dubins car. This section briefly reviews Dubins car paths, which were originally developed in Dubins (1957) using the notation and methods defined in Beard and McLain (2012).

The Dubins car model is a subset of (68.4) given by

$$\begin{aligned}\dot{r}_n &= V \cos \psi \\ \dot{r}_e &= V \sin \psi \\ \dot{\psi} &= u,\end{aligned}\tag{68.16}$$

where $|u| \leq \bar{u}$. For the Dubins car, the minimum turn radius is given by

$$R_{\min} = V/\bar{u}.\tag{68.17}$$

The Dubins car path is defined as the minimum-distance path from the start configuration (z_{ns}, z_{es}, ψ_s) to the end configuration (z_{ne}, z_{ee}, ψ_e) . As shown in Dubins (1957), the minimum-distance path between two different configurations consists of a circular arc of radius R_{\min} that starts at the initial configuration, followed by a straight line, and concluding with another circular arc of radius R_{\min} that ends at the final configuration.

As shown in Fig. 68.5, for any given start and end configurations, there are four possible paths consisting of an arc, followed by a straight line, followed by an arc. RSR is a right-handed arc followed by a straight line followed by another right-handed arc. RSL is a right-handed arc followed by a straight line followed by a left-handed arc. LSR is a left-handed arc followed by a straight line followed by a right-handed arc. LSL is a left-handed arc followed by a straight line followed by another left-handed arc. The Dubins path is defined as the case with the shortest path length.

As explained in Beard and McLain (2012), the guidance algorithm for following a Dubins car path consists of switching between orbit following and straight-line following. Figure 68.6 shows the parameters that are required by the guidance

Fig. 68.5 Given a start configuration (z_{ns}, z_{es}, ψ_s) , an end configuration (z_{ne}, z_{ee}, ψ_e) , and a radius R , there are four possible paths consisting of an arc, a straight line, and an arc. The Dubins path is defined as the case that results in the shortest path length, which for this scenario is RSR

Fig. 68.6 The parameters that are required by the guidance algorithm to follow a Dubins car path

algorithm to follow a Dubins car path. Given that the vehicle configuration is close to the start configuration (\mathbf{z}_s, ψ_s) , the vehicle is initially commanded to follow an orbit with center \mathbf{c}_s and orbit direction λ_s . The orbit is followed until the vehicle crosses half-plane $\mathcal{H}_s(\mathbf{w}_s, \mathbf{q}_s)$, or in other words until its position \mathbf{r} satisfies

$$(\mathbf{r} - \mathbf{w}_s)^\top \mathbf{q}_s \geq 0,$$

where \mathbf{w}_s is a position on the half-plane and \mathbf{q}_s is a unit vector orthogonal to the half-plane. The vehicle then follows the straight line defined by $(\mathbf{w}_s, \mathbf{q}_s)$ until it crosses half-plane $\mathcal{H}_\ell(\mathbf{w}_\ell, \mathbf{q}_\ell)$. It then follows the orbit with center \mathbf{c}_e and direction λ_e until it crosses half-plane $\mathcal{H}_e(\mathbf{w}_e, \mathbf{q}_e)$ and completes the Dubins car path. Accordingly the parameters that define a Dubins car path are given by

$$\mathcal{D}_{\text{car}} = (R, \mathbf{c}_s, \lambda_s, \mathbf{w}_s, \mathbf{q}_s, \mathbf{w}_\ell, \mathbf{q}_\ell, \mathbf{c}_e, \lambda_e, \mathbf{w}_e, \mathbf{q}_e). \quad (68.18)$$

The length of the Dubins car path depends explicitly on the turning radius R and will be denoted as $L_{\text{car}}(R)$. Details of how to compute $L_{\text{car}}(R)$ as well as the parameters \mathcal{D}_{car} are given in Beard and McLain (2012).

68.4.2 Dubins Airplane Paths

Dubins airplane paths are more complicated than Dubins car paths because of the altitude component. As described in Chitsaz and LaValle (2007) there are three different cases for Dubins airplane paths that depend on the altitude difference between the start and end configuration, the length of the Dubins car path, and the flight-path limit $\bar{\gamma}$. The three cases are defined to be *low altitude*, *medium altitude*, and *high altitude*. In contrast to (68.17), the minimum turn radius for a Dubins airplane is given by

$$R_{\min} = \frac{V^2}{g} \tan \bar{\phi}. \quad (68.19)$$

The altitude gain between the start and end configuration is said to be *low altitude* if

$$|z_{de} - z_{ds}| \leq L_{\text{car}}(R_{\min}) \tan \bar{\gamma},$$

where the term on the right is the maximum altitude gain that can be obtained by flying at flight-path angle $\pm \bar{\gamma}$ for a distance of $L_{\text{car}}(R_{\min})$. The altitude gain is said to be *medium altitude* if

$$L_{\text{car}}(R_{\min}) \tan \bar{\gamma} < |z_{de} - z_{ds}| \leq [L_{\text{car}}(R_{\min}) + 2\pi R_{\min}] \tan \bar{\gamma},$$

where the addition of the term $2\pi R_{\min}$ accounts for adding one orbit at radius R_{\min} to the path length. The altitude gain is said to be *high altitude* if

$$|z_{de} - z_{ds}| > [L_{\text{car}}(R_{\min}) + 2\pi R_{\min}] \tan \bar{\gamma}.$$

The following three sections describe how Dubins car paths are modified to produce Dubins airplane paths for low, high, and medium-altitude cases.

68.4.2.1 Low-Altitude Dubins Paths

In the low-altitude case, the altitude gain between the start and end configurations can be achieved by flying the Dubins car path with a flight-path angle satisfying constraint (68.3). Therefore, the optimal flight-path angle can be computed by

$$\gamma^* = \tan^{-1} \left(\frac{|z_{de} - z_{ds}|}{L_{\text{car}}(R_{\min})} \right).$$

The length of the Dubins airplane path is given by

$$L_{\text{air}}(R_{\min}, \gamma^*) = \frac{L_{\text{car}}(R_{\min})}{\cos \gamma^*}.$$

The parameters required to define a low-altitude Dubins airplane path are the same parameters for the Dubins car given in (68.18) with the addition of the optimal flight-path angle γ^* and the angles of the start and end helices ψ_s and ψ_e . Note that for the Dubins car path ψ_s and ψ_e are not required since the orbit is flat and does not have a starting location. However, as described in Sect. 68.3.3, to follow a helix, the start angle is required. Figure 68.7 shows several Dubins airplane paths for the low-altitude case where the altitude difference is 25 m over a typical Dubins car path length of 180 m.

68.4.2.2 High-Altitude Dubins Paths

In the high-altitude case, the altitude gain cannot be achieved by flying the Dubins car path within the flight-path angle constraints. As shown in Chitsaz and LaValle (2007), the minimum-distance path is achieved when the flight-path angle is set at its limit of $\pm\bar{\gamma}$, and the Dubins car path is extended to facilitate the altitude gain. While there are many different ways to extend the Dubins car path, this chapter extends the path by spiraling a certain number of turns at the beginning or end of the path and then by increasing the turn radius by the appropriate amount.

For UAV scenarios, the most judicious strategy is typically to spend most of the trajectory at as high an altitude as possible. Therefore, if the altitude at the end configuration is higher than the altitude at the start configuration, then the path will be extended by a climbing helix at the beginning of the path, as shown in the RSR and RSL cases in Fig. 68.8. If on the other hand, the altitude at the start configuration is higher than the end configuration, then the path will be extended by a descending helix at the end of the path, as shown in the LSR and LSL cases in Fig. 68.8. If multiple turns around the helix are required, then the turns could be split between the start and end helices and still result in the same path length. For high-altitude Dubins paths, the required number of turns in the helix will be the smallest integer k such that

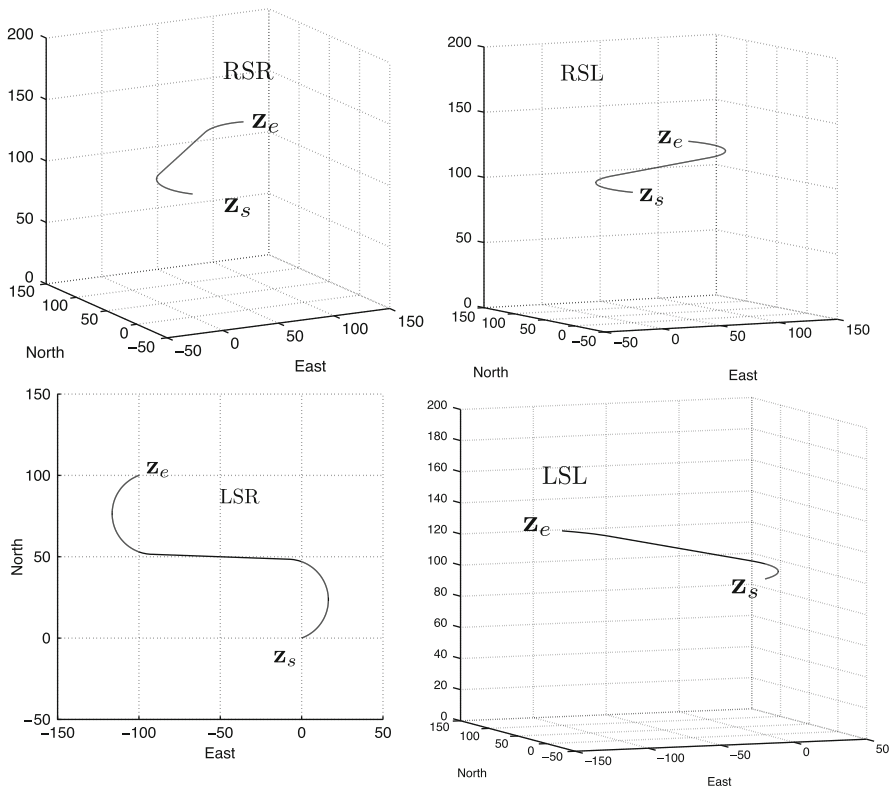

Fig. 68.7 Dubins airplane paths for the low-altitude case

$$(L_{\text{car}}(R_{\min})+2\pi kR_{\min})\tan\bar{\gamma}\leq|z_{de}-z_{ds}|<(L_{\text{car}}(R_{\min})+2\pi(k+1)R_{\min})\tan\bar{\gamma},$$

or in other words

$$k=\left\lfloor\frac{1}{2\pi R_{\min}}\left(\frac{|z_{de}-z_{ds}|}{\tan\bar{\gamma}}-L_{\text{car}}(R_{\min})\right)\right\rfloor,$$

where $\lfloor x \rfloor$ is the floor function that rounds x down to the nearest integer. The radius of the start and end helices is then increased to R^* so that

$$(L_{\text{car}}(R^*)+2\pi kR^*)\tan\bar{\gamma}=|z_{de}-z_{ds}|. \tag{68.20}$$

A bisection search is used to find R^* satisfying (68.20). The resulting path is a minimum-distance Dubins airplane path with path length

$$L_{\text{air}}(R^*,\bar{\gamma})=\frac{L_{\text{car}}(R^*)}{\cos\bar{\gamma}}.$$

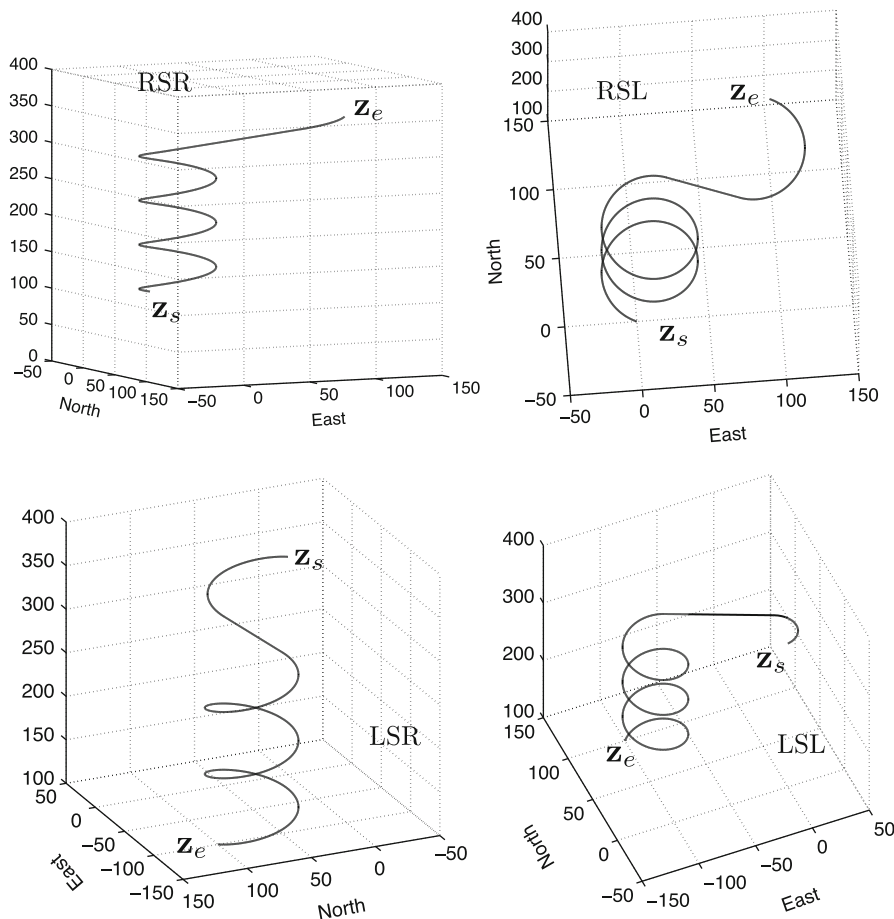

Fig. 68.8 Dubins airplane paths for the high-altitude case

The parameters required to define a high-altitude Dubins airplane path are the same parameters for the Dubins car given in (68.18) with R_{\min} replaced by R^* , the addition of the optimal flight-path angle $\pm \bar{\gamma}$, the additions of the start and end angles ψ_s and ψ_e , and the addition of the required number of turns at the start helix k_s and the required number of turns at the end helix k_e . Figure 68.8 shows several Dubins airplane paths for the high-altitude case where the altitude difference is 300 m over a typical Dubins car path length of 180 m.

68.4.2.3 Medium-Altitude Dubins Paths

In the medium-altitude case, the altitude difference between the start and end configurations is too large to obtain by flying the Dubins car path at the flight-path

Fig. 68.9 The start position of the intermediate arc is found by varying φ

angle constraint, but small enough that adding a full turn on the helix at the beginning or end of the path and flying so that $\gamma = \pm \bar{\gamma}$ results in more altitude gain than is needed. As shown in Chitsaz and LaValle (2007), the minimum-distance path is achieved by setting $\gamma = \text{sign}(z_{de} - z_{ds}) \bar{\gamma}$ and inserting an extra maneuver in the Dubins car path that extends the path length so that the altitude gain when $\gamma = \pm \bar{\gamma}$ is exactly $z_{de} - z_{ds}$. While there are numerous possible ways to extend the path length, the method proposed in this chapter is to add an additional intermediate arc to the start or end of the path, as shown in Fig. 68.9. If the start altitude is lower than the end altitude, then the intermediate arc is inserted immediately after the start helix, as shown for cases RLSR and RLSL in Fig. 68.11. If on the other hand, the start altitude is higher than the end altitude, then the intermediate arc is inserted immediately before the end helix, as shown for cases LSLR and LSRL in Fig. 68.11.

To find the Dubins path in the medium-altitude case, the position of the intermediate arc is parameterized by φ as shown in Fig. 68.9, where

$$\mathbf{z}_i = \mathbf{c}_s + R(\varphi)(\mathbf{z}_s - \mathbf{c}_s).$$

A standard Dubins car path is planned from configuration $(\mathbf{z}_i, \psi_s + \varphi)$ to the end configuration, and the new path length is given by

$$L(\varphi) = \varphi R_{\min} + L_{\text{car}}(\mathbf{z}_i, \psi_s + \varphi, \mathbf{z}_e, \psi_e).$$

Fig. 68.10 Parameters that define Dubins airplane path when an intermediate arc is inserted

A bisection search algorithm is used to find the angle φ^* so that

$$L(\varphi^*) \tan \bar{\gamma} = |z_{de} - z_{ds}|.$$

The length of the corresponding Dubins airplane path is given by

$$L_{\text{air}} = \frac{L(\varphi^*)}{\cos \bar{\gamma}}.$$

The parameters needed to describe the Dubins airplane path for the medium-altitude case are shown in Fig. 68.10. The introduction of an intermediate arc requires the additional parameters \mathbf{c}_i , ψ_i , λ_i , \mathbf{w}_i , and \mathbf{q}_i . Therefore, in analogy to (68.18), the parameters that define a Dubins airplane path are

$$\mathcal{D}_{\text{air}} = (R, \gamma, \mathbf{c}_s, \psi_s, \lambda_s, \mathbf{w}_s, \mathbf{q}_s, \mathbf{c}_i, \psi_i, \lambda_i, \mathbf{w}_i, \mathbf{q}_i, \mathbf{w}_\ell, \mathbf{q}_\ell, \mathbf{c}_e, \psi_e, \lambda_e, \mathbf{w}_e, \mathbf{q}_e). \quad (68.21)$$

Figure 68.11 shows several Dubins airplane paths for the medium-altitude case where the altitude difference is 100m over a typical Dubins car path length of 180m.

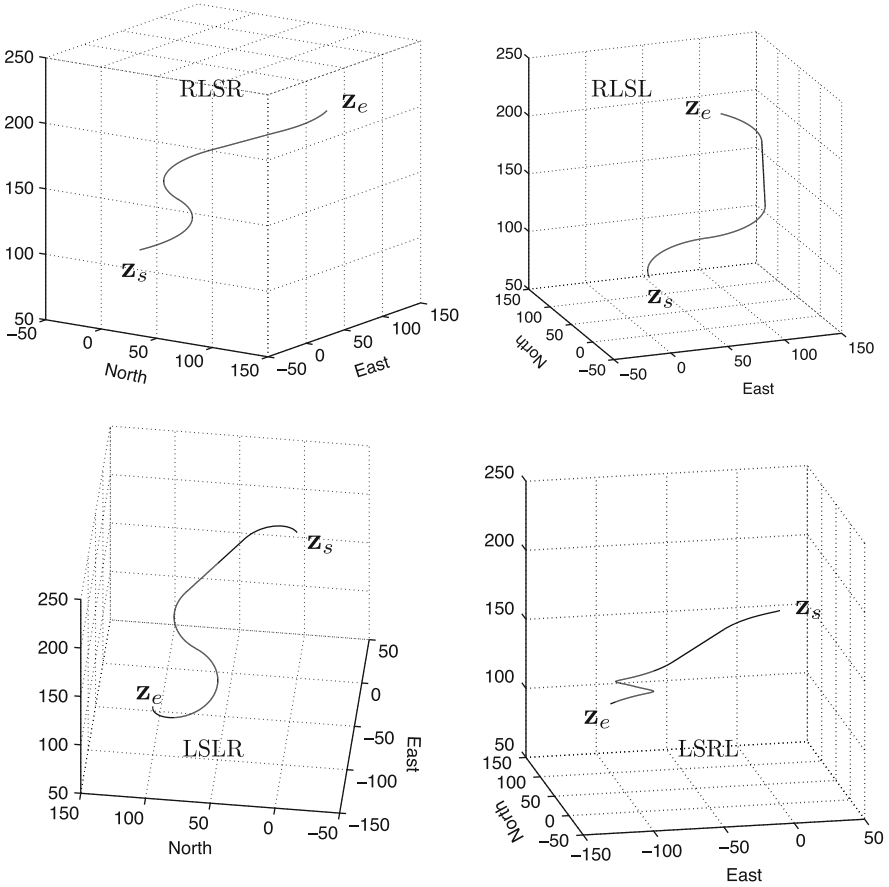

Fig. 68.11 Dubins airplane paths for the medium-altitude case

68.4.3 Path Manager for Dubins Airplane

The path manager for the Dubins airplane is shown in Fig. 68.12. With reference to (68.14), the start helix is defined as $\mathcal{P}_{\text{helix}}(\mathbf{c}_s, \psi_s, \lambda_s, R, \gamma)$. Similarly, the intermediate arc, if it exists, is defined by $\mathcal{P}_{\text{helix}}(\mathbf{c}_i, \psi_i, \lambda_i, R, \gamma)$, and the end helix is given by $\mathcal{P}_{\text{helix}}(\mathbf{c}_e, \psi_e, \lambda_e, R, \gamma)$. With reference to (68.9), the straight-line path is given by $\mathcal{P}_{\text{line}}(\mathbf{w}_\ell, \mathbf{q}_\ell)$.

68.4.4 Simulation Results

This section provides some simulation results where Dubins airplane paths are flown on a full six-degree-of-freedom UAV simulator. The aircraft used for the

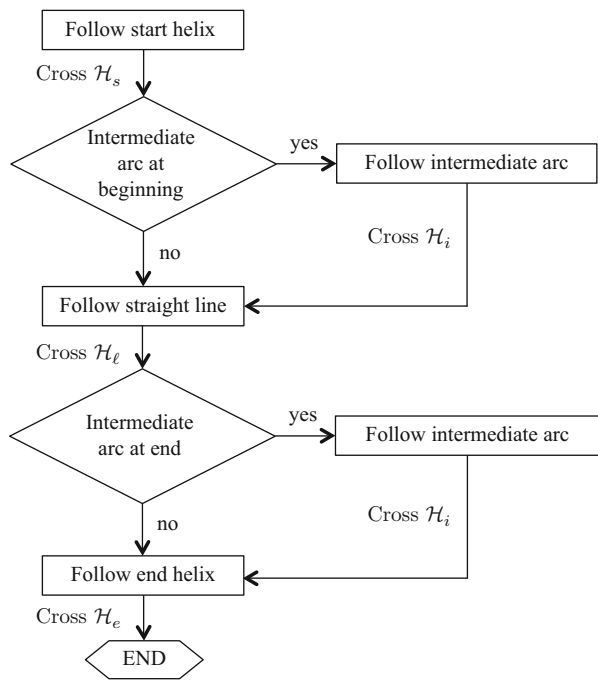

Fig. 68.12 Flow chart for the path manager for following a Dubins airplane path

simulation is the Aerosonde model described in Beard and McLain (2012). A low-level autopilot is implemented to regulate the commanded airspeed, bank angle, and flight-path angle. The windspeed in the simulation is set to zero. The simulation is implemented in Matlab/Simulink.

The simulation results for a low altitude gain maneuver are shown in Fig. 68.13, where the planned trajectory is shown in green and the actual trajectory is shown in black. The difference between the actual and planned trajectories is due to fact that the actual dynamics are much more complicated than the kinematic model given in (68.1). Simulation results for a medium altitude gain maneuver are shown in Fig. 68.14, and simulation results for a high altitude gain maneuver are shown in Fig. 68.15.

68.5 Conclusion

This chapter describes how to plan and implement Dubins airplane paths for small fixed-wing UAVs. In particular, the Dubins airplane model has been refined to be more consistent with standard aeronautics notation. A complete architecture for following Dubins airplane paths has been defined and implemented and is shown in Fig. 68.1. Dubins airplane paths consist of switching between helical and

Fig. 68.13 Simulation results for Dubins path with low altitude gain

Fig. 68.14 Simulation results for Dubins path with medium altitude gain

straight-line paths. The vector-field method described in Gonçalves et al. (2010) has been used to develop guidance laws that regulate the Dubins airplane to follow the associated helical and straight-line paths. For medium and high altitude gain scenarios, there are many possible Dubins paths. This chapter suggests selecting the path that maximizes the average altitude of the aircraft during the maneuver.

There are many possible extensions that warrant future work. First, there is a need to extend these methods to windy environments, including both constant wind and heavy gusts. Second, the assumed fast inner loops on airspeed, roll angle, and flight-path angle are often violated, especially for flight-path angle. There may be

Fig. 68.15 Simulation results for Dubins path with high altitude gain

some advantage, for path optimality in particular, to factoring the time constants of the inner loops into the planning procedure. Third, this chapter assumes a decoupling between flight-path angle and airspeed. Except for highly overpowered vehicles, however, achieving a positive flight-path angle will reduce the airspeed, and achieving a negative flight-path angle will increase the airspeed. Taking these effects into account will obviously change the optimality of the paths. Finally, there are a variety of methods that have been proposed for achieving vector-field following (see Lawrence et al. 2008; Park et al. 2007; Nelson et al. 2007). The method used in this chapter is only one possibility, that, in fact, proved challenging to tune. One of the issues is that the method assumes single integrator dynamics in each direction of motion. More robust 3D vector-field following techniques that account for the nonholonomic kinematic model of the Dubins airplane need to be developed.

Abstract

Safe and reliable operation of formations unmanned aerial vehicles (UAVs) necessitates developing situational awareness capacities for assessing and predicting the health status of both network and assets, particularly when evolving in adversarial environments. This chapter proposes a dynamic feature that is instrumental in achieving vulnerability assessment of a network of UAVs, whose control system is possibly affected by the diffusion of malware. The feature consists of the characterization of the transition from stability to instability with

probability one. The stability of the networked UAVs can be indirectly affected by malicious attacks targeting the communication units or the control systems. The network is modeled as a discrete-time, jump, linear system whose state-space variables represent the probabilities that each node receives a malware and is infected by it. The stability analysis is obtained by means of a stochastic Lyapunov function argument and yields a sufficient condition expressed as a linear matrix inequality (LMI). This LMI involves the networked asset state-space matrices and the probability that each UAV's control system is infected. An approximation to the sufficient condition is proposed so that convergence of the system trajectories could be monitored online. The proposed detection technique is validated by simulations of a UAV formation.

69.1 Introduction

Despite local and global failure detection and recovery mechanisms (see Rabbath and L  chevin (2010) and references therein), networks are prone to malfunction or to outages. In a military context, the concept of network-centric warfare, which puts forward the use of communications network, aims to increase the capability of networked weapons and surveillance, reconnaissance, intelligence, and command-and-control systems. Yet, network-centric assets, whether it be weapons or unmanned vehicles, such as aerial robotic drones, are prone to attacks at the physical layer, data-link layer, and network layer through enemy actions including jamming, deception, destruction, and information overloading. For instance, potential risks affecting air defense systems (Fig. 69.1) include (i) uplink jamming of satellite communication regarding ground communications and ground positioning (Felstead 2007); (ii) intervehicle communications systems among cooperative UAVs, which are prone to be jammed by areal intruders, thus jeopardizing the stability of the flight (see Bhattacharya and Ba  sar (2010) and references therein for related problems); (iii) invading and hacking networked air defense from a malevolent aircraft by sending data streams along with advanced algorithms (Fulghum et al. 2007); (iv) disruption of commercial-off-the-shelf microprocessor function by sending a preprogrammed code that is part of a data stream produced by malevolent aircraft and that targets radars (Adee 2008); (v) malware with the potential to corrupt and to deceive control, guidance, and navigation systems. Malware could enter the network following a strategy similar to Stuxnet (Falliere et al. 2011), which was introduced by removable disk and which has the ability to self-replicate and to execute itself on remote computers in order to modify code on programmable logic controllers. The infection by a computer virus of ground-operating cockpits used to send command signals to Predator and Reaper drones has been detected at Creech Air Force Base in Nevada (Shachtaman 2011). It is believed that a mechanism based on infected removable hard drives introduced a computer virus to the ground-operating cockpits of Predator and Reaper drones.

Other critical vehicle-based applications that necessitate accounting for potential mishaps of the communications networks include vehicle networked control

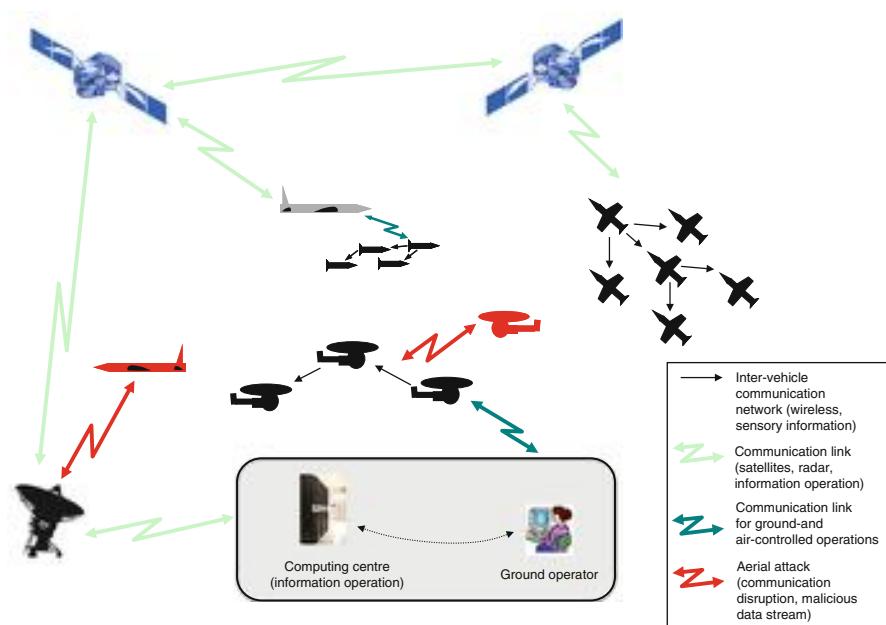

Fig. 69.1 Decentralized air system. The operation of semi-autonomous, cooperative, aircraft drones, possibly in formation flight, and of weapons is prone to vulnerabilities such as (i) intervehicle aerial communication disruption entailed by malevolent intruders and (ii) the sensitivity of satellite system's embedded protection, control, and communication devices to malicious data streams

pertaining to the automated highway (Seiler and Sengupta 2001), cooperative mobile sensor coverage (Wang and Hussein 2008; Wood et al. 2007), and wireless communications among a team of cooperative unmanned aerial vehicles (Bhattacharya and Başar 2010).

It is proposed, in this chapter, to derive stability and boundedness conditions that are expected to be implemented online for the health monitoring of a network of assets (NA). The assets consist of stabilized UAVs, each of which is equipped with a local-information-based outer-loop control law (formation controller) that ensures the stability of the formation. A healthy UAV indicates operation under nominal conditions. The network of UAVs is subject to disturbances resulting from the prevalence and propagation of infectious malicious codes (or malware) through communications network links. Malicious code includes self-replicating program such as a virus or a worm (Ford 2005). The malware affects the formation controller in such a way that the affected sensor's data are intermittently misinterpreted. In this chapter, the probability of infection is assumed to lie within the contraction region (Lohmiller and Slotine 1998) of the malware propagation's endemic state, that is, the probability that each UAV's control system is infected is always nonzero (Léchevin et al. 2011b).

Standard fault detection and identification algorithm are mostly designed to react to faulty sensors and actuators. The technique aiming to monitor the stability of networked jump dynamical systems consists in monitoring eigenvalues of an appropriate matrix of the jump system in order to detect possible stability-instability transitions. This characterization of system vulnerabilities is part of the features leveraged by the PREVU vulnerability recognition toolbox (L  chevin et al. 2011a).

The chapter is structured as follows. The context and problem formulation are presented in Sect. 69.2. The system model used for the stability analysis is given in Sect. 69.3. A stability condition, expressed as linear matrix inequalities (LMIs), and an approximate expression of this condition for online monitoring are derived in Sect. 69.4. Simulation results are presented and discussed in Sect. 69.5.

69.2 Stability Monitoring System and Recognition of Vulnerabilities

The tools proposed in this chapter for monitoring the stability of a drone formation are part of the Prediction and REcognition of VULnerabilities in very large socio-technical complex networks (PREVU) toolbox being developed at DRDC Valcartier. This toolbox relies on pattern recognition of possibly disruptive events occurring in networked dynamical systems, including infrastructures and vehicle swarms. In that framework, the vulnerability monitoring system requires a specific feature-based representation of networks, that is, feature extraction and selection is carried out to predict networks' vulnerabilities. This representation solves a classificatory problem consisting in determining the set $\theta(\omega)$ of local representations S_i of the network ω under investigation by generating a classifier ψ such that $\theta(\omega) = \{S_i \in S | \psi(\mathbf{z}_{m+1}^r, \mathbf{x}_i) = V\}$, where $\mathbf{z}_{m+1}^r = (\mathbf{x}_m^r, \mathbf{y}^r)$ is the training dataset. $\mathbf{y}^r = [y^1 \dots y^r]^T$ and \mathbf{x}_m^r are the vector of labels and the table of features representing the set of local representations (nodes, edges, clusters). V represents the vulnerability label, which is determined from a cost function expressing performance degradation, inoperability, or decrease of the quality of service of the network. The pattern recognition leverages features that are extracted from various classes (see Fig. 69.2), namely, structural features, signal and system features, and complexity features (L  chevin et al. 2011a).

Eigenvalues monitoring is proposed next to verify the stability of NA. Eigenvalues are identified as system features and are expected to complement the structural features used to analyze and predict the behavior of complex networks (L  chevin et al. 2011a; Joussetme et al. 2012).

69.3 Problem Formulation

The stability monitoring tool is applied to the chain-type formation of five autonomous quad-rotor UAVs shown in Fig. 69.3. Each vehicle is represented by a 6-degree-of-freedom (DOF), nonlinear state-space model in closed loop with a

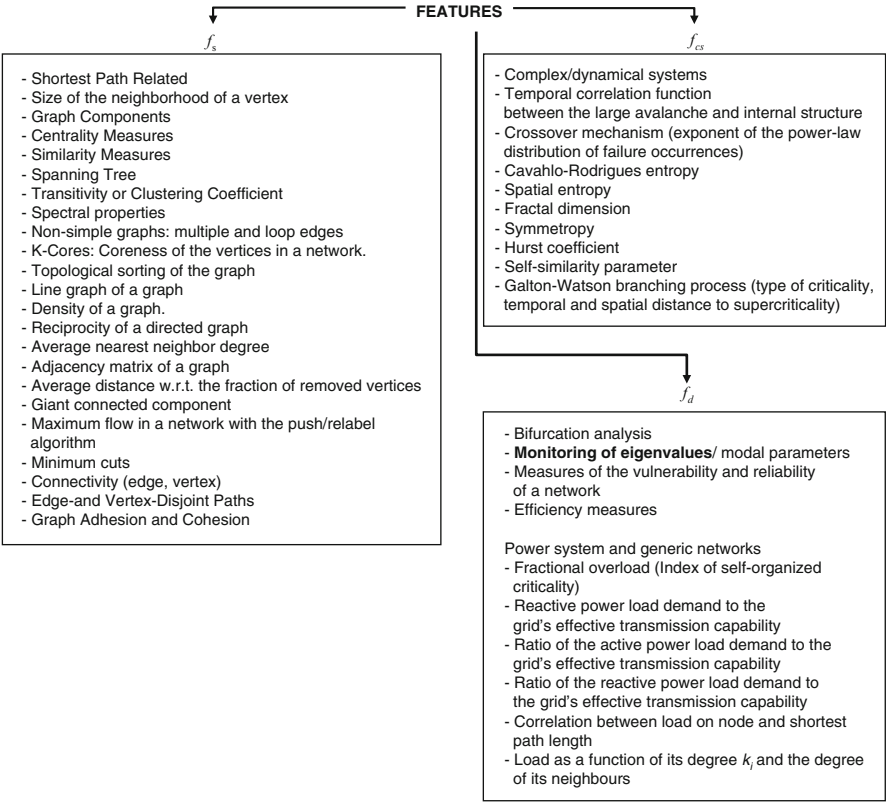

Fig. 69.2 List of features used by the classifier. This list is by no means exhaustive, for example, various measures may define the notion of centrality (Csárdi and Nepusz 2006)

control system. To account for sensor imperfection, white Gaussian measurement noise is added to the state-space vector, which comprises data from GPS and inertial measurement units (IMUs). The reader is referred to Rabbath and Léchevin (2010) for a mathematical description of the model.

The control system consists of two feedback loops (Fig. 69.4a); namely, the autopilot, which leverages the information obtained from the IMUs, and the formation controller, which is a distributed control law using local information about its neighboring vehicles (Léchevin et al. 2006). A neighbor of vehicle i is defined as any vehicle that can be sensed by i . Each of vehicles two to five of the formation illustrated in Fig. 69.3 has exactly one neighbor. Each vehicle may be affected by failures whether intended or not. In this section, the focus is on the effect of the presence of a malicious code that has been inadvertently uploaded on the electronic board of at least one drone. One can think of an infection similar to Stuxnet propagation through removable disks (Falliere et al. 2011). The coding and implementation details of such malware are not considered in this chapter.

Fig. 69.3 Formation of drone aircraft affected by unexpected events. Possible trajectories are drawn following the occurrence of a malware-induced disturbance (red) and a hardware/software failure (orange). Malware-induced behavior is considered in this chapter. The interested reader may refer to Rabbath and Léchevin (2010) for body damage and control effector fault detection

Instead, a high-level abstraction of the malware effect on the control system, as shown in Fig. 69.4b, is opted for. It is thus assumed that the high-level effect can be coded by some malicious individual or organization. The reader may refer to Rabbath and Léchevin (2010) for other types of failures that might affect teams of autonomous vehicles. It should be noted that the fault detection algorithms proposed in the aforementioned references are based on the derivation of residues, which are designed to be sensitive to actuator errors. Other algorithms are developed to be sensitive to sensor faults. In the remainder of this chapter, it is shown that monitoring the spectrum of some appropriately designed matrix is useful to detect anomalies originating from the activation of a malware designed to target the control system of a team of networked autonomous vehicles.

The malware consists, as suggested in Fig. 69.4b, of a simple process that multiplies the data x_i of vehicle i by $+1$ with a probability p^* and by -1 with a probability $1-p^*$. The formation controller operating in normal condition feeds back x_i . Therefore, it is expected that using the corrupted data $-x_i$ has a destabilizing effect on the vehicle's dynamics and thus on the formation's dynamics.

Interestingly, it should be noted that this simple malicious mechanism may be interpreted as a model for intermittent losses of communications should this mechanism be applied to data x_{i-1} while assuming that x_{i-1} is obtained by means of a communications network rather than by onboard sensors. The malware could disable receiver and emitter components onboard the drones.

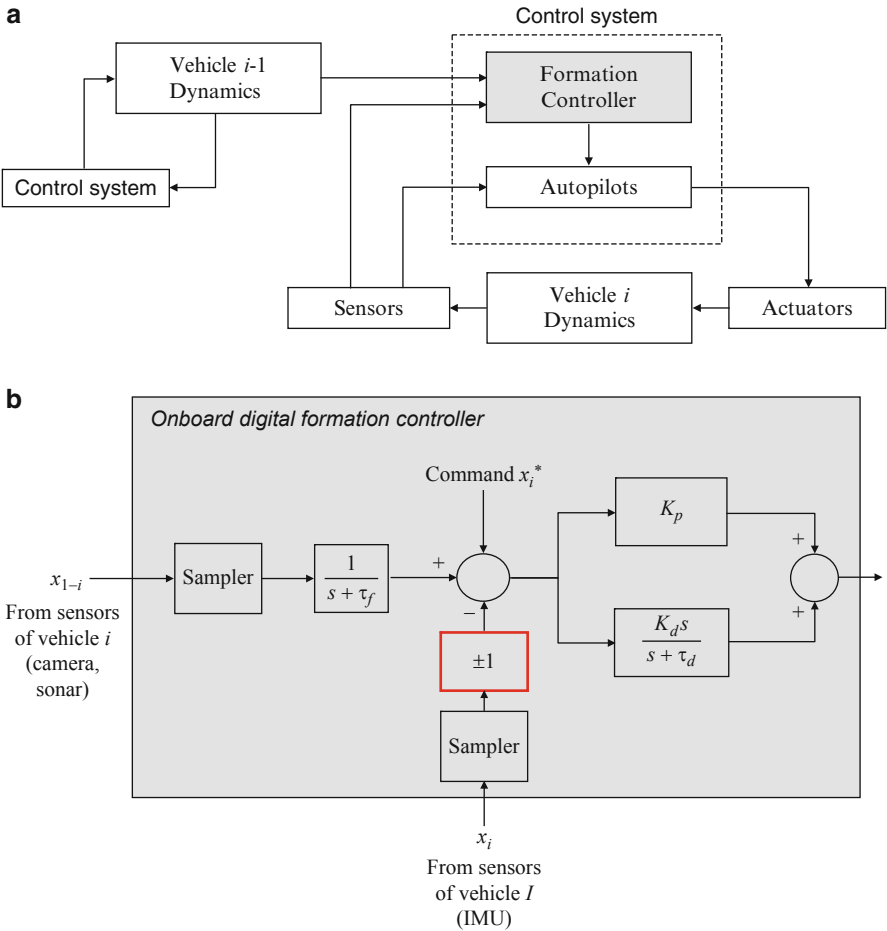

Fig. 69.4 Control system of vehicle i . **(a)** The inner-loop controller (autopilot) stabilizes the vehicle around the commanded trajectory provided by the outer-loop controller (formation controller). **(b)** Based on state vectors x_i and x_{i-1} measured by means of vehicle i 's sensors, the formation controller computes the trajectory tracked by the autopilot (Rabbath et al. 2011). The effect of the malicious code on the formation controller, implemented on vehicle i 's electronic board, is modeled by a sign change ± 1 , whose occurrence is ruled by probability p^* . An uncorrupted control system would operate with $+1$ instead of -1

Achieving system stability is a hard constraint that networked systems must satisfy. Therefore, the following stability monitoring problem is defined.

Problem Objective: To conduct online monitoring of possible stability-instability transitions of NA, the following two tasks should be carried out: (i) conditions under which the trajectories of the formation of UAVS, whose controllers are possibly corrupted by a malware of the type depicted in Fig. 69.4, converge to zero with

probability 1 (almost-sure convergence), and (ii) derive approximations of (i) that uses the information available to each UAV such as its state.

It is assumed that the ground control station is able to access at least those elements of information so that the monitoring technique can be applied. However, it is shown in the simulation section that decentralized monitoring of stability, whereby each asset monitors its health status and that of its neighbors as a means to anticipate critical situations to the NA, is possible although it does not result from a rigorous derivation.

69.4 System Model

An approximate model of each vehicle's nonlinear dynamics is used. A linearized, second-order model is selected. Parameter identification of this model is carried out from data obtained by simulating the full 6-DOF nonlinear dynamics (Rabbath and L  chevin 2010). Vehicle i 's dynamics along the x- and y-axes are decoupled in the model expressed as follows:

$$\begin{aligned} \begin{bmatrix} \dot{X}_i \\ \dot{Y}_i \end{bmatrix} &= \begin{bmatrix} A_{ix} & 0 \\ 0 & A_{iy} \end{bmatrix} \begin{bmatrix} X_i \\ Y_i \end{bmatrix} + u + W, \\ Z_i &= \begin{bmatrix} X_i \\ Y_i \end{bmatrix} + N, \\ X_i &= \begin{bmatrix} x_i - x_i^* \\ \dot{x}_i \end{bmatrix}, Y_i = \begin{bmatrix} y_i - y_i^* \\ \dot{y}_i \end{bmatrix} \end{aligned} \quad (69.1)$$

where W and N stand for the process and observation noises, respectively, which are assumed white and Gaussian. x_i^* and y_i^* are piecewise constant trajectories to be tracked by the leader. A_x and A_y are the state-space matrices of a standard second-order, linear-time, invariant system. u represents the formation controller of vehicle i . u equals zero at equilibrium.

Following (Eq. 69.1), the UAV formation equipped with the local-information-based controller (L  chevin et al. 2006) is represented by a network of assets (NA), comprised of n nodes each of which is modeled by the following discrete-time, jump, linear system

$$x_{i,k+1} = \mathbf{A}_{i,k}(\omega_{i,k})x_{i,k} + \sum_{j \in N_i^a} \mathbf{B}_{ij,k}(\omega_{i,k})x_{j,k}, \quad (69.2)$$

where N_i^a , $x_{i,k} \in \mathbb{R}^{n_i}$, and $\omega_{i,k}$ are the set of neighbors of node i , the state-space vector of asset i at t_k , and the random variable that expresses the asset i 's health status at t_k , respectively. The process and measurement noises are disregarded in (Eq. 69.2) but will be considered in simulations.

The health state of a node depends on its possible infection by the malicious code, which may affect the asset through its control system as explained in the last section.

The random matrix $\mathcal{A}_{i,k}(\omega_{i,k})$ is defined as follows. $\mathcal{A}_{i,k}(\omega_{i,k} = 0) = \bar{A}_i$ when the corresponding node i in NA is infected, which occurs with probability $p_{i,k} = P(\omega_{i,k} = 0)$, and $\mathcal{A}_{i,k}(\omega_{i,k} = 1) = A_i$ with probability $1 - p_{i,k} = P(\omega_{i,k} = 1)$, when node i is healthy. Similarly, $\mathcal{B}_{ij,k}(\omega_{i,k} = 0) = \bar{B}_{ij}$ with probability $p_{i,k}$, and $\mathcal{B}_{ij,k}(\omega_{i,k} = 1) = B_{ij}$ with probability $1 - p_{i,k}$. The interconnection matrix $\mathcal{B}_{ij,k}(\omega_{i,k})$ in (Eq. 69.2) represents the dependency of i on j . Bidirectional dependency between i and j is thus characterized by the matrix pair $(\mathcal{B}_{ij,k}(\omega_{i,k}), \mathcal{B}_{ji,k}(\omega_{j,k})) \in \{B_{ij}, \bar{B}_{ij}\} \times \{B_{ji}, \bar{B}_{ji}\}$, which is determined as a function of the state (infective or susceptible) of corresponding nodes, i on j , in NA. From (Eq. 69.2), the overall dynamics of the network of assets is given by the jump linear system

$$x_{k+1} = \mathbf{A}_k(\omega_k)x_k, \quad (69.3)$$

where $x_{k+1} = [x_{1,k}^T, \dots, x_{n,k}^T]^T$ and $\omega_k = [\omega_{1,k}, \dots, \omega_{n,k}]^T \in \{0,1\}^n$. $x_{i,k}$, and $\omega_{i,k}$ are given in (Eq. 69.2). Matrix $\mathcal{A}_k(\omega_k)$ is straightforwardly obtained from $\mathcal{A}_{i,k}(\omega_{i,k})$ and $\mathcal{B}_{ij,k}(\omega_{i,k})$ in (Eq. 69.2) for all $i \in \{1, \dots, n\}$ and $j \in N_i^a$, and is characterized by a graph Laplacian-like structure (Godsile and Royle 2001).

A nonlinear probabilistic model of malware propagation (Chakrabarti et al. 2008) is applied, in Léchevin et al. (2011b), to a communications network (CN) connected to a network of assets, where the concept of assets can be generalized to such systems as infrastructures. A contraction analysis is then carried out to derive a sufficient stability condition of CN. Here, it is assumed that the presence of the malware within NA is endemic that is the probability $p_{i,k}$ that node i is infected converges, as $k \rightarrow \infty$, to a nonzero probability $p_{i,k}^*$.

69.5 Stability Condition

69.5.1 Stability Analysis of NA

Select the following positive definite function:

$$V(x_k) = x_x^T x_k. \quad (69.4)$$

V is instrumental in the definition of the stochastic Lyapunov function candidate used for the stability analysis. Then,

$$\begin{aligned} E[V(x_{k+1})|\mathbf{F}_n] &= E[x_x^T \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k) x_k] \\ &= x_x^T \bar{p}_k A^T A x_k + \sum_{\omega_k \in I_k \setminus \mathbf{1}_n} \prod_{i=1}^n \rho_{i,k} x_x^T \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k) x_k, \end{aligned} \quad (69.5)$$

where \mathcal{F} stands for a sequence of nonincreasing σ -algebras measuring $\{x_i, i \leq n\}$, $A = \mathcal{A}_k(\omega_k = \mathbf{1}_n)$, $\rho_{i,k} \in \{p_{i,k}, 1 - p_{i,k}\}$, $I_{i,k} = \{0,1\}$, $I_i = I_{1,k} \times \dots \times I_{n,k}$, $\mathbf{1}_n$ is the $1 \times n$ unitary vector, and $\bar{p}_k = \prod_{i=1}^n (1 - p_{i,k})$.

Letting $\rho_{i,k} = \rho_{i,k}^* + \tilde{\rho}_{i,k}$, where $\rho_{i,k}^*$ and $\tilde{\rho}_{i,k}$ correspond to the endemic state and to deviation with respect to $\rho_{i,k}^*$, respectively, and $\bar{p}_k = \bar{p}_k^* + \tilde{p}_k$, where the definition of \bar{p}_k^* and \tilde{p}_k is similar to that of $\rho_{i,k}^*$ and $\tilde{\rho}_{i,k}$; (Eq. 69.5) can be expressed as

$$E[V(x_{k+1})|\mathbf{F}_n] = x_x^T (\bar{p}_k^* A^T A + \sum_{\omega_k \in I_k \setminus I_n} \prod_{i=1}^n \rho_{i,k}^* \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k)) x_k + \tilde{V}_k. \quad (69.6)$$

In (Eq. 69.6), \tilde{V}_k is defined as follows:

$$\begin{aligned} \tilde{V}_k = x_x^T & \left(\sum_{\omega_k \in I_k} M_k(\rho_{i,k}^*, \tilde{\rho}_{j,k}, i \in I, j \in J) \right. \\ & \left. \times \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k) \right) x_k, \end{aligned} \quad (69.7)$$

where $I \subset \{1, \dots, n\}$ and $J \subset \{1, \dots, n\} \setminus I$.

M_k in (Eq. 69.7) is the sum of all products expressed as $\prod_{i \in I} \rho_{i,k}^* \prod_{j \in J} \tilde{\rho}_{j,k}$, therefore $\lim_{\tilde{\rho}_k \rightarrow 0} M_k = 0$, implying that

$$\lim_{\tilde{\rho}_k \rightarrow 0} \tilde{V}_k = 0. \quad (69.8)$$

The stability analysis will thus consist in deriving a stochastic Lyapunov function candidate V_k , to be determined in the sequel. V_k is based on V and on a perturbation term, δV_k , that compensates for \tilde{V}_k in (Eq. 69.7) and that approaches zero as k goes to infinity by exploiting the fact that $p_{i,k}^*$ is attracting.

Letting

$$\begin{aligned} \bar{\lambda}(\tilde{\rho}_k) = \sup_j & \left| \lambda_j \left(\sum_{\omega_k \in I_k} M_k(\rho_{i,k}^*, \tilde{\rho}_{j,k}, i \in I, j \in J) \right. \right. \\ & \left. \left. \times \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k) \right) \right|, \end{aligned} \quad (69.9)$$

where $\lambda_j(P)$ denotes the j th eigenvalue of matrix P ; \tilde{V}_k in (Eq. 69.7) can be bounded as

$$\tilde{V}_k \leq \bar{\lambda}(\tilde{\rho}_k) \|x_k\|^2. \quad (69.10)$$

$\|x\|$ stands for the Euclidean norm of vector x . It should be noted that $\lim_{\tilde{\rho}_k \rightarrow 0} \bar{\lambda}(\tilde{\rho}_k) = 0$ since $\lim_{\tilde{\rho}_k \rightarrow 0} M_k = 0$.

The stochastic Lyapunov function candidate is now selected as follows

$$V_k(x_k) = V(x_k) + \delta V_k, \quad (69.11)$$

where $V(x_k)$ is defined in (Eq. 69.4) and

$$\delta V_k = \bar{\lambda}(\tilde{\rho}_k) \sum_{i=k}^{+\infty} \|x_i\|^2 I(\|x_i\|^2 < \|x_k\|^2 + K), \quad (69.12)$$

for some $K > 0$. δV_k is positive and can be bounded by

$$\delta V_k \leq \sup_{i \geq k} (\bar{\lambda}(\tilde{\rho}_i)) \underbrace{\sum_{i=k}^{+\infty} (\|x_k\|^2 + K)}_{S_k}. \quad (69.13)$$

The supremum in (Eq. 69.13) exits from the definition of $\bar{\lambda}(\tilde{\rho}_k)$ in (Eq. 69.9) and from the fact that $p_{i,k}^*$ is attracting. Since $S_{k+1} - S_k = -K - \|x_k\|^2 < 0$ and S_k is positive, S_k is convergent which, in turn, implies that δV_k is convergent. The convergence of $\bar{\lambda}(\tilde{\rho}_k)$ to zero as $\tilde{\rho}_k$ approaches zero, that is, as k goes to infinity, implies that

$$\lim_{k \rightarrow +\infty} \delta V_k = 0. \quad (69.14)$$

Employing (Eq. 69.5), (Eq. 69.10), (Eq. 69.11), and the fact that

$$\delta V_{k+1} - \delta V_k = -\bar{\lambda}(\tilde{\rho}_k) \|x_k\|^2 \quad (69.15)$$

yields the difference

$$\begin{aligned} E[V_{k+1}(x_{k+1})|\mathbf{F}_n] - V_k(x_k) &= x_k^T \left(\bar{p}_k^* A^T A \right. \\ &\quad \left. + \sum_{\omega_k \in I_k \setminus 1_n} \prod_{i=1}^n \rho_{i,k}^* \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k) - I \right) x_k + \tilde{V}_k \\ &\quad - \bar{\lambda}(\tilde{\rho}_k) \|x_k\|^2. \end{aligned} \quad (69.16)$$

Provided that there exists a symmetric, positive definite matrix L such that

$$\bar{p}_k^* A^T A + \sum_{\omega_k \in I_k \setminus 1_n} \prod_{i=1}^n \rho_{i,k}^* \mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k) + L < I, \quad (69.17)$$

(Eq. 69.16) is simplified as

$$E[V_{k+1}(x_{k+1})|\mathbf{F}_n] - V_k(x_k) \leq -\kappa \|x_k\|^2, \quad (69.18)$$

where $\kappa > 0$ is the smallest eigenvalue of L . The main result of this chapter is now stated.

Applying Theroem 4.2 in Kushner and Yin (1997, p. 81) to (Eq. 69.11), whose time difference is expressed in (Eq. 69.18), taking account of the convergence property of δV_k established in (Eq. 69.14), and assuming that LMI in (Eq. 69.17) is satisfied for all $k \in \mathbb{N}$, then the state x_k of NA in (Eq. 69.3) converges to zero with probability 1.

The analysis can be extended to a class of jump systems, which are excited by an additive disturbance, yielding an almost-sure boundedness of the trajectories (L  chevin et al. 2011b).

69.5.2 Approximation for Monitoring

The way online monitoring is carried out depends on the type of information that is available to the control-and-command center.

Case 1: When the identity of infected hosts is known, empirical frequency f_k^* is substituted for p_k^* in (Eq. 69.17), recalling that $\rho_{i,k}^* \in \{p_{i,k}^*, 1 - p_{i,k}^*\}$. The stability condition is monitored by direct inspection of the eigenvalues of the left-hand side of LMI in (Eq. 69.5).

Case 2: Should the estimate of the limit set p_k^* be unavailable, the left-hand side of (Eq. 69.17) can be approximated by leveraging the state x_k , which is assumed known either from measurement or from state estimation. Noting that

$$E[\mathbf{A}_k^T(\omega_k)\mathbf{A}_k(\omega_k)] = \bar{p}_k^* A^T A + \sum_{\omega_k \in I_k \setminus I_n} \prod_{i=1}^n \rho_{i,k}^* \mathbf{A}_k^T(\omega_k)\mathbf{A}_k(\omega_k), \quad (69.19)$$

and selecting $N \in \mathbb{N}$ sufficiently large, the following approximation is used:

$$E[\mathbf{A}_k^T(\omega_k)\mathbf{A}_k(\omega_k)] \cong \frac{1}{N} \sum_{j=k-N}^N A_{(j)}^T A_{(j)}, \quad (69.20)$$

where $A_{(j)}$ denotes the realization of $\mathbf{A}_j(\omega_j)$ at t_j . A least-square estimate of the average of $A_{(j)}^T A_{(j)}$ in (20) can be computed as follows. Concatenating the following expression: $x_{j+1}^T x_{j+1} = x_j^T A_{(j)}^T A_{(j)} x_j$ for all $j \in [k, k + N - 1]$ where $N \gg \text{size}(x_k)$ yields

$$X_{k,N} = Y_{k,N-1} \text{vec}_2(E_{k,N}) + \varepsilon_k, \quad (69.21)$$

where

$$\begin{aligned}
 X_{k,N-1}^T &= [x_k^T x_k, \dots, x_{k+N-1}^T x_{k+N-1}], \\
 Y_{k,N-1}^T &= [\text{vec}_1(x_k x_k^T) \dots \text{vec}_1(x_{k+N-1} x_{k+N-1}^T)] \\
 E_{k,N} &= \frac{1}{N} \sum_{j=k}^{k+N-1} A_{(j)}^T A_{(j)}, \\
 \tilde{E}_j &= A_{(j)}^T A_{(j)} - E_{k,N} \\
 \varepsilon_k^T &= [\varepsilon_{k,1}, \dots, \varepsilon_{k,j}, \dots, \varepsilon_{k,N}], \varepsilon_{k,j} = x_j^T \tilde{E}_j x_j.
 \end{aligned} \tag{69.22}$$

$\text{vec}_1(E)$ denotes the column vector formed by concatenating the rows of the upper triangular block of matrix E . $\text{vec}_2(E) = \text{vec}_1(F)$, where entries f_{ii} and e_{ii} of F and E , respectively, are such that $f_{ii} = e_{ii}$ for all i and $f_{ij} = 2e_{ij}$ for all $i \neq j$. N is such that $E(\mathcal{A}^T(\omega_i) \mathcal{A}(\omega_i)) \cong E_{k,N}$. The least-square estimate of $E_{k,N}$, which is a symmetric matrix, is given by

$$\text{vec}_2(\hat{E}_{k,N}) = (Y_{k,N-1}^T Y_{k,N-1})^{-1} Y_{k,N-1}^T X_{k,N}, \tag{69.23}$$

The approximate in (Eq. 69.23) can thus be expressed as follows:

$$E[\mathbf{A}_k^T(\omega_k) \mathbf{A}_k(\omega_k)] \cong \hat{E}_{k,N}^T. \tag{69.24}$$

The online monitoring thus consists in verifying that

$$\sup_i \lambda_i(\hat{E}_{k,N}) < 1, \tag{69.25}$$

where $\hat{E}_{k,N}$ is obtained from $\text{vec}(\hat{E}_{k,N})$ in (Eq. 69.23).

69.6 Simulation Results

A formation of quadrotor drones, whose speed is about 1 m/s, is required to track a straight line trajectory of 100 m. At time instant 75 s, the malicious mechanism is triggered with probability p^* . Intuitively, the chance of facing instabilities increases as p^* decreases. This idea is confirmed in Fig. 69.5 where it is shown that, when $p^* = 0.5$, the prescribed straight line trajectory is unstable for followers two to five. The formation remains stable for larger values of p^* , while vehicles two to five follow the leader with a nonzero steady-state error.

The simulation time step is 10 ms. $N = 3,000$, that is, a time window of 30 s is adopted. The largest eigenvalue of $\hat{E}_{k,N}$, given in (Eq. 69.23) and computed from

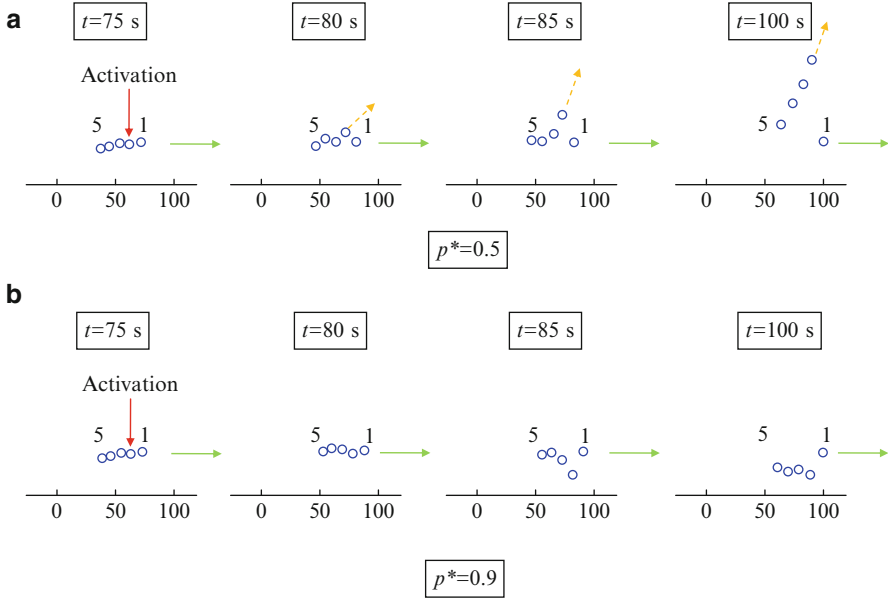

Fig. 69.5 Stability-instability transition as a function of p^* . The malicious code is activated at $t=75$ s. When $p^* \leq 0.5$, the formation's dynamics is unstable. It remains stable, although with a nonzero steady-state error, otherwise. *Green arrows* denote the desired trajectory. *Orange arrows* denote the speed vector of vehicle 2, which is affected by the malware over (75 s, 100 s)

the measurement vector $Z=[Z_1, Z_2, Z_3, Z_4, Z_5]^T$, is shown in Fig. 69.6a. It should be noted that, owing to the presence of noisy signals, a hypothesis testing is implemented to verify whether or not the maximum eigenvalue of matrix $\hat{E}_{k,N}$ is greater than one. The cumulative sum (CUSUM) algorithm is implemented (Basseville and Nikiforov 1993). The decision function is shown in Fig. 69.6b.

Setting the threshold h to 150 gives a detection time equal to 4 s, that is, the anomaly is detected at $t = 79$ s. The process by which the threshold is selected depends on the level of noise and aims to minimize the detection time while maintaining the false alarm rate below some prescribed limit.

Interestingly, the largest eigenvalue of $\hat{E}_{k,N,i}$, which is computed for each vehicle i from Z_i and not for the whole formation, is also informative. Indeed, this decoupling property could be exploited to implement a distributed version of (Eq. 69.23), which requires the knowledge of the whole formation. Applying a first-order, low-pass filter with a time constant of 10 s to the noisy signals entering the expression in (Eq. 69.23), which is now applied to each follower, yields the eigenvalue time variations in Fig. 69.6c–f, each of which corresponds to a vehicle $j \in \{2, 3, 4, 5\}$ whose unstable dynamics is detected locally whenever $\max(\hat{E}_{k,N,i})$ exceeds one. Since the malware is activated in vehicle 2, the devious motion of this vehicle is detected first. The dynamic couplings that result from the implementation of the distributed formation controllers propagate the unstable behavior of vehicle 2 to the remaining followers in the formation.

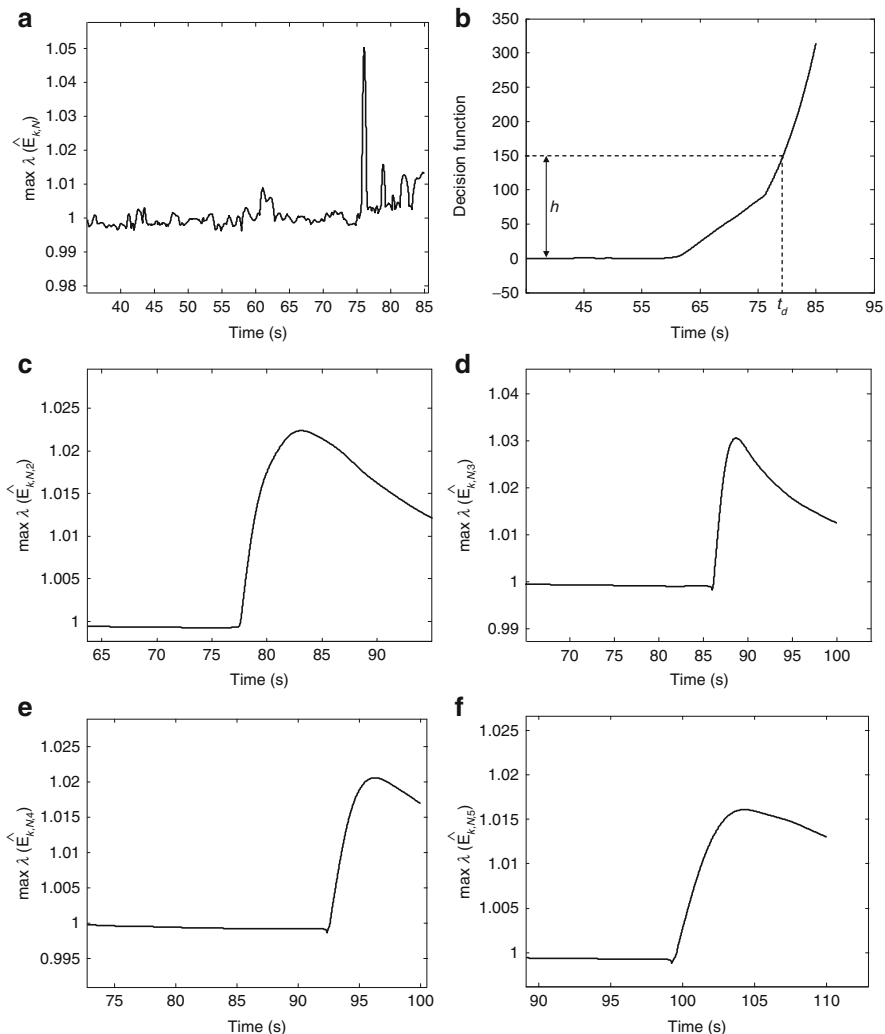

Fig. 69.6 Largest eigenvalues of $\hat{E}_{k,N}$. (a) Largest eigenvalue of the matrix $\hat{E}_{k,N}$ corresponding to the formation of five vehicles; (b) decision function of the CUSUM algorithm compared with a threshold h ; (c), (d), (e), and (f) show the largest eigenvalue of matrices $\hat{E}_{k,N,2}$, $\hat{E}_{k,N,3}$, $\hat{E}_{k,N,4}$, and $\hat{E}_{k,N,5}$, respectively

69.7 Conclusion

A great deal of effort has been devoted to the detection, identification, and mitigation of hardware-software faults and failures on critical systems such as aircraft. It is also highly desirable to analyze and possibly predict the vulnerabilities of such asset when integrated in networks, which are particularly prone to loss of efficiency and

even to potential disruption caused by the propagation of malicious code. Indeed, the activation of a malware, once it has reached some of its targets, may jeopardize the proper operation of the networked assets. Consequences range from the occurrence of stable, off-nominal operating condition to the transition to unstable operating condition, possibly leading to catastrophic events, such as mission failure and avalanche, and placing civilian and military personnel at risk in case of a network of mobile platforms.

Sufficient stability conditions are derived in this chapter, suggesting an approach for the monitoring of a network of UAVs, provided the entire state of the model is available. The model is expressed as a jump linear system. The proposed approach relies on the monitoring of the eigenvalues of a matrix expressed as a function of the measured signals.

The stability monitoring reports satisfactory results when applied to a formation flight of drone aircraft, which are stabilized by means of distributed controllers. Feedbacks are based on local information such as the relative position between two neighboring vehicles. A simple malicious mechanism corrupts the digital realization of the controller in such a way that the formation becomes unstable provided the probability of malware occurrence is less than a threshold.

Extensions of the work presented in this memorandum include (i) real-time implementation of a decentralized estimator whereby the stability monitoring is carried out with local signals, (ii) the prediction of stability-instability transitions rather than just monitoring it, and (iii) the study of best possible actions or drone adaptation techniques following the monitoring process.

Section XIII

UAV Autonomy

***Christos Cassandras, David Castañón
and LoraWeiss***

Kimon P. Valavanis and George J. Vachtsevanos

UAV Autonomy addresses perhaps the most challenging and important topic that is central to unmanned aircraft performance, autonomy. Autonomous flight is a major target goal of all technologists. The ability of a UAV to take off, execute a mission, and return to its base without significant human intervention (this is the human-on-the-loop concept rather than the human-in-the-loop current requirement) promises to enhance UAV deployment in many application domains. Contributions in this part of the handbook address levels of autonomy and those specific technical challenges that must be overcome if one aims at approaching eventually “full UAV autonomy.” Hardware and software requirements for increased autonomy are discussed with emphasis on algorithms that will bestow to the UAV features of autonomy.

► **Integrated Hardware/Software Architectures to Enable UAVs for Autonomous Flight** by Pippin describes hardware and software architecture components that enable autonomous flight operation, also presenting some recommended architectural approaches and best practices. This is deemed essential as UAVs become increasingly more autonomous and ubiquitous and system hardware and software designers need to consider system requirements that contribute to increased levels of autonomy. Autonomous UAV architectures need to be modular and open and provide visibility for operators and testers, also embracing open and extensible architectures that can be configured and deployed for robust and safe autonomous operation. Future UAVs will operate with varying levels of human interaction

and will require the ability to process sensor data onboard and to operate using high-level, autonomous behaviors. The chapter concludes with a case study of the hardware and software architecture for an autonomous UAV research platform.

► **Distributed Optimization of Autonomous UAVs with Event-Driven Communication** by Zhong and Cassandras considers problems where multiple autonomous UAVs cooperate to control their individual state so as to optimize a common objective while communicating with each other to exchange state information. Since communication costs can be significant, especially when the UAVs operate with limited energy, conditions are sought under which communication of state information among nodes can be restricted while still ensuring that the optimization process converges. An asynchronous, event-driven scheme is described which limits communication to instants when some state estimation error function at a node exceeds a threshold. This scheme guarantees convergence to an optimal even in the presence of communication delays as long as they are bounded. This approach is applied to a UAV network coverage control problem where the objective is to maximize the probability of detecting events occurring in a given region, and it is shown that it may significantly reduce communication costs, hence also prolonging the system's lifetime, without any performance degradation.

► **UAV Guidance Algorithms via Partially Observable Markov Decision Processes** by Ragi and Chong presents a path-planning algorithm to guide UAVs to track multiple ground targets based on the theory of *partially observable Markov decision processes* (POMDPs). This method shows how to exploit the generality and flexibility of the POMDP framework by incorporating a variety of features of interest naturally into the framework, which is accomplished by plugging in the appropriate models. Specifically, this study shows how to incorporate the following features by appropriately formulating the POMDP action space, state transition law, and objective function: (1) control UAVs with both forward acceleration and bank angle subject to constraints, (2) account for the effect of wind disturbance on UAVs, (3) avoid collisions between UAVs and obstacles and among UAVs, (4) track targets while evading threats, (5) track evasive targets, and (6) mitigate track swaps.

Collectively, chapters in this section pave the way to addressing the road map to unmanned aircraft full autonomy.

Integrated Hardware/Software Architectures to Enable UAVs for Autonomous Flight

will need to be modular, open, and provide visibility for operators and testers. These future UAVs will need to embrace open and extensible architectures that can be configured and deployed for robust and safe autonomous operation. In addition, the systems will operate with varying levels of human interaction and will require the ability to process sensor data onboard and to operate using high-level, autonomous behaviors. This chapter describes hardware and software architecture components that enable autonomous flight operation. It also presents some recommended architectural approaches and best practices. Finally, a case study is presented of the hardware and software architecture for an autonomous UAV research platform.

71.1 Introduction

Imagine a scenario in the not too distant future, in which there is a natural disaster and first responders from several different organizations arrive on the scene. They each launch their own unmanned aerial systems to perform search missions over the disaster area. Rather than being tele-operated, each UAV launched is able to operate autonomously and accept mission requests from the operators, through their ground control stations. This frees the first responders to focus more of their energies on the jobs that they do best. The UAVs from the various groups have different capabilities, sensors, and ownership. Yet, as the UAVs are assigned new search tasks by their operators, they are able to use standard protocols to coordinate with the other UAVs in the area to perform their missions more quickly, efficiently, and effectively.

Now, imagine another future scenario, in which UAVs are able to perform surveillance missions with fewer numbers of operators than are required today. Rather than tele-operating the UAV or entering detailed waypoint by waypoint routes, the mission planners input higher-level missions, such as to survey a specific area, along with operational constraints, such as no-fly zones. The operators rely on the autonomous behaviors of the UAV for the low-level flight planning and control. In addition, the UAV has the ability to perform processing of the sensor data onboard and therefore relieves the need for multiple ground-based data analysts and high-bandwidth communications.

Today, there are thousands of fielded UAVs in use by the United States alone. They come from various manufacturers and have a wide range of capabilities and uses. Future unmanned systems will need increased levels of autonomy, be able to perform processing onboard, utilize open standards for interoperability, and be extensible and allow for introspection. While these scenarios are very different from the current operational standards for UAVs, much of the technology exists today to support them. Consider just some of the benefits that could be available with these improved levels of autonomy: Fewer operators would be required to operate a UAV, making them cheaper and easier to deploy. This also frees the operators to focus on high-level tasks, rather than low-level mundane jobs.

1. With increased autonomy and planning capabilities, UAVs will be able to respond faster to meet operational needs, rather than requiring teams of analysts.

2. With more of the sensor data being processed onboard, fewer analysts will be required to support each UAV. Rather, the system would point out the areas of interest to the analysts, allowing them to focus on the most important aspects of their job and reducing the communication requirements.
3. With increased autonomy, UAVs would be less susceptible to operator error and communication link failures and therefore safer to operate.

However, to support these scenarios, fundamental components of the UAV software and hardware will be required:

1. The onboard mission level autonomy will need to support high-level, behavior-based planning rather than just low-level waypoint or tele-operated control.
2. The autonomous UAVS will need to perform more processing of sensor data onboard the aircraft and have the capability to notify operators and other processes when necessary.
3. The system architecture should be extensible and loosely coupled, so that additional sensors, components, and behaviors can be easily introduced.

Both of these scenarios will be possible in the near future. However, both will require additional autonomy, interoperability, and extensibility in the UAV system architecture. This chapter will discuss design considerations that will support these capabilities and present a case study of a UAV research platform.

71.2 Architecture

71.2.1 System Architecture

The recommended architecture to support autonomous UAV operations leverages the *frontseat-backseat* driver paradigm that is used in many autonomous robotic systems (Benjamin et al. 2009). In essence, the *frontseat* driver is considered to be the flight control system, which includes the autopilot and avionics and related controller hardware related to direct flight control. The *backseat* driver is represented by the mission computer, which is more deliberative and concerned with longer-range planning. The central idea of this paradigm is to decouple the low-level control from the higher-level autonomous operations. A high-level view of this paradigm is shown in Fig. 71.1.

In this architecture, the flight control system can operate standalone, through tele-operation or predefined waypoint routes, or be driven by the mission processor. In principle, the flight control system can operate as a “black box” and it does not matter where the commands originate, while the mission processor also operates as a separate entity and has little knowledge of the internal details of the flight control system.

The flight control system (FCS) typically includes an autopilot, GPS system, gyros, IMS, and a dedicated link to a ground station computer which can be used to send waypoint and control commands to the autopilot. The FCS also directly generates the control signals for aircrafts control surfaces and throttle. Note that the FCS should be able to operate independently and isolated from the mission

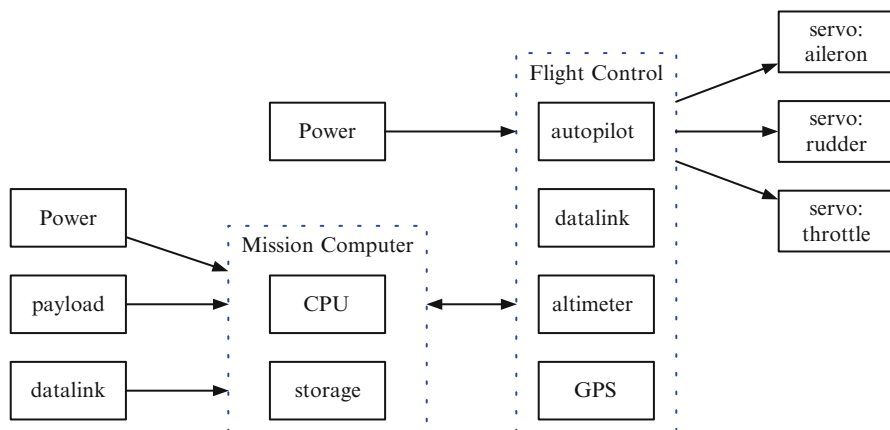

Fig. 71.1 UAV system architecture. The recommended UAV system architecture uses the *frontseat-backseat* paradigm to logically and physically separate low-level control from high-level autonomy

computer by having one or more dedicated datalinks and power sources. This provides for a level of fault tolerance in the system, as well as enabling it to be easily extensible.

For the mission processor, the design goals for extensibility dictate the use of readily available processors and components that can be easily extensible to accommodate future processing needs, autonomous behaviors, and sensor payloads. Furthermore, the processor should have multiple input/output options and relatively low power requirements and be lightweight. An example of this type of processor is the PC-104 mini computer form factor, which can be stacked in parallel to increase processing power as mission requirements dictate.

Note that the mission processor should have its own power source and datalinks for communications to the ground. In addition, it will be connected to the sensor payloads directly to allow the behaviors to incorporate the perception data. The perception data could be processed directly on the mission computer or processed on a separate payload computer, with the relevant output being passed to the mission computer. With this design, future sensor payloads can be easily added to the system and consumed by the autonomous behaviors.

71.2.2 UAV Software Architecture

The purpose of the mission processor is to run high-level mission planning and behavior processes and to exchange messages between processes, other vehicles, and the ground station. Furthermore, a key design goal of the system should be that it is flexible in regard to the architecture and potential expansion. In the future, additional autonomous behaviors, sensors, and communication capabilities may be added.

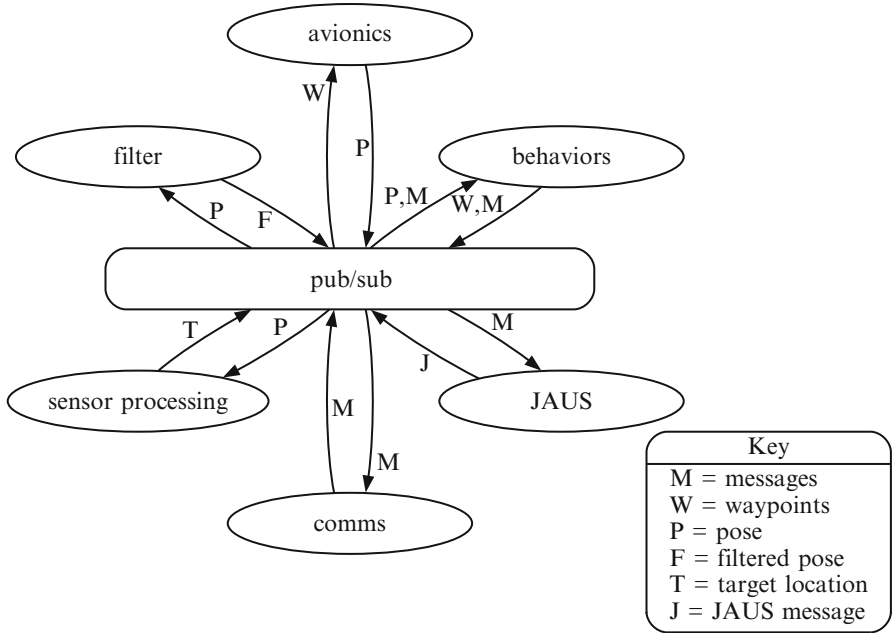

Fig. 71.2 UAV logical software architecture. The recommended UAV software architecture uses a publish/subscribe mechanism for passing messages between processes and is easily extensible

This functionality may even run across multiple processors on separate payload computers. Therefore, it is important that the software components be loosely coupled and communicate using open and flexible architectures.

One approach to providing for an extensible and open architecture is through the use of message-oriented middleware, in which separate processes send messages to each other and are loosely coupled. A typical software pattern to enable this type of flexibility is the publish-subscribe pattern. In this pattern, each process can define messages that it publishes and can subscribe to other messages that will be sent by other processes. Typically, these processes can be written in different languages and even on different computers (as long as they can communicate over a network). The messages are posted to and pulled from a logical data bus. Depending on the actual publish-subscribe implementation, the data bus could be a separate process or may be implemented in a distributed fashion. An implementation of this pattern on a UAV research platform is presented in Tisdale et al. (2006). A similar diagram of the pattern is reproduced here, in Fig. 71.2.

Consider the example of a loosely coupled UAV architecture using a publish-subscribe mechanism as shown in Fig. 71.2. Here, several processes encapsulate the details of interacting with various sensors, the autopilot system, the datalinks, and the autonomous behaviors. Each process can publish messages or subscribe to known messages from others. The design allows for new processes to be added

in the future without changing the existing system. Several sample processes and message types are described below:

Avionics The avionics process interacts with the flight control computer and receives messages from the autopilot and avionics components related to the aircraft's status. The process could publish *Pose*-related messages that include information about the aircraft's position and orientation. Similarly, the process might subscribe to *waypoint* or other command messages from the autonomous behaviors. These messages would be checked for accuracy and forwarded on to the flight control computer.

Sensor processing Multiple sensor processes can operate to process perception data from cameras, radar, or other sensors, onboard the aircraft. These processes could send specialized messages related to their sensors that could be consumed by others. For example, a process might send a message indicating that a target was detected at a given location or the level of a pollutant in the atmosphere. These processes might also subscribe to information from other sensors (to perform sensor fusion) or to messages from the avionics process to include *Pose* information.

Behaviors The high-level autonomy processes operate as sets of behaviors that perform high-level autonomous operations and planning. As an example, a search behavior might generate a pattern of *Waypoint* messages that would be consumed by the avionics process and sent to the flight control computer. The behaviors could subscribe to messages from the sensor processes and change behaviors based on the messages received. The behaviors also publish mission commands and status messages for the communications and other processes to consume.

Comms The communications process encapsulates access to the mission datalink and serves as a gatekeeper between the physical data-link and the onboard processes.

Filter The filter processes could subscribe to any of the messages such as *Pose* or sensor data and perform additional filtering or data fusion and publish the results.

JAUS JAUS or other standards-related processes could be used to transform messages between standard formats to support interoperability.

This approach supports extensibility and encapsulates lower-level components from other processes. For instance, in the future, additional sensors could be added to the system that subscribe to the *Pose* messages and publish *Target Found* messages. In another example, a new standards process could be added to support the translation from one standard to another to further support interoperability.

71.2.3 Test and Evaluation Considerations

Perhaps the most important consideration related to autonomous UAV flight is safety, and any discussion of software architectures for enabling autonomous operation should include this consideration. Autonomous UAVs will need to pass through rigorous test and evaluation procedures before they can be certified and trusted.

To facilitate this, UAV designers should consider how to incorporate safety and test harnesses at each step of the process.

71.2.3.1 Introspection

Rather than operating as a “black box,” autonomous behaviors need to provide an ability for designers and testers to evaluate what the system perceives as the state of the world. For instance, perception components need the ability for operators to visualize data as well as labeled classifications. Autonomous behaviors should regularly report and log their own state and steps toward a particular decision process. The level of logging and introspection should be configurable to allow for additional “debugging” information to be available when needed.

71.2.3.2 Health Monitoring

As part of the overall system reliability and safety, a separate health monitor process should also run on the mission computer. The purpose of this process is to monitor other processes and ensure that they are running within expected design parameters (i.e., they have not crashed, consumed too much memory or CPU, and are responding to messages.) Part of certifying each new process or autonomous behavior is to integrate it with the health monitor and validate that it handles failure gracefully. In addition, the ground station component should include separate, parallel health monitor capabilities that monitor the state of each autonomous behavior, the communications links, batteries, CPU usage, and disk space.

71.2.3.3 Software-in-the-Loop Simulations

The use of the autopilot software-in-the-loop (SIL) simulation environment allows for real-time feedback from the autopilot, as well as control using low-level bank angle commands in a simulation environment. Ideally, each component in the system should have the capability to run as part of a simulation. This would allow for the testers to exercise autonomous behaviors under different conditions. The simulation architecture should allow for the same autonomous behaviors to run either on the platform in real flight or in simulation. New behaviors and code can be tested in simulation first, before being certified for tests in autonomous flight.

71.2.4 On-Board Versus Off-Board Computation

Current and future unmanned systems will generate massive amounts of unstructured data that must be cataloged, stored, analyzed, and shared. Currently, there are more hours of video being generated than analysts are able to watch and UAV operators are facing the problem of a “data deluge” (Dillow 2011). As the number of unmanned systems increases, along with the number of sensors being carried, current procedures will not be sufficient to handle the data, analysis, and visualization requirements.

While there are efforts underway to analyze this data automatically, UAV designs will need to support this requirement as well: UAVs should process as much of the data onboard as possible because of security risks, lack of analysts to process the data, and lack of bandwidth; moreover, sensor data could be fused in real time where it makes sense. Finally, this would allow the autonomous behaviors to consume the output of this data and to respond quickly.

71.2.5 Interoperability and Standards

As unmanned vehicles (including air, ground, and sea) proliferate in dynamic domains, it will become necessary for autonomous, heterogeneous vehicles to coordinate with various ground stations and other manned and unmanned platforms as well. Unmanned vehicles may come from different manufacturers, may have different operators and owners, and may also have overlapping goals. However, as these vehicles become more autonomous, there will be opportunities for vehicle-to-vehicle cooperation and sharing, in order to improve efficiencies. Furthermore, as vehicles may be built by different manufacturers and be under the control of different command centers, interoperability will be important. As STANAG-4586 is becoming more mature in the unmanned systems community, there is a considerable push for new systems to be STANAG-4586 compliant. The SAE AS-4/Joint Architecture for Unmanned Systems (JAUS) standard was developed to provide an open architecture for unmanned ground systems. JAUS defines a message set and data format for passing messages between systems and also between individual components within a system. However, it may make sense for some UAVs to be able to send JAUS messages to communicate with certain ground stations or unmanned ground vehicles. The software architecture described above easily supports the incorporation of such standards.

71.3 Behavior-Based Autonomy

71.3.1 Mission-Level Autonomy

Mission-level autonomy is designed to work in a behavior-based framework, in which behavioral autonomy components are encapsulated into reusable modules or behaviors. Various sets of behaviors can be developed and unit tested before being incorporated into the system. Behaviors can encapsulate a basic and isolated action profile that represents the current state of the mission, such as navigating a search pattern or commanding waypoints, or higher-level operations, such as performing a cooperative task. For an excellent overview of behavior-based autonomy, see Arkin's overview (Arkin 1998).

In this architecture, behaviors are sequenced using a finite state machine that defines the states or behaviors that are possible and the events or triggers that cause

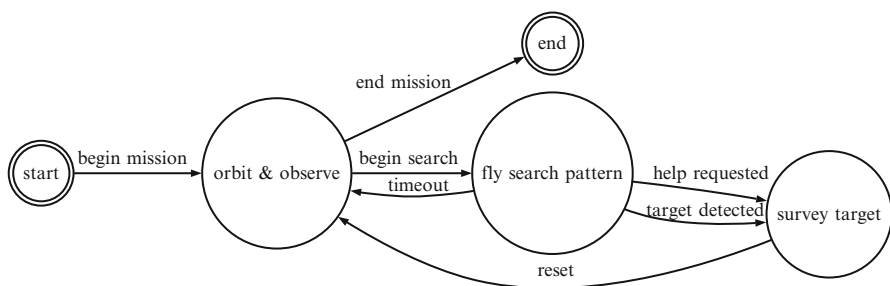

Fig. 71.3 Behavior-based autonomy. A behavior-based autonomy approach is used to encapsulate higher-level autonomy into reusable components. Behaviors are connected together with events to form a finite state machine
