Foreword: Civil RPAS In European Union Airspace – The Road To Integration

By Peter van Blyenburgh
President, UVS International¹

Preamble

The European remotely piloted aircraft systems (RPAS)² industrial community consists of two stakeholder groups (Industry³ & SMEs/SMIs⁴, which both encompass manufacturers and operators⁵. The civil RPAS market comprises three user groups: commercial, non-commercial (incl. corporate operations & research), and governmental non-military (state & non-state flights) operators (See Fig. 1). Currently, the regulatory responsibilities in the European Union (EU) for civil remotely piloted aircraft (RPA) with a maximum take-off mass (MTOM) of more than 150 kg lay with the European Aviation Safety Agency (EASA), and for RPA with a MTOM of less than 150 kg with the relevant national aviation authorities (NAAs)⁶.

Background

Various initial national regulations relative to the operation of civil RPAS are now in place (Austria, Czech Rep., Denmark, France, Germany, Ireland, Italy,

Sweden, UK), are about to enter into force (Belgium, Finland, Lithuania, Norway, Switzerland), or are in preparation (Malta, The Netherlands, Spain) – See Fig. 2. These regulations principally concern Light RPAS⁷ and they are not harmonized on a pan-European level. The coming into force of these regulations, which is fairly recent in most of these countries, has brought about a dynamic growth in approved⁸ and authorized⁹ RPAS operators supplying aerial operation services with an ever-growing diversity of applications¹⁰ (See Fig. 3). For reasons of simplicity, approved and authorized operators are hereinafter jointly referred to as certified operators¹¹. In fact, there are currently more than 1500 certified civil RPAS operators in the European Union (See Fig. 4). In practically all cases, current flight operations are taking place within visual line-of-sight (VLOS), at a flight altitude of less than 500 ft above ground level (AGL) with RPA with a MTOM of less than 25 kg, which are principally produced and operated by SMIs. It should also be mentioned that a significant amount of European NAAs facilitate RPAS operations by granting Permits-to-Fly on a case-by-case basis. The European RPAS industrial community now has as objective to initiate activities that will make it possible to start to enlarge the currently permitted flight envelopes, and to operate larger RPAS.

A growing number of governmental authorities in various EU countries involved with internal security matters (e.g. municipal & national police, anti-terrorist squads, municipal fire brigades, forest fire fighters, coast guard, civil defence, environmental protection agencies), as well as FRONTEX (European agency responsible for EU border security), have manifested great interest in the use of RPAS. In addition, large corporate entities (e.g. electric grid operators, pipeline network operators, railway operators, oil companies) have woken up to the fact that RPAS could fulfil functions that would be extremely beneficial to their corporate operations. However, in all cases the use of RPAS will depend on the acceptability of the proposed RPAS flight hour cost.

Fig. 3 Civil RPAS Aerial Work Categories

A considerable amount of civil RPAS related European Commission (EC) initiatives have taken place over the years, namely, the Hearing on Light RPAS (Oct. '09), the High Level UAS Conference (July '10)¹², the UAS Panel initiative (Jun. '11-Feb. '12)¹³, the European RPAS Steering Group initiative (Jun. '12 - today)¹⁴, and a significant amount of RPAS-related study contracts have been financed by various EC Directorate Generals (DG)¹⁵. It should be noted that two study contracts have recently been allocated by DG Enterprise & Industry concerning the societal topics of respectively Liability & Insurance, and Privacy & Data Protection. FRONTEX¹⁶ has financed several RPAS capability demonstrations in Spain and Greece to evaluate RPAS usage for illegal immigrant control. In addition, in November 2013 SESAR Joint Undertaking (SJU) announced the 9 consortia that had been selected for funded RPAS demonstration activities. The objective of these demonstrations, which will take place over a period of 24 months (ending in Oct. '15), is to prepare the integration of operational improvements in SESAR's ATM Master Plan that should contribute to the safe integration of RPAS operations into European non-segregated airspace starting in 2016.

The conclusions of the EC UAS Panel¹⁷, co-chaired by the EC's DG Enterprise & Industry and DG Mobility & Transport highlighted the potential of civil RPAS for the development of a wide range of commercial and non-commercial, as well as non-military governmental, applications. In addition, the EC concluded that civil RPAS offer significant potential for job creation in the industry and services sectors, and can generate positive economic growth. The underlying principal of the EC UAS Panel was to focus on civil RPAS applications with societal benefits for which a viable business could be made. The need to accelerate the safe integration of RPAS into European airspace - taking into account societal issues such as responsibility, liability, insurance, privacy, data protection, and public acceptance – was also recognized. Furthermore, it was brought to light that, viable business cases for civil RPAS operations can currently, and for the foreseeable future, only be made for Light RPAS.

The Joint Authorities for Rulemaking on Unmanned Systems (JARUS)¹⁸ federates the NAAs of 22 countries¹⁹, as well as EASA and EUROCONTROL. JARUS contributes to the harmonisation and coordination of the rulemaking, certification, and operational approval of civil RPAS, remote pilots and operators. Its intent

Fig. 4 RPAS (MTOM) Related Certification in Europe

is to eliminate the need for each country to write their individual requirements and to facilitate reciprocal acceptance of RPAS-related certificates, approvals and licenses. In November 2013, JARUS published its first certification specification (CS-LURS)²⁰ and the online comment period of its second specification (AMC RPAS.1309)²¹ ended on 28 March 2014.

The creation of the European RPAS Steering Group (ERSG), co-chaired by the EC's DG Enterprise & Industry and DG Mobility & Transport and representing 11 stakeholders²², was announced by the EC at the Paris Air Show in 2012. Its objective is to foster the development of civil RPAS operations by planning and coordinating all activities necessary to achieve the safe and incremental integration of civil RPAS into European air traffic starting in 2016. The ERSG has developed a comprehensive European RPAS Roadmap²³, consisting of three complementary sub-sets²⁴ that was remitted by Peter van Blyenburgh, as a representatives of UVS International, to Matthias Ruete, Director General Mobility & Transport & Philippe Brunet, Director DG Enterprise & Industry, as representatives of the European Commission at the Paris Air Show in 2013. The European RPAS Roadmap identified JARUS as a key player for its implementation - This fact will most probably bring with it the necessity to give JARUS, in the near future, a recognised status with a formal link-up to EASA.

The Current Situation

On Monday 3 February 2014, SJU published a tender²⁵, which has as purpose to select a consortium that will be entrusted with the preparation of the "Definition Phase" related to the insertion of civil RPAS into the European Aviation System; this tender should be seen in light of the guidelines defined by the European RPAS Roadmap, and within the context of the Single European Sky initiative. In order to be truly representative of the entire European RPAS industrial community and be able to stay in line with the conclusions of the EC Staff Working Document "Towards a European strategy for the development of civil applications of RPAS²⁶", as well as the European RPAS Roadmap, the selected consortium should federate large industrial enterprises and relevant SMEs/SMIs (manufacturers & operators) with measureable experience, so that it can effectively assure that the consortium's work will indeed address all the topics required for the incremental integration of all classes of civil RPAS, starting in 2016. The tender closing date was 2 April 2014 and the winning consortium should be announced before the summer of 2014.

At a news conference that took place in Brussels, Belgium on 8 April 2014, Siim Kallas, the vice president of the European Commission and Commissioner for Transport, officially announced the acceptance of the European RPAS Roadmap. On the same day, a communication to the European Parliament and the European Council entitled "A New Era for Aviation – Opening the aviation market to the civil use of remotely piloted aircraft systems in a safe & sustainable manner" was published by the EC. The EC also referred to the European Summit of 19 December 2013, which called for action to enable the progressive integration of RPAS into the

total aviation system and European airspace from 2016 onwards. In addition, the EC stated that the progressive integration of RPAS should be accompanied by adequate public debate on the development of measures that address societal concerns.

The implementation of the European RPAS Roadmap will be instrumental to lay the foundation for the creation of jobs and economic growth in the research, development, production and services sectors in Europe and will favourably position the European RPAS community on the world stage. This situation clearly demonstrates the coordinated and pragmatic European policy within the framework of the Single European Sky (SES) initiative, which has been made possible by the cooperation of multiple stakeholder groups.

In order to contribute in a positive and pro-active manner to this initiative UVS International has instigated the creation of a multi-disciplinary study group²⁷ to deal with the topics of responsibility, liability and insurance. It is the intent of this study group, which was announced in December 2013, to produce position papers relative to the topics identified in its Terms of Reference²⁷ and submit them for consideration to the European Commission, as well as all other interested parties. The first position papers produced by this group will be presented at the upcoming RPAS 2014 conference in Brussels, Belgium on 23-26 June 2014²⁸.

Considerations & Recommendations

RPAS encompass many different types of aircraft with a huge variety of airframe types and lift technologies, with maximum take-off weights ranging from several grams to well over 10 000 kg, with speeds varying from hovering to over 1 000 km/h, and with a very wide envelope of flight endurances (from minutes to days). Therefore, RPAS requires a very specific and proportionate approach to rulemaking, which does not impose an excessive burden on the SMEs/SMIs producing and operating them, but that also does not entail unacceptable administrative procedures for them, as well as for the NAAs. However, this proportionate approach should in no way comprise current aviation safety levels.

The current regulatory responsibility in the EU (MTOM <150 kg: NAAs; MTOM >150 kg: EASA), which is based on traditional airworthiness considerations, is not considered to be conducive for the creation of a coherent harmonised EU safety policy relative to RPAS. The challenge will be to create rules that are proportionate to risk, while taking into account some, or all, of the following points: MTOM, speed, system complexity, airspace class, population density in the area over-flown, and the specificity of operation.

Besides the technical and research aspects relative to the air traffic management and related issues, that will be addressed by SJU's aforementioned "Definition Phase" tender, there are a number of other just as critical topics that have to be addressed within the context of European and international harmonisation, and with the objective to be able to comply with the EU principal of free movement of persons, products and services throughout the 28 EU Member States.

These topics include, amongst others:

- a) Operator (commercial & non-commercial) certification & assessment;
- b) Remote pilot training (theoretical & practical), licensing & proficiency assessment;
- c) Airworthiness & continued airworthiness assessment;
- d) Design organization approval; e) Manufacturer organization approval.

In addition, particular attention should be paid to harmonizing the criteria relative to:

- 1) Remote pilot training syllabus;
- 2) RPAS operation manuals;
- 3) RPAS instruction manuals (supplied by the manufacturer);
- 4) RPAS maintenance manuals;
- 5) RPAS & operation categories;
- 6) Terminology.

As mentioned earlier, the following societal issues should also be addressed:

- a) Manufacturer, operator & remote pilot responsibility;
- b) Manufacturer, operator & remote pilot liability & insurance;
- c) Privacy & data protection;
- d) Positive awareness creation with the general public relative to RPAS.

Many of these subject matters will have to be dealt with by industry through standards organizations (EUROCAE) and dedicated industry working groups, in close coordination with the EC, JARUS (and NAAs), EASA, EUROCONTROL, SJU, the European Space Agency (ESA), and the European Defence Agency (EDA). It should be noted that the two study contracts awarded by EC DG Enterprise & Industry relative to RPAS Liability & Insurance and Privacy & Data Protection should be seen within this framework. It should also be noted that a substantial part of the initially required rules can be developed by JARUS and can be harmonised by the participating NAAs.

In view of the many “remote pilot schools” that are currently mushrooming up in a steadily increasing number of countries, the enormous differences between their training courses, the explosive growth of the number of certified RPAS operators, and the necessity of European harmonisation, there appears to be a urgent requirement to address all facets of remote pilot training, as well as the assessment of remote pilot schools. The recognition of remote pilot certificates (and operator certificates) beyond national borders should be a prime objective for the commercial RPAS community.

Within the context of the aforementioned, and taking into account the limited resources of the majority of the NAAs, as well as the fact that many of the SMEs/SMIs involved with RPAS as manufacturers or operators are relative “new comers” to aviation, the potential role that Qualified Entities (QEs)²⁹ can play should be closely evaluated. In addition, the concept of QE should be better understood by both NAAs and industry. Only then will it be possible for the relevant stakeholders to recognize the very positive role that QEs can play to help open up the commercial RPAS market, without putting an unnecessary burden on NAAs, in terms of finance and personnel. At the time of going to press, only one EU country (UK) had appointed two QEs. However, these QEs are also recognised in Ireland

and The Netherlands. In the near future, QEs are expected to be appointed by the NAAs in three additional EU countries.

Mutual recognition, without requirements for additional certificates, licenses, approvals or other documents relative to RPAS operators, remote pilots and RPAS, would appear to be the necessary way forward, in order to create a level commercial playing field for the European RPAS community, and it would influence investment in the civil RPAS sector in a positive way.

Lastly, it should be recognised that the principal of “regulator proximity”, will be of critical importance for SMIs/SMIs in the EU. In order to reduce the costs of travel and fees, but also for cultural and linguistic reasons, as well as reasons of comprehension, it seems imperative that all certificates, licenses and approvals inside the EU are based on common rules, but that they are issued by the NAAs in their country’s native language.

In order to realise the aforementioned, various stakeholder communities, including RPAS operators (commercial & non-commercial), remote pilot schools, and QEs, have to be federated on a European level. This task is being addressed by the European RPAS Coordination Council, which consists of representatives of the 10 European national RPAS associations (Austria, Belgium, France, Germany, Italy, The Netherlands, Norway, Romania, Spain, UK) and UVS International, in coordination with the national RPAS operator associations in Australia, Botswana, Namibia and South Africa.

Conclusion

The European civil RPAS community has grown substantially and has come a long way in a relatively short period of time, and has now passed through the first of several gates on its way to incremental integration into European airspace. All RPAS stakeholders and particularly the European industrial community, now have to demonstrate understanding and maturity, and jointly work together in order to successfully get through the remaining gates on the road to full RPAS integration. By doing so, they will not only serve themselves, but they will also be doing an immense favour to the global RPAS community, by showing that full RPAS integration is indeed reachable objective.

Explanations

- ¹ UVS International is a non-profit association registered in The Netherlands and operating out of offices in Paris, France which is dedicated to the promotion of RPAS (manufacturers & operators). In addition to having corporate, non-corporate & natural person members, it also federates European national RPAS associations & working groups* in Austria (AAI), Belgium (BeUAS), Denmark (UAS Denmark*), France (FPDC), Germany (UAV-DACH), Italy (ASSORPAS), The Netherlands (DARPAS), Norway (UAS Norway), Romania (UVS Romania), Spain (AERPAS), UK (ARPAS), as well as Australia (ACUO), and South

Africa + Botswana + Namibia (CUAASA). UVS International has a partnership agreement with the European Spatial Data Research Network, a not-for-profit organisation linking national mapping and cadastral agencies with research institutes & universities for the purpose of applied research in spatial data provision, management & delivery. See: www.eurosdnr.net

UVS International represents over 800 companies & organisations. See www.uvs-international.org

- ² Remotely Piloted Aircraft (RPA) & remotely piloted aircraft system (RPAS) - These terms are recommended by ICAO for current use [instead of unmanned aircraft system (UAS), unmanned aerial vehicle (UAV)] - The acronyms are invariant.
- ³ Industry = Enterprise with > 250 employees & annual turnover of > Euro 50 million.
- ⁴ Small & medium-sized enterprise (SME) & Small & medium-sized Industry (SMI) = < 250 employees & annual turnover < Euro 50 million.
- ⁵ Operators = persons, enterprises or organizations engaged in or offering to engage in an RPAS operation.
- ⁶ The NAA of each of the 28 EU member states is responsible in their country for rulemaking, certification & operational approval of civil RPAS with a MTOM < 150 kg, their RPAS flight crews (pilots) & RPAS operators employing the flight crews.
- ⁷ Light RPA = MTOM < 150 kg.
- ⁸ Approved operators = Operators approved by the NAA in countries with regulation in place:
- ⁹ Authorised operators = Operators authorized by the NAA in countries without regulation in place where flight permits are given on a case-to-case basis.
- ¹⁰ Civil RPAS applications (commercial & non-commercial): advertising, agriculture, cinema, forestry, inspection, monitoring, observation, patrol, photogrammetry, photography, survey & mapping, research, search & rescue, training/ instruction.
- ¹¹ Certified operators = A form of official recognition of compliance with the applicable requirements by means of the issuance of a certificate attesting such compliance: Belgium (10), Czech Rep. (24), Denmark (12), Finland (33), France (497), Germany (400 – estimate), Ireland (12), Italy (1), Netherlands [13 (& 30 in the pipeline)], Norway (76), Spain (1), Sweden (216), UK (212).
- ¹² UVS International was a member of the organising committee.
- ¹³ UVS International was a member of the EC UAS Panel.
- ¹⁴ UVS International is a member of the European RPAS Steering Group.

- ²⁹ Qualified Entity: Entity to which a specific certification task has been allocated by the European Aviation Safety Agency (EASA) or a NAA (*and in the latter case is not necessarily compliant with EC Regulation No 216/2008*).

Preface

On December 30, 2013, the U.S. Federal Aviation Administration (FAA) announced the selection of six unmanned aircraft systems (UAS) research and test site operators across the USA that are tasked to study a broad range of issues and challenges related to unmanned aircraft. This announcement was the outcome of a rigorous 10-month selection process involving 25 proposals from 24 states. The selected sites are headed by the University of Alaska, the State of Nevada, New York's Griffiss International Airport, the North Dakota Department of Commerce, Texas A&M University – Corpus Christi, and Virginia Polytechnic Institute and State University. The six test sites can operate until February 13, 2017, with Congress expected to consider extending their operations beyond that date. Furthermore, “The FAA is committed to the safe and efficient integration of UAS into the National Airspace System (NAS), thus enabling this emerging technology to safely achieve its full potential.”

Along the same lines, the International Civil Aviation Organization (ICAO), which is a special agency of the United Nations (UN), has long been committed to “the safe and orderly development of international civil aviation throughout the world,” being the organization that also sets standards and regulations necessary for aviation safety, security, efficiency, and regularity, as well as aviation environmental protection.

Regardless, the December 30, belated and much overdue, announcement from the FAA will perhaps mark the dawn of a new era for unmanned aircraft, worldwide, as it opens the door of civil UAS to be utilized for a wide range of civilian and public domain applications, also outlining actions and considerations that are prerequisite to enabling integration of UAS into NAS. Whether unmanned aircraft are called Unmanned Aerial Vehicles (UAVs) or Remotely Piloted Aircraft (RPA), Unmanned Aircraft Systems (UAS) or Remotely Piloted Aircraft Systems (RPAS), a “domino effect” is soon expected to: accelerate research and development; increase funding; create new jobs; generate provable novel and cutting-edge technologies for increased safety and security of unmanned aircraft; contribute to developing functional and operational “standards” for unmanned aviation; enforce closer collaboration and coordination among national and international interested parties; bring closer academia, government, industry, and the private sector; engage

interested parties in discussions and eventual resolution of ethical, legal, and privacy issues, to say the least and name but a few opportunities.

From that point of view, the *Handbook of Unmanned Aerial Vehicles* (the preferred and most known name at the time this project started) offers a unique opportunity to the interested reader as its main objective is to become a comprehensive reference text for the academic and research communities, industry, manufacturers, users, practitioners, the Federal Government, Federal and State Agencies, and the private sector, as well as all organizations that are and will be using UAS in a wide spectrum of applications. The handbook covers all aspects of UAVs, from design to logistics and ethical issues. The contents of the handbook include material that addresses the needs and *know-how* of all of the above sectors, targeting a very diverse audience. It is also targeting the young investigator, the future inventor and entrepreneur by providing an overview and detailed information of the state of the art as well as useful new concepts that may lead to innovative research.

The handbook offers a unique and comprehensive treatise of everything one needs to know about UAVs/UAS, from conception to operation, from technologies to business activities, users, OEMs, reference sources, conferences, publications, professional societies, etc. It may serve as a thesaurus, an indispensable part of the library of everyone involved in the area. For the first time, contributions by the world's top experts from academia, industry, and the government are brought together to provide unique perspectives on the current state of the art in UAS, as well as future directions. The handbook is intended for the expert/practitioner who seeks specific technical/business information and for the technically oriented scientists and engineers, but also for the novice who wants to learn more about the status of UAS and UAS-related technologies.

The handbook is arranged in a user-friendly format divided into 22 parts: Introduction; UAV Design Principles; UAV Fundamentals; Sensors and Sensing Strategies; UAV Propulsion; UAV Control; UAV Communication Issues; UAV Architectures; UAV Health Management Issues; UAV Modeling, Simulation, Estimation, and Identification; MAVs and Bio-inspired UAVs; UAV Mission and Path Planning; UAV Autonomy; UAV Sense and Avoid Systems; Networked UAVs and UAV Swarms; UAV Integration into the National Airspace; UAV-Human Interfaces and Decision on Support Systems; Human Factors and Training; UAV Logistics Support; UAV Applications; Social and Ethical Implications; and Epilogue, highlighting the economics and future of this rapidly expanding area. Each part contains either original material or enhanced versions of already published work, written by internationally renowned authors who are authorities in their respective fields.

At this stage, it is essential and crucial to state that the reader should not be confused with the different names that have already been used to describe unmanned aircraft, as the context in which such names are used in the handbook is self-explanatory in the respective chapters. For example, the terms UAVs and UAS have distinct definitions and it should be clear why, at first, UAVs became UAS: A UAV refers to a pilotless aircraft, a flying machine without an onboard human pilot or passengers. As such, "unmanned" implies total absence of a human who directs

and actively pilots the aircraft. Control functions for unmanned aircraft may be either on-board or off-board (remote control). The term UAS was introduced by the U.S. Department of Defense, followed by the FAA and the European Aviation Safety Agency (EASA). This term was meant to signify that UAS are aircraft and as such their airworthiness will need to be demonstrated and they are also systems consisting of ground control stations, communication links and launch and retrieval systems in addition to the aircraft itself. Other names include Remotely Piloted Vehicles (RPVs), a term that was used in the Vietnam War, while the U.S. military also calls them Remotely Piloted Aircraft (RPA), a term used to include both the aircraft and the pilot, while the UK and the ICAO have designated them as Remotely Piloted Air (or Aircraft) System (RPAS), to demonstrate the presence of the man-in-the-loop to control them. The ICAO-recommended definition for RPAS is “A set of configurable elements consisting of a remotely-piloted aircraft, its associated remote pilot station(s), the required command and control links and any other system elements as may be required, at any point during flight operation.”

However, despite any terminology issues, one thing is certain: The unmanned aircraft arena is moving forward at a rapid pace. New models, users, relevant technologies and events are finding the light of publicity on a daily basis. Even a massive handbook of this type is not sufficient to capture all aspects and developments in this emerging field. There bound to be omissions and this unique volume will require updates as the technology marches on. It is the editors’ hope that, in collaboration with Springer, subsequent editions will follow with new and updated information as the field continues to rapidly expand, and it is very likely that “standards” will soon be introduced.

We realize that the Handbook is not complete. It is being produced amidst “rapidly evolving developments” in unmanned aviation with new information surfacing on a daily basis. Regardless, we did not want this to be an endless project, thus, we brought closure to it.

We would like to thank wholeheartedly the section editors and the contributing authors who have made this project a reality. We are grateful to the Springer team, headed by Ms. Nathalie Jacobs, who have been patient, very understanding, very cooperative, and easy to work with.

June, 2014

Kimon P. Valavanis, Denver, USA
George J. Vachtsevanos, Atlanta, USA
Editors-in-Chief

About the Editors

Kimon P. Valavanis received the Diploma in Electrical and Electronic Engineering – Diplôme d'Ingénieur (5 years of study) – from the National Technical University of Athens (<http://www.ntua.gr>), Greece, in 1981, and he completed the Professional Engineer (PE) exams in Electrical and Mechanical Engineering in February 1982. He has been a member of the Technical Chamber of Greece since 1982. He received the MS degree in Electrical Engineering and the PhD degree in Computer and Systems Engineering from Rensselaer Polytechnic Institute (RPI) (<http://www.renselaer.edu>) in 1984 and 1986, respectively.

From 1987 to 1990, he held the Analog Devices Career Development Chair for Assistant Professors in the Department of Electrical and Computer Engineering (ECE), Northeastern University (<http://www.northeastern.edu>), Boston, where he was also Director of the Robotics Laboratory. From 1991 to 1999, he was with the Center for Advanced Computer Studies (CACS), University of Louisiana, at Lafayette (<http://www.cacs.louisiana.edu>), where he served as Associate Professor from 1991 to 1995 and as Professor of Computer Engineering since 1995. He was also Associate Director for Research at the A-CIM Center (1993–1999) and Director of the Robotics and Automation Laboratory. He also held the A-CIM/[TC]²/Regents Professorship in Manufacturing.

From 1999 to 2003, he was Professor in the Department of Production Engineering and Management (DPEM), Technical University of Crete (TUC) (<http://www.tuc.gr>), Greece, where he also established and served as Founding Director of the Intelligent Systems and Robotics Laboratory (ISRL). He was also Director of the DPEM Graduate Program and Chair of the TUC Industrial Advisory Board (IAB) and Technical Council.

From August 2003 to August 2008, he was Professor in the Department of Computer Science and Engineering (CSE), University of South Florida (<http://www.cse.usf.edu>), where he also served as Deputy Director of the Center for Robot-Assisted Search and Rescue (CRASAR) until the summer of 2005. In late 2005, he established the Unmanned Systems Laboratory (USL) in the College of Engineering, in which he served as Founding Director. He was also the Managing Director of the National Institute for Applied Computational Intelligence (NIACI) and a Faculty Associate at the Center for Urban Transportation Research (CUTR). From 2004 to March 2006, he was also the Managing Director of the American Foundation for Greek Language and Culture (AFGLC) (<http://www.afglc.org>).

He joined the University of Denver on September 1, 2008, as Chair of the ECE Department, where he also is the John Evans Professor. He also served as Interim/Acting Chair of the Computer Science (CS) Department for 2 years (July 2009 to June 2011). He is also the Founding Director of the DU Unmanned Systems Laboratory (DU²SL), which he established in early 2009. In November 2012, he officially established the DU Unmanned Systems Research Institute (DU²SRI), in which he serves as Founding Director.

Further, since the mid-1990s, he has been Guest Professor in the Faculty of Electrical Engineering and Computing, Department of Telecommunications, University of Zagreb (<http://www.fer.hr>), Croatia. He was also invited through the European Union PhD Research Program in Italy to teach Robotics and Unmanned Systems at the Dipartimento di Ingegneria Informatica, Gestionale e dell' Automazione, Università Politecnica delle Marche, Ancona, Italy.

During his career thus far, Dr. Valavanis has graduated 34 PhD students and more than 80 MS students. He has attracted more than \$35 million in research funds from federal and state agencies, industry, and the private sector, while in Europe he was funded by the Greek Secretariat of Research and Technology, the European Union, industry, and from the Croatian Ministry of Science and Technology (joint projects).

Dr. Valavanis' research interests are focused in the areas of unmanned systems, distributed intelligence systems, robotics, and automation. He has published over 350 book chapters, technical journals/transactions, refereed conference papers, invited papers, and technical reports. He has authored, coauthored, and/or edited the following books: *Intelligent Robotic Systems: Theory, Design and Applications* (with Dr. G. N. Saridis), Kluwer Academic Publishers, 1992; *Control Problems in Robotics and Automation* (coedited with B. Siciliano), Lecture Notes in Control and Information Sciences, Vol. 230, Springer-Verlag, 1998; *Intelligent Manufacturing Systems: Programming and Control* (with J. Balic, N. Tsourveloudis, and S. Ioannidis), University of Maribor Publications, 2003; *Advances in Unmanned Aerial Vehicles: State of the Art and the Road to Autonomy* (editor and coauthor

of nine chapters), Springer, 2007; *Unmanned Aircraft Systems – International Symposium on Unmanned Aerial Vehicles, UAV’08*, (coedited with P. Oh and L. A. Piegl), Springer, 2009; *On Integrating Unmanned Aircraft Systems into the National Airspace System: Issues, Challenges, Operational Restrictions, Certification, and Recommendations* (with K. Dalamagkidis and L. A. Piegl), Springer, 2009, with a second edition published in 2012; *Intelligent Control Applications to Engineering Systems* (editor), Springer, 2009; *Unmanned Aircraft Systems – 2nd International Symposium on Unmanned Aerial Vehicles, UAV’09* (coedited with R. Beard, P. Oh, A. Ollero, L. Piegl, and H. D. Shim), Springer, 2010; *Unmanned Aerial Vehicles* (editor), Springer, 2011; *Linear and Nonlinear Control of Small-Scale Unmanned Helicopters* (coauthored with I. A. Raptis), Springer, 2012; *Recent Developments in Unmanned Systems* (editor), Springer, 2012; and *Unmanned Aircraft Systems: Challenges and state of the art* (editor), Springer, 2013. In addition, he is the coauthor (with G. Atsalakis and K. Zopounidis) of the book *Stock Market Forecasting Techniques* (in Greek), Klidarithmos, 2008. He also holds several patents.

Dr. Valavanis has organized two International Advanced Robotics Programme (IARP) meetings in Lisbon, Portugal, and Lafayette, LA, which were funded by the National Science Foundation. He has taught tutorial workshops at the IEEE CDC, ACC, and ICRA, at the Conference on Telecommunications (ConTel), and at the Mediterranean Conference on Control and Automation. He served as Associate Editor of the IEEE Transactions in Robotics and Automation from February 1996 to February 1999, as the Robotics and Automation Society “Discrete Event Dynamic Systems Technical Committee” Co-chair for 2 years, and as an Associate Editor of the *IEEE Robotics & Automation Magazine* from 1994 to 1995. He was Editor in Chief of the same magazine for 10 years (1996 to 2005). He was also the Book Review Editor of the *Journal of Intelligent and Robotic Systems (JINT)* until 2006, and since then he serves as the Editor in Chief of JINT. He serves on the Editorial Advisory Board of the International Series on Microprocessor-Based and Intelligent Systems Engineering published by Springer. He also served as a member of the IEEE Robotics and Automation Society Awards Committee for 3 years and as Cochair/Chair of the Aerial Robotics and Unmanned Aerial Vehicles Technical Committee (2008–2012).

Dr. Valavanis has also received invitations by the Hellenic Quality Assurance Agency (HQAA) for Higher Education of the Hellenic Republic to evaluate Greek universities (ABET Evaluation) and by the European Union to be an evaluator of IP and STREP projects as part of the 7th European Union (EU) Framework Programme for Research and Technology Development (FP7) – Information and Communication Technologies (ICT-2009.2.1 Cognitive Systems and Robotics), and he also served as a member of the Hearing Committee panel in Luxemburg. He is an appointed Scientific Project Reviewer in projects financed by the Ministry of Science, Education and Sports of the Republic of Croatia and in research projects evaluated by the Italian Evaluation of Research Quality exercise (VQR 2004-2010).

Dr. Valavanis has been on the organizing committee of many conferences, serving as General, Program, Registration, as well as Local Arrangements Chair, including Registration Chair of the 36th IEEE CDC; Local Arrangements Chair of

the 34th IEEE CDC; General Chair (with F. Lewis) of the 11th Mediterranean Conference on Control and Automation, June 2003; Program Chair of the 2004 IEEE ICRA; General Chair (with P. Antsaklis) of the 15th Mediterranean Conference on Control and Automation, June 2007; General Chair (with W. Gruver) of the IEEE SMC International Conference on Distributed Human-Machine Systems, March 2008; General Chair of the 2011 IEEE Multi-Conference on Systems and Control, September 2011; and General Chair (with P. Antsaklis) of the 21st Mediterranean Conference on Control and Automation, June 2013. He has also served as General Chair of the International Conference on Unmanned Aircraft Systems (ICUAS), which he created in 2008. In addition, he is the Founding President of the ICUAS Association, Inc., a nonprofit organization that organizes and sponsors the annual ICUAS technical meeting. In 1998, he was elected Vice President – Administration of the IEEE Mediterranean Control Association (MCA). He was a Distinguished Speaker in the IEEE Robotics and Automation Society (–2003), a Senior Member of IEEE, and a Fellow of the American Association for the Advancement of Science. He is also a Fulbright Scholar.

George J. Vachtsevanos is currently serving as Professor Emeritus at the Georgia Institute of Technology. He served as Professor of Electrical and Computer Engineering at Georgia Tech from 1984 until September 2007. He also served on a part-time basis as the Chief Scientist of Impact Technologies, LLC. Dr. Vachtsevanos directs at Georgia Tech the Intelligent Control Systems Laboratory where faculty and students are conducting interdisciplinary research in intelligent control, fault diagnosis and failure prognosis of complex dynamical systems with emphasis on rotorcraft, and hierarchical/intelligent control of unmanned aerial vehicles. His work in unmanned aerial vehicles dates back to 1994 with major projects funded by the U.S. Army and DARPA. He has served as the Co-PI for DARPA's Software Enabled Control program and directed the development and flight testing of novel fault-tolerant control algorithms for unmanned aerial vehicles. He has represented Georgia Tech at DARPA's HURT program where multiple UAVs performed intelligence, surveillance, reconnaissance, and tracking missions in an urban environment. Under AFOSR sponsorship, his research team has been developing a biologically inspired micro aerial vehicle. Under ARO sponsorship, his team has been developing game-theoretic and reasoning strategies for target recognition and tracking with multiple UAVs. Under support by NASA, his research team has been developing and testing an autonomous hovercraft. This research effort is aiming at the design and operation of unmanned systems that possess improved attributes of autonomy and fault tolerance. Dr. Vachtsevanos and his research team were involved in a series of programs since 1985 in diagnostics and more recently in prognostics funded by the government and industry. His research work has been supported over the years by ONR, NSWC, the MURI Integrated Diagnostic program at Georgia Tech, the U.S. Army's Advanced Diagnostic program, General Dynamics, General Motors Corporation, the Academic Consortium for Aging Aircraft program, the U.S. Air Force Space Command, Bell Helicopter, and Fairchild Controls, among others. The innovative technologies have relied on

both data-driven and model-based algorithms from the domains of soft computing, Dempster-Shafer theory, and Bayesian estimation techniques with emphasis on particle filtering and physics-based modeling architectures. The application domains range from UAVs to automotive electrical storage and distribution systems, high-power amplifiers, environmental control systems, and critical engine and drive system aircraft components. Dr. Vachtsevanos has developed and has been administering an intensive four-day short course on “Fault Diagnostics/Prognostics for Equipment Reliability and Health Maintenance.” He is a member of the board of directors of the Prognostics and Health Management Society. He has published over 300 technical papers and is the recipient of the 2002–2003 Georgia Tech School of ECE Distinguished Professor Award and the 2003–2004 Georgia Institute of Technology Outstanding Interdisciplinary Activities Award. His research team has been awarded numerous awards for its technical presentations at professional conferences. He is the lead author of the book *Intelligent Fault Diagnosis and Prognosis for Engineering Systems* published by Wiley in 2006.

Section Editors

Randal W. Beard received his BS degree in electrical engineering from the University of Utah, Salt Lake City, in 1991; MS degree in electrical engineering in 1993; MS degree in mathematics in 1994; and PhD degree in electrical engineering in 1995, all from Rensselaer Polytechnic Institute, Troy, NY. Since 1996, he has been with the Electrical and Computer Engineering Department at Brigham Young University, Provo, UT, where he is currently professor. In 1997 and 1998, he was a Summer Faculty fellow at the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA. In 2006–2007, he was a National Council Research fellow at the Air Force Research Laboratory, Munitions Directorate, Eglin AFB, FL. His research interests include guidance and control, autonomous systems, and multiple-vehicle coordination and control with particular emphasis on small and miniature air vehicles.

Christos G. Cassandras is head of the Division of Systems Engineering and professor of electrical and computer engineering at Boston University. He is also the cofounder of Boston University's Center for Information and Systems Engineering (CISE). He received his degrees from Yale University, Stanford University, and Harvard University. In 1982–1984, he was with ITP Boston, Inc. In 1984–1996, he was a faculty member at the University of Massachusetts, Amherst. He specializes in the areas of discrete event and hybrid systems, cooperative control, stochastic optimization, computer simulation, and applications to computer and sensor networks, manufacturing systems, and transportation systems. He has published over 300 refereed papers in these areas and five books. He has collaborated with the MathWorks, Inc., in the development of the discrete event and hybrid system simulator SimEvents. Dr. Cassandras was editor-in-chief of the *IEEE Transactions on Automatic Control* from 1998 to 2009 and has served on several journal editorial boards. He was the 2012 president-elect of the IEEE Control Systems Society (CSS) and has served as vice president for publications. He has been a plenary speaker at various international conferences and an IEEE distinguished lecturer (2001–2004). He is the recipient of several awards, including the Distinguished Member Award of the IEEE Control Systems Society (2006), the 1999 Harold Chestnut Prize (IFAC Best Control Engineering Textbook) for *Discrete Event Systems: Modeling and Performance Analysis*, a 2011 prize for the IBM/IEEE Smarter Planet Challenge competition, a 1991 Lilly Fellowship, and a 2012 Kern Fellowship. He is a member of Phi Beta Kappa and Tau Beta Pi. He is also a fellow of the IEEE and a fellow of the IFAC.

David A. Castañón is professor and chair of the Department of Electrical and Computer Engineering at Boston University. He received his BS degree in electrical engineering from Tulane University and his PhD in applied mathematics from MIT in 1976. He was a research scientist in LIDS at MIT from 1976 to 1981 and then chief scientist with AlphaTech, Inc., until joining Boston University in 1990. At Boston University, he is codirector of the Center for Information and Systems Engineering, deputy director of the Gordon-CenSSIS NSF Engineering Research Center on Subsurface Sensing and Imaging, and associate director for the Department of Homeland Security Center of Excellence on Explosives. He has served in numerous positions for the IEEE Control Systems Society, including president in 2008, and served on the Air Force Scientific Advisory Board. His research includes stochastic control, estimation, game theory, and optimization, with applications to cooperative control.

Konstantinos Dalamagkidis has been research associate at the Technische Universität München since June 2010. He holds a PhD in computer science and engineering from the University of South Florida (2009), and before his current appointment, he was a postdoctoral research associate at the University of Denver. He is currently the coordinator of the EU FP7-ICT Myrobotics project and has been involved in different capacities in several research projects in the EU and the USA.

In the past, he was also employed as an instructor at the Technological Educational Institute of Crete in Greece. He is the author of the first book on the integration of unmanned aircraft systems into the national airspace, as well as a number of peer-reviewed conference and journal publications. His research interests include mobile robotics and in particular modeling, simulation, control, and planning topics, especially as they relate to unmanned aircraft safety and reliability.

Graham Drozeski is a program manager and chief engineer for advanced aircraft development programs at Aurora Flight Sciences. His current programs target improved autonomy for vertical takeoff and landing platforms and extended reach for ship-launched unmanned systems. Dr. Drozeski specializes in flight technologies including flight control, simulation, handling qualities, vehicle management, mission management, and human–systems interaction. Formerly, Dr. Drozeski was Karem Aircraft’s Director of Flight Technologies and served as program manager for the Karem Aircraft–Lockheed Martin team on the Joint Heavy Lift (JHL) program. He holds a doctorate from Georgia Tech for his development of novel control technologies for unmanned aerial vehicles. Graham is a former US Army aviator. While a company commander, he oversaw operational testing of the first UH-60 A2C2S (Army Airborne Command and Control System).

Eric W. Frew is an associate professor in the Aerospace Engineering Sciences Department and the director of the Research and Engineering Center for Unmanned Vehicles (RECUV) at the University of Colorado Boulder (CU). He received his BS in mechanical engineering from Cornell University in 1995 and his MS and PhD in aeronautics and astronautics from Stanford University in 1996 and 2003, respectively. Dr. Frew's research efforts focus on autonomous flight of heterogeneous unmanned aircraft systems, optimal distributed sensing by mobile robots, controlled mobility in ad hoc sensor networks, miniature self-deploying systems, and guidance and control of unmanned aircraft in complex atmospheric phenomena. He is currently the CU site director for the National Science Foundation Industry/University Cooperative Research Center (I/UCRC) for Unmanned Aircraft Systems. He received his NSF Faculty Early Career Development (CAREER) Award in 2009 and was selected for the 2010 DARPA Computer Science Study Group.

Kai Goebel is a deputy area lead of the Discovery and Systems Health Technology Area at NASA Ames Research Center. He also coordinates the Prognostics Center of Excellence and is the technical lead for Prognostics and Decision Making in NASA's System-wide Safety and Assurance Technologies Project. Prior to joining NASA in 2006, he was a senior research scientist at General Electric Corporate Research and Development Center since 1997. Dr. Goebel received his PhD at the University of California at Berkeley in 1996. He has carried out applied research in the areas of real-time monitoring, diagnostics, and prognostics, and he has fielded numerous applications for aircraft engines, transportation systems, medical systems, and manufacturing systems. He holds 17 patents and has coauthored more than 250 technical papers in the field of systems health management. Dr. Goebel was an adjunct professor of the CS Department at Rensselaer Polytechnic Institute (RPI), Troy, NY, between 1998 and 2005 where he taught classes in Soft Computing and Applied Intelligent Reasoning Systems. He has been the co-advisor of 6 PhD students. Dr. Goebel is a member of several professional societies, including ASME, AAAI, AIAA, IEEE, VDI, SAE, and ISO. He was the general chair of the Annual Conference of the PHM Society, 2009, has given numerous invited and keynote talks, and held many chair positions at the PHM conference and the AAAI Annual meetings series. He is currently member of the board of directors of the PHM Society and associate editor of the International Journal of PHM.

Michael A. Goodrich received his PhD at Brigham Young University (BYU) in 1996 from the Electrical and Computer Engineering Department. Following graduation, he completed a two-year postdoctoral research associate position at Nissan CBR in Cambridge, Massachusetts. He is currently a professor within the Computer Science Department at BYU. He is the director of the Human Centered Machine Intelligence (HCMI) laboratory with research focused on human-robot interaction, multi-agent learning, artificial intelligence, and decision theory. He has published extensively in the field of human-robot interaction and has been heavily involved in serving in that community as conference chair, as steering committee chair, and currently as managing editor of the *Journal of Human-Robot Interaction*.

Jonathan P. How is the Richard C. Maclaurin professor of aeronautics and astronautics at the Massachusetts Institute of Technology. He received his BASc from the University of Toronto in 1987 and his SM and PhD in aeronautics and astronautics from MIT in 1990 and 1993, respectively. He then studied for two years at MIT as a postdoctoral associate for the Middeck Active Control Experiment (MACE) that flew onboard the Space Shuttle Endeavour in March 1995. Prior to joining MIT in 2000, he was an assistant professor in the Department of Aeronautics and Astronautics at Stanford University. He has graduated a total of 30 PhD students while at MIT and Stanford University on topics related to GPS navigation, multi-vehicle planning, and robust/hybrid control. He has published more than 290 articles in peer-reviewed proceedings and 84 papers in technical journals. His current research interests include (1) design and implementation of distributed robust planning algorithms to coordinate multiple autonomous vehicles in dynamic uncertain environments; (2) spacecraft navigation, control, and autonomy, including GPS sensing for formation-flying vehicles; and (3) adaptive flight control to enable autonomous agile flight and aerobatics. Professor How was the planning and control lead for the MIT DARPA Urban Challenge team that placed fourth in the recent race at Victorville, CA. He was the recipient of the 2002 Institute of Navigation Burka Award, recipient of the AIAA Best Paper Award in the Guidance Navigation and Control Conference in 2011 and 2012, and recipient of the 2011 IFAC Automatica Award for best applications paper and is an associate fellow of AIAA and a senior member of IEEE.

Isaac Kaminer received his PhD in electrical engineering systems from the University of Michigan in 1992. Before that, he spent four years working at Boeing Commercial first as a control engineer in 757/767/747-400 Flight Management Computer Group and then as an engineer in Flight Control Research Group. Since 1992, he has been with the Naval Postgraduate School first at the Aeronautics and Astronautics Department and currently at the Department of Mechanical and Aerospace Engineering where he is a professor. He has a total of over 20 years of experience in the development and flight testing of guidance, navigation, and control algorithms for both manned and unmanned aircraft. His more recent efforts were focused on the development of coordinated control strategies for multiple UAVs and vision-based guidance laws for a single UAV. Professor Kaminer has coauthored more than a hundred refereed publications. Over the years, his research has been supported by ONR, NASA, US Army, NAVAIR, and USSOCOM.

George Lucas is Class of 1984 Distinguished Chair in Ethics in the Vice Admiral James B. Stockdale Center for Ethical Leadership at the United States Naval Academy (Annapolis) and professor of Ethics and Public Policy at the Graduate School of Public Policy at the Naval Postgraduate School (Monterey, CA). He has taught at Georgetown University, Emory University, Randolph-Macon College, and the Catholic University of Louvain, Belgium, and served as Philosophy Department Chairman at Santa Clara University in California. He has received research fellowships from the Fulbright Commission and the American Council of Learned Societies and has served three times (in 1986, 1990, and 2004) as the director of National Endowment for the Humanities Summer Institutes for College and University Faculty. Dr. Lucas is the author of five books, more than fifty journal articles, translations, and book reviews and has also edited eight book-length collections of articles in philosophy and ethics. Among these titles are *New Warriors/New Weapons: Ethics and Emerging Military Technologies* [a special issue of the *Journal of Military Ethics* 9/4 (2010)]; *Anthropologists in Arms: The Ethics of Military Anthropology* (AltaMira Press, 2009); *Perspectives on Humanitarian Military Intervention* (University of California Press, 2001); *Lifeboat Ethics: The Moral Dilemmas of World Hunger* (Harper & Row, 1976); and *Poverty, Justice, and the Law: Essays on Needs, Rights, and Obligations* (UPA, 1986). His essays and peer-reviewed scholarly articles have appeared in *The Journal of Philosophy*, the *Journal of the History of Philosophy*, the *Journal of Military Ethics*, *Ethics and International Affairs*, the *Journal of National Security Law & Policy*, the *Case-Western Review of International Law*, the *Columbia Review of Law and Technology*, and the *International Journal of Applied Ethics*. Dr. Lucas is also coeditor (with Capt. Rick Rubel, US Navy, retired) of the textbook, *Ethics and the Military Profession: the Moral Foundations of Leadership*, and a companion volume, *Case Studies in Military Ethics*, both published by Longman/Pearson Education (New York, 2004; 3rd edition 2010). These texts are used in core courses devoted to ethical leadership at the United States Naval Academy, the United States Air Force Academy, and at Naval ROTC units at over 57 colleges and universities throughout the nation.

Robert C. Michelson is an American engineer and academic widely known for inventing the Entomopter, a biologically inspired flapping-winged aerial robot, and for having established the International Aerial Robotics Competition. He has received degrees in electrical engineering from Virginia Polytechnic Institute and Georgia Institute of Technology. He is the president of Millennial Vision, LLC and SEPDAC Inc., he is Principal Research Engineer Emeritus at the Georgia Tech Research Institute, and adjunct associate professor (Ret.) in the School of Aerospace Engineering at the Georgia Institute of Technology. He is the author of three US patents and over 87 journal papers, book chapters, and reports. Michelson also developed classes in avionics and taught in the School of Aerospace Engineering at the Georgia Institute of Technology and as a Visiting Technology professor in six other nations. Michelson is an associate fellow of the American Institute of Aeronautics and Astronautics (AIAA), senior member of the Institute of Electrical and Electronics Engineers (IEEE), and a full member of the Scientific Research Society of North America, Sigma Xi. During the 1990s, he served as president and member of the board of directors of the Association for Unmanned Vehicle Systems (AUVSI) International organization. He is the recipient of the 1998 AUVSI Pioneer Award and the 2001 Pirelli Award for the diffusion of scientific culture as well as the first Top Pirelli Prize.

Nafiz Alemdaroğlu received his Bsc. degree from the Mechanical Engineering Department of Middle East Technical University (METU) in 1972. He got his masters and Ph degrees from The Engineering School in Poitiers France (Ecole Nationale Supérieure de Mécanique et D'Aérotechnique, ENSMA), in 1975 and 1979 respectively.

After completing his PhD studies he returned to METU and joined the faculty of ME department in 1981. He was promoted to associate professor in 1984. Same year he joined the California State University in Long Beach (CSULB) as a visiting professor where he worked first in the Mechanical Engineering Department and then he helped the founding of the new Aerospace Engineering Department. In 1991 he returned back to METU but this time to the Department of Aeronautical Engineering. In 1992, he was promoted to full professor in the same department. Since then, he is a faculty member of the Aerospace Engineering Department. Between 1997 and 2006, he served as the chairman of the Aerospace Engineering Department.

Prof. Alemdaroğlu served as the Turkish panel member for the Flight Vehicle Integration (FVP) panel of NATO-AGARD between 1994 and 1998. After the establishment of the Research and Technology Organization (RTO) of NATO in 1998, he served as a panel member in the Systems Concepts and Integration Panel (SCI) of this organization. Between 2000 and 2004 he was the chairman of the Systems Concepts and Integration Panel. In 2010 he was assigned as the Turkish national board member for NATO Research and Technology Organization (RTO). He is still a board member in the same organization. However, the name of the organization is changed to NATO, Science and Technology Organization (STO). Prof. Alemdaroğlu also served and is still serving in the Flight Test Technology Team (FTTT) of the SCI panel since 1995.

Between 1991 and 2010 Prof Alemdaroğlu was consultant to Roketsan Inc., Turkish Missile Industries Company, and contributed significantly to the development of various missile systems.

Prof. Alemdaroğlu teaches courses related to aerodynamics, aeronautical design, heat transfer, fluid dynamics, boundary layer theory, experimental aerodynamics, and turbulent flows.

Prof. Alemdaroglu is heavily involved with research in Unmanned Aerial Systems. Since 2004 he has developed three Unmanned Aerial Systems, two man portable/man launchable mini UAS and one tactical-level UAS. He has been working with ASELSAN Inc., the leading Turkish Military Electronics Company since 2010, for the development of mini and tactical-level unmanned aerial systems.

Paul Oh is the Lincy Professor of Unmanned Aerial Systems in the Mechanical Engineering Department at the University of Nevada, Las Vegas (UNLV). Formerly, from 2000 to 2014, he served as a mechanical engineering professor at Drexel University in Philadelphia and both founded and directed the Drexel Autonomous Systems Laboratory (DASL). He received his Mechanical Engineering degrees from McGill (B.Eng. 1989), Seoul National (MSc 1992), and Columbia (PhD 1999). Honors he received include faculty fellowships at NASA Jet Propulsion Lab (2002) and Naval Research Lab (2003), the NSF CAREER Award (2004), and the SAE Ralph Teetor Award for Engineering Education Excellence (2005). He was named a Boeing Welliver fellow (2006), elected as ASME fellow (2011), and appointed as Senior Faculty Fellow (2013) at the Naval Seas Systems Command (NAVSEA) for the Office of Naval Research (ONR). He was also the founding chair of the IEEE Technical Committee on Aerial Robotics and UAVs. He served for two years (2008–2010) at the National Science Foundation (NSF) as the program director managing the robotics research portfolio.

Aníbal Ollero (<http://grvc.us.es/aollero>) is full professor and head of the GRVC Group (55 researchers) at the University of Seville and scientific advisor of the Center for Advanced Aerospace Technologies in Seville. He has been full professor at the Universities of Santiago de Compostela and Malaga in Spain and researcher at Carnegie Mellon University (Pittsburgh, USA) and LAAS-CNRS (Toulouse, France). He is author/coauthor of 460 publications, including 9 books and 110 papers in SCI journals. He led about 120 projects and is currently the coordinator of the ARCAS and EC-SAFEMOBIL FP7 Integrated Projects of the European Commission and associated coordinator of FP7 PLANET and CONET Network of Excellence. He is the recipient of 13 national and international awards for his R&D activities including the second 2010 EUROP-EURON Technology Transfer Award and the IV Javier Benjumea Award by Scientific Excellence and Social Impact. He has been advisor of 25 PhD thesis.

Daniel J. Pack is Mary Clark professor and chair of the Electrical and Computer Engineering Department at the University of Texas, San Antonio. He was a professor of electrical and computer engineering and director of the Academy Center for Unmanned Aircraft Systems Research at the United States Air Force Academy, CO. He currently holds the Professor Emeritus position at the Academy. He received his Bachelor of Science degree in electrical engineering, the Master of Science degree in engineering sciences, and the PhD degree in electrical engineering from the Arizona State University, the Harvard University, and the Purdue University, respectively. He was a visiting scholar at the Massachusetts Institute of Technology-Lincoln Laboratory. Dr. Pack has coauthored six textbooks on embedded systems (including 68HC12 Microcontroller: Theory and Applications and Embedded Systems: Design and Applications with the 68HC12 and HCS12) and published over 120 book chapters, technical journal/transactions articles, and conference papers on unmanned systems, cooperative control, robotics, pattern recognition, and engineering education. He is the recipient of a number of teaching and research awards including the Carnegie US Professor of the Year Award, the Frank J. Seiler Research Excellence Award, the Tau Beta Pi Outstanding Professor Award, the Academy Educator Award, and the Magoon Award. He is a member of Eta Kappa Nu (Electrical Engineering Honorary), Tau Beta Pi (Engineering Honorary), IEEE (senior member), and the American Society of Engineering Education. He is a registered professional engineer in Colorado. His research interests include unmanned aerial vehicles, intelligent control, automatic target recognition, and robotics.

Fulvia B. Quagliotti took the degree of doctor in Aeronautical Engineering at the Politecnico di Torino (Torino Technical State University), Italy. Then she was consultant for development of European space programs, at the Italian Delegation at OCSE, in Paris. Then she was at FIAT Aviation Division (later AERITALIA and now ALENIAAERMACCHI), Space Division, taking part in several programs: the development of the Italian satellite SIRIO, the project of the thermal shields for the European launcher Europa III, the GEOS Satellite program, the METEOSAT program, as program manager for AERITALIA and, finally, the first development of the SPACE LAB program, responsible for project control.

Since November 1974 she is staff member at Politecnico di Torino, where she is presently an associate professor of Flight Mechanics, in the Department of Mechanical and Aerospace Engineering (formerly Aerospace Engineering Department). She is responsible of several research activities in the field of theoretical and experimental Flight Mechanics and experimental Aerodynamics, Flight Simulation, Flight Control and design of Micro and Mini aerial vehicles (she is holding a patent for the configuration). She joined the AGARD Flight Mechanics Panel in 1992 till 1997, when NATORTO (Research and Technology Organization), now NATO-STO (Scientific and Technology Organization), was stated. In those organizations she is the Italian Academia representative in the Applied Vehicle Technology Panel. Previously she represented the Italian Academia in the System Concept Integration Panel, where she served as vice-chairman of the Panel and chairman of the Program Committee for seven years. Within the AVT Panel, she is a member of the Strategic Committee and panel mentor for a Task Group on UASs.

She is an international editor of Journal of Aircraft and an associate fellow of AIAA, senior editor for Springer, member of the editorial board of Automatic Control in Aerospace – online journal.

Michael J. Roemer is the cofounder of Impact Technologies, now part of Sikorsky Aircraft, with over 20 years experience in the development of automated health monitoring, diagnostic and prognostic systems for a wide range of military and commercial applications. He is currently the Sikorsky Technical fellow for Prognostics and Health Management (PHM). His experience includes a wide range of integrated vehicle health management system implementations to detect and predict system faults in real time and perform automated troubleshooting and maintenance planning. He is the cofounder and past vice president of the PHM Society, chairman of the SAE HM-1 Integrated Vehicle Health Management Committee, board member and past chairman of the Machinery Failure Prevention Technology (MFPT) Society, Member of the IGTI Marine Committee and ASME Controls and Diagnostics Committee and Adjunct Professor of Mechanical Engineering at the Rochester Institute of Technology. He is the coauthor of a recent book titled “Intelligent Fault Diagnosis and Prognosis for Engineering Systems” and has written or coauthored more than 100 technical papers related to integrated systems health management.

David Hyunchul Shim received his BS and MS degrees in Mechanical Design and Production Engineering from Seoul National University, Seoul, Korea, and the PhD degree in Mechanical Engineering from the University of California, Berkeley, in 1991, 1993, and 2000, respectively. From 1993 to 1994, he was with Hyundai Motor Company, Korea, as transmission design engineer. From 2001 to 2005, he was with Maxtor Corporation, California, USA, as staff servo engineer. From 2005 to 2007, he was with UC Berkeley as principal engineer, in charge of the Berkeley Aerobot Team, working on advanced UAV research. In 2007, he joined the Department of Aerospace Engineering at KAIST, South Korea, as assistant professor. He is now associate professor and also director of KAIST Field Robotics Research Center, working on various research projects on unmanned aerial and ground vehicles in the area of novel platform development and control, advanced navigation, and multi-agent coordination.

L.J.P. (Lennaert) Speijker is employed as senior scientist at the Air Transport Safety Institute of NLR, where he started in 1995. He focuses on aviation safety and certification research and consultancy for EC, EASA, EUROCONTROL, ANSPs, manufacturers, and regulators. He is currently managing the EC Project ASCOS (Aviation Safety and Certification of new Operations and Systems). Within a multi-year cooperation agreement between FAA and CAA Netherlands, he worked on safe integration of RPAS in non-segregated airspace. His RPAS research includes safety risk management, safety risk criteria, safety methods, research on detect and avoid systems, and risk analysis of command and control. For EASA, he investigated the use of detect and avoid systems to improve “See and Avoid” for manned general aviation. He is a member of Joint Authorities for Rulemaking on Unmanned Systems (JARUS, on behalf of CAA Netherlands) and the European General Aviation Safety Team (EGAST).

Richard S. Stansbury is an associate professor of computer engineering and computer science at Embry-Riddle Aeronautical University (ERAU) in Daytona Beach, FL. He is the coordinator for the Master of Science in Unmanned and Autonomous Systems Engineering program, a multidisciplinary engineering program focused upon air, ground, and sea-based robotic systems. He currently teaches Introduction to Artificial Intelligence and Data Structures and Algorithms courses. From 2007 to 2013, he co-taught the capstone senior design course for electrical engineering, computer engineering, and software engineering students.

As a graduate student at the University of Kansas, where he received his BS and MS in computer engineering and his PhD in computer science, Dr. Stansbury developed autonomous ground vehicles for operation in Greenland and Antarctica. His research as part of the NSF Center for Remote Sensing of Ice Sheets supported the autonomous surveys of radar data to measure properties of the polar ice sheets. He and his two prototype vehicles MARVIN I and II traveled to Greenland and Antarctica for field exercises.

At ERAU, his research has transitioned from ground robots to unmanned aircraft systems (UAS). His early UAS research funded by the FAA focused upon the survey of current and near-term future UAS technologies and their regulatory impact (through a regulatory gap analysis). This research has been continued under a grant from NASA. Starting in 2010, Dr. Stansbury began development as part of a multidisciplinary team on an unmanned aircraft for NOAA to provide in situ measurement of atmospheric conditions within tropical cyclones. This unmanned aircraft, Gale, is expected to be test flown in 2012.

Dr. Stansbury is involved in a variety of professional service activities in support of UAS research. He advises ERAU's Team Blackbird at the AUVSI Student UAS competition. He is a member of the AUVSI UAS Advocacy Committee and the AUVSI 2013 Unmanned Systems Conference Program Committee. He is also a member of the AIAA Unmanned Systems Program Committee.

Salah Sukkarieh received his BE in mechatronics in 1997 and PhD in robotics in 2000 at the University of Sydney. He is the director of Research and Innovation at the Australian Centre for Field Robotics and professor of Robotics and Intelligent Systems at The University of Sydney. His interests in UAS are on data fusion techniques for mapping, tracking and localization, and in the area of cooperative perception and decision making. He was the project and research lead on a number of grants in the application of UAS in security and the environment, including funding from BAE Systems, US Air Force, Land and Water Australia, Meat and Livestock Australia, US Office of Naval Research, Ministry of Defense UK, the Department of Agriculture, Forestry and Fishery, and the Australian Research Council.

Ben Upcroft received his undergraduate degree (with honors) in science and his PhD degree in Ultracold Atomic Physics from the University of Queensland, Australia, in 2003. He subsequently joined the Australian Research Council (ARC) Centre of Excellence for Autonomous Systems, The University of Sydney, Sydney, N.S.W., Australia, as a postdoctoral fellow where he was engaged in the field of robotics. He then moved to the University of Queensland as a senior lecturer in mechatronics and focused on computer vision-aided localization and navigation for autonomous ground and aerial vehicles. He is now a senior lecturer of mechatronics at the Queensland University of Technology, Brisbane, QLD, Australia, and has participated in major industrial projects involving autonomous aircraft, off-road and urban vehicles, and network communications. His current research interests include computer vision for navigation and environment classification applied to mobile robots.

Lora Weiss is a lab chief scientist and technical director of Autonomous Systems at the Georgia Tech Research Institute. Her research focus is on the design, development, and implementation of technologies for unmanned and autonomous systems. She has conducted research on unmanned systems spanning the domains of air, ground, sea-surface, and undersea. She has chaired technical sessions at professional conferences and has provided over 300 technical presentations. Dr. Weiss was on the board of directors for the Association of Unmanned Vehicle Systems International (AUVSI), which is the world's largest unmanned systems organization. She was on the Technical Advisory Board of the Robotics Technology Consortium, and she was an executive board member of the National Defense Industrial Association. She currently chairs the ASTM Committee on Unmanned Maritime Vehicle Autonomy and Control and is a member of the Information Science and Technology Study Group for DARPA. In 2012, Dr. Weiss received the AUVSI Foundation Award for Academic Champion. In 2012, she also received Women in Technology's Women of the Year Award for medium-sized businesses.

Contents

Volume 1

| | |
|---|------------|
| Section I Introduction | 1 |
| <i>Konstantinos Dalamagkidis, George J. Vachtsevanos and Kimon P. Valavanis</i> | |
| 1 Introduction..... | 3 |
| Kimon P. Valavanis and George J. Vachtsevanos | |
| 2 Introduction to the Handbook on UAVs | 5 |
| Kimon P. Valavanis and George J. Vachtsevanos | |
| 3 Definitions and Terminology | 43 |
| Konstantinos Dalamagkidis | |
| 4 Aviation History and Unmanned Flight | 57 |
| Konstantinos Dalamagkidis | |
| 5 Classification of UAVs..... | 83 |
| Konstantinos Dalamagkidis | |
| 6 Military and Civilian Unmanned Aircraft | 93 |
| George J. Vachtsevanos and Kimon P. Valavanis | |
| Section II UAV Design Principles | 105 |
| <i>Daniel J. Pack and Graham Drozeski</i> | |
| 7 UAV Design Principles: Introduction | 107 |
| Kimon P. Valavanis and George J. Vachtsevanos | |
| 8 Computational and Experimental Design of a Fixed-Wing UAV | 109 |
| Helen Ryaciotaki-Boussalis and Darrell Guillaume | |

| | | |
|--|--|------------|
| 9 | UAV Handbook: Payload Design of Small UAVs | 143 |
| | Scott Gruber, Hyukseong Kwon, Chad Hager, Rajnikant Sharma, Josiah Yoder, and Daniel Pack | |
| 10 | Small UAV Design Development and Sizing | 165 |
| | Steven A. Brandt | |
| 11 | Systematic Design Methodology and Construction of Micro Aerial Quadrotor Vehicles | 181 |
| | Swee King Phang, Kun Li, Ben M. Chen, and Tong H. Lee | |
| 12 | Dexterous UAVs for Precision Low-Altitude Flight | 207 |
| | Guangying Jiang and Richard M. Voyles | |
| Section III UAV Fundamentals | | 239 |
| <i>Isaac I. Kaminer</i> | | |
| 13 | UAV Fundamentals: Introduction | 241 |
| | Kimion P. Valavanis and George J. Vachtsevanos | |
| 14 | Kinematics and Dynamics of Fixed-Wing UAVs | 243 |
| | Vladimir Dobrokhodov | |
| 15 | Dynamic Model for a Miniature Aerobatic Helicopter | 279 |
| | Vladislav Gavrillets | |
| 16 | Quadrotor Kinematics and Dynamics | 307 |
| | Caitlin Powers, Daniel Mellinger, and Vijay Kumar | |
| 17 | Dynamics and Control of Flapping Wing MAVs | 329 |
| | David B. Doman, Michael W. Oppenheimer, and David O. Sigthorsson | |
| 18 | Principles of Guidance, Navigation, and Control of UAVs | 347 |
| | Gabriel Hugh Elkaim, Fidelis Adhika Pradipta Lie, and Demoz Gebre-Egziabher | |
| Section IV Sensors and Sensing Strategies | | 381 |
| <i>Ben Upcroft and Salah Sukkarieh</i> | | |
| 19 | Sensors and Sensing Strategies: Introduction | 383 |
| | Kimion P. Valavanis and George J. Vachtsevanos | |
| 20 | Sensors for Missions | 385 |
| | Luis Mejias, John Lai, and Troy Bruggemann | |
| 21 | Inertial Sensor-Based Simultaneous Localization and Mapping for UAVs | 401 |
| | Mitch Bryson and Salah Sukkarieh | |

| | | |
|-----------|--|------------|
| 22 | UAV Localization Using Inertial Sensors and Satellite Positioning Systems | 433 |
| | Mitch Bryson and Salah Sukkarieh | |
| 23 | Data Fusion and Tracking with Multiple UAVs | 461 |
| | Matthew F. Ridley, Ben Uperoft, and Salah Sukkarieh | |
| | Section V UAV Propulsion | 491 |
| | <i>George J. Vachtsevanos and Kimon P. Valavanis</i> | |
| 24 | UAV Propulsion: Introduction | 493 |
| | Kimon P. Valavanis and George J. Vachtsevanos | |
| 25 | Power Managements of a Hybrid Electric Propulsion System Powered by Solar Cells, Fuel Cells, and Batteries for UAVs | 495 |
| | Bohwa Lee, Poomin Park, and Chuntaek Kim | |

Volume 2

| | |
|---|---|
| Section VI UAV Control | 525 |
| <i>Jonathan P. How</i> | |
| 26 UAV Control: Introduction | 527 |
| | Kimon P. Valavanis and George J. Vachtsevanos |
| 27 Linear Flight Control Techniques for Unmanned Aerial Vehicles ... | 529 |
| | Jonathan P. How, Emilio Frazzoli, and Girish Vinayak Chowdhary |
| 28 Nonlinear Flight Control Techniques for Unmanned Aerial Vehicles | 577 |
| | Girish Vinayak Chowdhary, Emilio Frazzoli, Jonathan P. How, and Hugh Liu |
| 29 Adaptive Control of Unmanned Aerial Vehicles: Theory and Flight Tests | 613 |
| | Suresh K. Kannan, Girish Vinayak Chowdhary, and Eric N. Johnson |
| 30 Robust and Adaptive Control Methods for Aerial Vehicles | 675 |
| | Eugene Lavretsky |
| Section VII UAV Communication Issues | 711 |
| <i>Eric W. Frew</i> | |
| 31 UAV Communication Issues: Introduction | 713 |
| | Kimon P. Valavanis and George J. Vachtsevanos |

| | | |
|--|---|-------------|
| 32 | Problem of UAV Communications..... | 715 |
| | Stephen B. Heppe | |
| 33 | Cognitive Networking for UAV Swarms | 749 |

Section I

Introduction

***Konstantinos Dalamagkidis,
George J. Vachtsevanos and
Kimon P. Valavanis***

Kimon P. Valavanis and George J. Vachtsevanos

This Introduction of the handbook presents background information related to unmanned aircraft in general. It is mostly nontechnical, focusing on introducing the concept and idea of the unmanned/pilotless aircraft and how unmanned aircraft evolved over the years reaching their current state.

To begin with, it is crucial to understand that the field of unmanned aircraft has been plagued with different terms, which basically describe the same “concept.” Even the term UAV is controversial, and it is being replaced in many places with RPA, UAS, or RPAS. Different terms often result from the different requirements and concepts between military and civilian systems or from regulatory and legal considerations. Regardless, ►[definitions](#) for some of the most widely used terminology are presented in this section. Further, throughout the handbook, the different acronyms/terms that define unmanned aircraft are used interchangeably; however, the context in which such terms are used is clear and noncontroversial.

►[A historical and pictorial perspective of unmanned aviation](#) is also presented, which depicts that unmanned flight has a rich history that goes back all the way to ancient times, although the first systems that qualify with the modern definition of UAVs are quite recent and mainly involve the reconnaissance drones developed and deployed during the Cold War.

►[Proposed UAV classification](#) schemes from a variety of sources, both ►[civilian and military](#), are included to help differentiate existing systems based on their

G.J. Vachtsevanos

Professor Emeritus, School of Electrical and Computer Engineering, The Georgia Institute of Technology, Atlanta, GA, USA

e-mail: gjv@ece.gatech.edu

operational characteristics and their capabilities. Several of these schemes are also of regulatory importance since the metrics used directly correlate with risk from ground impact or midair collision accidents.

Concise information about the rest of the handbook is also included in this part, since it aims at familiarizing the reader with the unmanned/pilotless aircraft concept at large and the potential of unmanned aviation for a very wide and diverse spectrum of applications.

In summary, this section educates the reader who will be ready to continue with the basic UAV design principles at a technical level.

Abstract

This chapter presents an overall introduction and overview of the handbook, including each section objectives along with summaries of the chapters included in each section. The goal of this chapter is twofold: (i) familiarize the reader with the contents of each section and (ii) provide the reader with a choice to prioritize reading based on her/his specific interest and knowledge level. After reading this chapter, the reader will have a rather complete picture of the material included in the handbook.

2.1 Introduction

The *Handbook of Unmanned Aerial Vehicles* presents a unique and comprehensive treatise of everything one needs to know about unmanned aircraft, from conception to operation, from technologies to business activities, users, OEMs, reference sources, conferences, publications, and professional societies. The main objective is for the handbook to serve as a Thesaurus, an indispensable part of the library of everyone involved in the area of unmanned aviation. For the first time, contributions by the world's top experts from academia, industry, government, and the private sector are brought together to provide unique perspectives on the current state of the art in unmanned aviation, as well as future directions.

The handbook is intended for the academic and research communities, industry, manufacturers, users, practitioners, federal government, federal and state agencies, the private sector, as well as all organizations that are and will be using unmanned aircraft in a wide spectrum of applications. It covers all aspects of UAVs, from design to logistics and ethical issues. It is also targeting the young investigator, the future inventor, and entrepreneur by providing an overview and detailed information of the state of the art as well as useful new concepts that may lead to innovative research. The contents of the handbook include material that addresses the needs and *know-how* of all of the above sectors targeting a very diverse audience.

The title of the handbook, *Handbook of Unmanned Aerial Vehicles*, reflects nothing more but the preferred term at the time the proposal was made to the publisher, and it should be treated as such. It is noted that different names are being used to describe unmanned aviation and aircraft (UAV, RPA, UAS, RPAS) in subsequent chapters, but the context in which such names are used in the handbook is self-explanatory. For example, the terms UAVs and UAS have distinct definitions, and it should be clear why, at first, UAVs became UAS: A UAV refers to a pilotless aircraft, a flying machine without an onboard human pilot or passengers. As such, "unmanned" implies total absence of a human who directs and actively pilots the aircraft. Control functions for unmanned aircraft may be either onboard or offboard (remote control). The term UAS was introduced by the U.S. Department of Defense, followed by the FAA and the European Aviation Safety Agency (EASA). This term was meant to signify that UAS are aircrafts, and as such airworthiness will need to be demonstrated, and they are also systems consisting of ground control stations,

communication links and launch, and retrieval systems in addition to the aircraft itself. Similar distinctions are true for RPA versus RPAS. Other names include remotely piloted vehicles (RPVs), a term that was used in the Vietnam War, while the U.S. military also calls them RPA, a term used to include both the aircraft and the pilot, while the UK and ICAO have designated them as RPAS, to demonstrate the presence of the man in the loop to control them. The ICAO recommended definition for RPAS is “A set of configurable elements consisting of a remotely-piloted aircraft, its associated remote pilot station(s), the required command and control links and any other system elements as may be required, at any point during flight operation.”

Material in the handbook is arranged in a user-friendly format divided into twenty-one (21) sections in addition to the Introduction section. Each section contains either original material or enhanced versions of already published work, written by internationally renowned authors who are authorities in their respective fields. The corresponding sections are:

- UAV Design Principles
- UAV Fundamentals
- UAV Sensors and Sensing Strategies
- UAV Propulsion
- UAV Control
- UAV Communication Issues
- UAV Architectures
- UAV Health Management Issues
- UAV Modeling, Simulation, Estimation, and Identification
- MAVs and Bio-inspired UAVs
- UAV Mission and Path Planning
- UAV Autonomy
- UAV Sense, Detect, and Avoid Systems
- Networked UAVs and UAV Swarms
- UAV Integration into the National Airspace
- UAV-Human Interfaces and Decision Support Systems
- Human Factors and Training
- UAV Logistics Support
- UAV Applications
- Social and Ethical Implications
- Epilogue

The Introduction section of the handbook presents background information related to unmanned aircraft in general. It is mostly nontechnical, focusing on introducing the concept and idea of the unmanned/pilotless aircraft and how unmanned aircraft evolved over the years reaching their current state. A historical and pictorial perspective of unmanned aviation is also presented, which depicts that unmanned flight has a rich history that goes back all the way to ancient times, although the first systems that qualify with the modern definition of UAVs are quite recent and mainly involve the reconnaissance drones developed and deployed during the cold war.

Section ► [UAV Design Principles](#) presents the basic design principles of UAVs and the components that comprise a complete unmanned aircraft system, avoiding in-depth technical details. It aims at creating the “overall picture” with respect to UAV functionality and, consequently, to indirectly motivate the reader about the challenges that need to be overcome in order to make UAVs fully operational, reliable, and safe.

Section ► [UAV Fundamentals](#) details what constitutes the foundational elements of UAV design technologies, covering kinematics and dynamics for fixed-wing, rotorcraft, quadrotors, and flapping-wing MAVs, as well as *principles* of UAV guidance, navigation, and control.

Section ► [UAV Sensors and Sensing Strategies](#) focuses on what enables an unmanned aircraft to “sense,” “see,” “hear,” and “understand” the world around it so that it may function intelligently in an unknown and cluttered environment and in the absence of an onboard pilot. In essence, sensors and sensing strategies are crucial since they provide the technologies that will result in “unmanned aircraft operating as if there were a human pilot onboard.”

Section ► [UAV Propulsion](#) refers to that critical and indispensable module of the UAV structure, which provides the necessary thrust to maintain a flight. The UAV performance, effectiveness, and utility depend strongly on the onboard propulsion capabilities. Jointly with other UAV design considerations, the propulsion system determines the endurance, size, weight, and application domain of all UAV classes.

Section ► [UAV Control](#) presents a very comprehensive treatment of UAV control and related technologies. The inherently unstable nature of typical UAV configurations necessitates a rigorous approach to the analysis and design of UAV control technologies, as well as a thorough understanding of stability issues.

Section ► [UAV Communication Issues](#) discusses the development and application of robust, effective, and secure communication technologies that will enable unmanned aircraft to unmanned aircraft, unmanned aircraft to ground or mother ship communications, and unmanned aircraft to air traffic controller communications. Unmanned aircraft control and communication issues are tightly coupled, and they are treated as such, since the *Achilles heel* of UAVs is controlling them when they are out of range.

Section ► [UAV Architectures](#) refers to UAVs as complex engineered systems requiring combination of a diverse grouping of hardware and software technologies for their performance and effectiveness. UAVs must incorporate in their design and operation sophisticated hybrid architectures that integrate in a rather robust way and meet stringiest performance requirements. This section presents and discusses UAV system concepts migrating from the individual UAV component technologies toward a *system of systems* view addressing and answering the question *how do we put it all together?*

Section ► [UAV Health Management](#) addresses fundamental technologies and their application to UAVs that relate to monitoring and sensing strategies for health management, data acquisition and processing/analysis onboard and offboard the vehicle, fault diagnosis, and failure prognosis algorithms, as well as fault-tolerant control routines that enhance the UAV’s useful life and mitigate potential

catastrophic events. Condition-based maintenance methods and tools are also covered that take advantage of the prevailing paradigm shift from scheduled or breakdown maintenance toward maintenance practices that are based on the current condition of these assets.

Section ►[UAV Modeling, Simulation, Estimation, and Identification](#) presents a treatment of these topics from first principles to mechanisms that lead to UAV qualification and certification. Modeling and simulation techniques are essential and crucial in the design, operation, and performance assessment of UAVs. Together with estimation and identification, they are integral components of the overall UAV design process. They afford the opportunity to develop, test, and evaluate sensing, control, and cooperative control algorithms, among others. Software-in-the-loop and hardware-in-the-loop simulations are typical prerequisites to flight testing.

Section ►[MAVs and Bio-inspired UAVs](#) addresses the emerging UAV area of micro aerial vehicles (MAVs) and bio-inspired MAVs and UAVs. Research and development activities in MAVs have accelerated significantly over the past years, driven by a need for small autonomous vehicles that can execute a variety of tasks, such as intelligence, surveillance, and reconnaissance (ISR) in complex urban environments, search and rescue operations, and security and border patrol, among other applications. A substantial component of the MAV research is inspired by the exceptional flying behaviors of biological species, i.e., birds and insects. MAVs can be operated by a single person offering low weight and cost, extreme maneuvering capabilities, and rapid response times to requests for visual observations. Innovative MAV concepts are motivating advanced research and development sponsored by government and industry.

Section ►[UAV Mission and Path Planning](#) moves beyond fundamental UAV technologies to higher-level functionalities such as mission and path planning for single and multiple UAVs, as UAVs are employed to execute a variety of “missions” in both military and civilian environments. Planning and executing a mission in terms of prescribing the path or trajectory generation and other related topics are challenging problems that require careful consideration. A plethora of methods and techniques are presented, along with specific examples from the utility of mission- and path-planning technologies, suitable to assist the planner to complete an assigned mission.

Section ►[UAV Autonomy](#) addresses perhaps the most challenging and important topic that is central to unmanned aircraft performance, autonomy. Autonomous flight is a major target goal of all technologists. The ability of a UAV to take off, execute a mission, and return to its base without significant human intervention (this is the human-on-the-loop concept rather than the human-in-the-loop current requirement) promises to enhance UAV deployment in many application domains. Contributions address levels of autonomy and those specific technical challenges that must be overcome if one aims at approaching eventually “full UAV autonomy.” Hardware and software requirements for increased autonomy are discussed with emphasis on algorithms that will bestow to the UAV features of autonomy.

Section ►[UAV Sense, Detect, and Avoid Systems](#) introduces the reader to those sensing, processing, and control enabling technologies that constitute the

“sense-detect-and-avoid” technical foundations. Requirements, technologies, and future trends in sense, detect, and avoid are covered thoroughly. Sense and avoid (SAA) remains one of the key enabling capabilities required for the safe airspace integration of UAS into the global airspace system. Very little has been done to satisfy the technical and operational requirements necessary for allowing the unfettered access to civil airspace, domestically and internationally, projected to be needed by the U.S. DoD and the civil/commercial market. Although standard organizations like RTCA and EUROCAE are focusing on the problem, the current lack of specific UAS standards is clearly slowing the progress of the defense and commercial development of this exploding technology. In addition, as it relates to SAA, the impact of the lack of a SAA focused “program of record” within one or all of the federal agencies, and the associated funding that will be required and/or the lack of existing technical capability to move toward an autonomous solution believed by many to be necessary for complete, unfettered access to the national airspace appears to be slowing progress.

Section ► [Networked UAVs and UAV Swarms](#) addresses sensing, supervisory control, coordination and cooperation, computing, and communication issues that constitute the basic ingredients of safe and effective flight for multiple UAVs, emphasizing the “intelligence” requirements for safe flight and cooperative and supervisory control. The unmanned aircraft military and civilian communities are already experimenting with UAV swarms flying in formation while cooperating in the execution of specific missions. Research in networked UAVs is also proceeding via simulation studies and limited experimentation.

Section ► [UAV Integration into the National Airspace](#) reviews and presents policies, procedures, and requirements for manned aviation and relates them to existing and under development equivalent policies and requirements for unmanned aviation. Integration of unmanned aviation into the (any) national airspace requires, again, that *UAVs function as if there were a human pilot onboard*. This requirement and restriction dictates that equivalent levels of safety (ELOS) must be derived for unmanned aviation (depending on the UAV classification), in addition to reliability and fault-tolerance requirements. The major deviation from manned aviation requirements is that a controlled crash may be allowed for UAVs provided that human lives are not endangered and that collateral damage is minimized.

Section ► [UAV-Human Interfaces and Decision Support Systems](#) focuses on research findings and efforts that are underway by the UAV user community to reduce the current UAV operator workload levels. Until a satisfactory level of autonomy is achieved, the human will continue to function as an integral part of the UAV ground control station (GCS) loop. Moreover, intelligence acquired by UAVs must be communicated in an appropriate format to humans on the ground or to a mother ship for further analysis, assessment, and action. The human must intervene when new intelligence suggests that the operational profile must be changed.

Section ► [Human Factors and Training](#) addresses the topic of training of OEMs, military, and other human operators to operate, monitor, and execute a complete mission for all classes of platforms currently available to the military and other sectors.

Section ► **UAV Logistics Support** refers to UAV lifetime operation support; scheduling issues; delivery of goods and services; maintenance, testing, and fielding of UAVs; design and operation for reliability, safety, availability, and maintainability; logistics for ground station support and mobile UAV platforms; and potentially human operator support.

Section ► **UAV Applications** offers a “taste” of possible civil and public domain applications in which single or multiple UAVs may be used. As the roadmap of the UAS integration into the global airspace is formulated amidst current obstacles and skepticism, it is only logical to consider that the spectrum of possible applications will be much wider in the years to come. At the present stage, UAVs have either been considered for or have seen (very) limited utilization in a wide range of applications that include but are not limited to power line inspection; pipeline inspection; ship inspection; mine inspection; dam inspection; anomaly detection/prevention; early fire detection and forest protection; hazard monitoring; traffic monitoring; environmental monitoring; search and rescue operations; emergency response; border patrol; harbor patrol; police surveillance; aerial photography; SWAT support; imaging and mapping; intelligence, surveillance, and reconnaissance (ISR); chemical spraying; crop dusting; night vision; and entertainment industry and filming.

Section ► **Social and Ethical Implications** offers comprehensive and detailed information aiming at answering the question *What are the social, legal and ethical concerns associated with the use of UAVs.*

The *Epilogue* concludes the handbook.

In what follows, UAVs are put in the context of “unmanned systems.” The term UAV is used loosely and freely representing (in the proper context) the also used terms like RPA, UAS, and RPAS.

2.2 UAVs in the Context of Unmanned Systems

Unmanned systems (US) are typically known as powered vehicles (air, maritime, and ground) that do not carry a human operator, can be operated autonomously or remotely, can be expendable or recoverable, and can carry a variety of payloads depending on their type, functionality, operational characteristics, and mission objectives.

Unmanned vehicles (UVs), the primary component of US, have captivated the imagination of humans for centuries. For example, the idea for a “flying machine” was first conceived close to 2,500 years ago, in ancient Greece and China! Pythagoras, Archimedes, and others studied the use of autonomous mechanisms for a variety of applications. The first known autonomous flying machine has been credited to Archytas of Tarentum in South Italy, known as Archytas the Tarantine. Archytas has been referred to as Leonardo da Vinci of the ancient world. In 425 B.C., he built a mechanical bird, which he called *the pigeon*. According to Cornelius Gellius in his *Noctes Atticae*, the bird was made of wood, nicely balanced with weights and flew using air (most likely steam) enclosed in its stomach. It is alleged that Archytas’ pigeon flew about 200 m before falling to the ground, once all energy

was used. During the same era in a different part of the Ancient World, China, at about 400 B.C., the Chinese were the first to document the idea of a vertical flight aircraft. The earliest version of the Chinese top consisted of feathers at the end of a stick. The stick was spun between the hands to generate enough lift before released into free flight. Several centuries later, Leonardo da Vinci, in 1483 A.D., designed an aircraft capable of hovering, called aerial screw or air gyroscope. Da Vinci also devised a mechanism bird in 1508 A.D. that would flap its wings by means of a double crank mechanism as it descended along a cable. A separate chapter is dedicated to the history of unmanned aviation later on in this section.

Nowadays, the world is witnessing an unprecedented flurry of US-related research and development activity. Pioneers in this area are experimenting with novel concepts and set the stage for even greater explosion in US development and applications.

Unmanned aerial vehicles (UAVs), unmanned ground vehicles (UGVs), unmanned surface vehicles (USVs), and unmanned underwater vehicles (UUVs) share common features in terms of their fundamental architectures, propulsion, communications, and those technologies that aim to improve their autonomy attributes. These types of vehicles are capable of many different applications in the fields of law enforcement, environmental monitoring, disaster relief, and recovery operations. They can also undertake routine and persistent surveillance of a nation's internal and external borders as well as critical oil and gas infrastructure inspection, to name but a few applications in which such vehicles may be utilized.

There are no significant differences for human interaction issues with the exception possibly in response times required by a given mission and operator culture. Major differences are observed in the operational environment – physical environment communications and vehicle dynamics. Payload types are also significantly different depending upon sensing requirements, mission objectives, etc.

The UAV segment has experienced the greatest growth, driven primarily by the military community and to a lesser extent by border security, environmental monitoring, and other application domains. This picture seems to change, and it is projected that UAVs will dominate civilian and public domain applications.

The UGV segment has exploded recently in response to urgent military needs. Future UGV missions will include perimeter surveillance, logistics support, rescue operations, communications relay, among other applications.

UUVs and USVs are still in their infancy. Unlike the UAV and UGV segments, unmanned maritime systems are funded at much lower levels in the USA and worldwide. The UUV segment is maturing more rapidly due to the commercial use of these systems by the offshore oil and gas industry. Despite challenges stemming from the current world economic conditions and others due to unmanned systems “growth pains,” demand for UUVs is high and will continue to grow over the coming years.

Unmanned systems in general raise new issues of improved autonomy, communications, interoperability, propulsion and power, man-machine interfaces, and manned-unmanned teaming that will challenge the R&D community. The need to maintain simplicity in US is also an ongoing challenge.

When focusing on unmanned system autonomy, improved system autonomy requires and will require new and innovative incipient failure detection, prediction of the useful life of the failing vehicle components, and innovative fault-tolerant control strategies. There is also a need for an open architecture (OA) that will accommodate attributes of interoperability, modularity, plug and play, and flexibility across unmanned platforms. By leveraging OA and open interfaces, the US community can overcome problems associated with proprietary robotic system architectures. These advances are bound to lower platform costs, open new application domains, and offer the opportunity for the deployment of multiple (mixed) types of unmanned systems for improved mission effectiveness.

Overall, the state of the unmanned system technology in general is mature, while the unmanned aviation and unmanned aircraft segment by itself or in combination with ground and maritime vehicles will play an increasing role in both the military and civilian domains.

In the sequel, a detailed outline of each section of the handbook is given, which includes a summary of the chapters comprising each section. Chapters are summarized in the order they appear in each section of the handbook.

2.3 Outline of the Handbook Sections

2.3.1 UAV Design Principles

Section ▶[UAV Design Principles](#) includes chapters ▶[Computational and Experimental Design of a Fixed-Wing UAV](#), ▶[Payload Design of Small UAVs](#), ▶[Small UAV Design Development and Sizing](#), ▶[Systematic Design Methodology and Construction of Micro Aerial Quadrotor Vehicles](#), and ▶[Dexterous UAVs for Precision Low-Altitude Flight](#).

Chapter ▶[Computational and Experimental Design of a Fixed-Wing UAV](#) by Ryaciotaki-Boussalis and Guillaume presents a comprehensive methodology for the design and manufacture of all aspects of a prototype fixed-wing UAV, which also allows for utilizing multi-segmented flight control surfaces on the wings of such UAVs. Adding multiple segments to UAV wings creates smaller control surfaces; thus, refined adjustments to UAV performance while airborne may be accomplished.

Chapter ▶[Payload Design of Small UAVs](#) by Gruber, Kwon, Hager, Sharma, Yoder, and Pack discusses payload design issues for small UAVs, which are essential to overcome various small UAV constraints imposed by stringent weight, power, and volume. The efficacy of design principles is demonstrated with the help of the payloads for a fixed-wing UAV developed by the Center for Unmanned Aircraft Systems Research at the U.S. Air Force Academy, and it is shown that the system requirements for specific applications are closely related to those for other small UAV applications.

Chapter ▶[Small UAV Design Development and Sizing](#) by Brandt describes a rationale for selecting a low-risk UAV configuration and a methodology for sizing and optimizing the shape of both fueled and electric-powered aircraft.

Three examples of low-risk UAV configurations are shown to be essentially similar from the point of view of optimization and sizing. The sizing methodology for fueled aircraft is described in detail, and a similar one for electric-powered aircraft is described to the extent that it differs from that for fueled aircraft. Typical values of technology-related parameters used in sizing calculations are given, followed by an example of a small UAV designed using the proposed methodology.

Chapter ►[Systematic Design Methodology and Construction of Micro Aerial Quadrotor Vehicles](#) by Phang, Li, Chen, and Lee presents guidelines to optimally and systematically design and construct an ultralight micro aerial quadrotor vehicle, including details of the steps to design a stable quadrotor with not more than 50 g take-off weight and flight duration of 8 min. The methodology covers, sequentially, structural analysis of the micro quadrotor air frame, design in a 3-D virtual simulator, design of the avionic system, controller implementation via simulation, and component fabrication and implementation. Finally, performance is evaluated, tested, and confirmed with real flight missions.

Chapter ►[Dexterous UAVs for Precision Low-Altitude Flight](#) by Jiang and Voyles follows the concept of force closure (a term from the dexterous manipulation community) to introduce a new type of dexterous six degree-of-freedom (6 DOF) UAV, which provides the unique capability of being able to resist any applied wrench, or generalized force-torque, providing more precise control during low-altitude flight. The major challenge that needs to be overcome in such designs is that low-altitude flight usually introduces ground-effect disturbances and other backwash issues, while in the new field of aerial mobile manipulation, it often includes close to structures operations for inspection or manipulation purposes. The presented design differs considerably from typical helicopters or quadrotors, which cannot instantaneously resist or apply an arbitrary force in the plane perpendicular to the rotor axis, thus, making such designs inadequate for complex mobile manipulation tasks.

2.3.2 UAV Fundamentals

Section ►[UAV Fundamentals](#) includes chapters ►[Kinematics and Dynamics of Fixed-Wing UAVs](#), ►[Dynamic Model for a Miniature Aerobatic Helicopter](#), ►[Quadrotor Kinematics and Dynamics](#), ►[Dynamics and Control of Flapping-Wing MAVs](#), and ►[Dynamic Modeling and Control of an Autonomous Quadrotor](#).

Chapter ►[Kinematics and Dynamics of Fixed-Wing UAVs](#) by Dobrokhodov provides a thorough review of the fundamentals required for accurate mathematical modeling of flight of a fixed-wing UAV, including kinematics and dynamics of motion, and transformation of forces and moments acting on the airplane. The main objective is to familiarize the reader with the “kinematics–dynamics–actions” triad as it applies to a generic fixed-wing UAV. Emphasis is given to the understanding of reference frames and their dynamics as this is essential for the design of the UAV guidance, navigation, and control systems.

Chapter ▶ [Dynamic Model for a Miniature Aerobatic Helicopter](#) by Gavrillets presents a nonlinear dynamic model of a miniature aerobatic helicopter following a component buildup to derive the model using simplified analytical expressions for the component forces and moments. Key parameters are estimated based on flight-test experiments. The derived model is used to design control logic for aerobatic maneuvers performed entirely under computer control.

Chapter ▶ [Quadrotor Kinematics and Dynamics](#) by Powers, Mellinger, and Kumar presents an overview of the rigid body dynamics of a quadrotor, starting from describing the Newton-Euler equations that govern the quadrotor motion. This is followed by the derivation of a linear controller based on a linearized model of the dynamics and a nonlinear controller derived from the original dynamic model. Experimental results that illustrate the dynamics and control of small quadrotors are also presented.

Chapter ▶ [Dynamics and Control of Flapping Wing MAVs](#) by Doman, Oppenheimer, and Sigthorsson focuses on presenting methods suitable for hover-capable flapping-wing vehicles. This is a challenging problem as flapping-wing motion is characterized by seven wing motion parameters like wing stroke amplitude, symmetric and asymmetric frequency, bias, upstroke and downstroke angle-of-attack limits, and wing stroke plane inclination. A method is presented that enables the designer to estimate how the seven wing motion parameters change in response to changes in the control mechanism position, followed by a method for estimating the combined effect of fuselage motion and flapping-wing motion. Control design considerations and simulation methods are also discussed.

Chapter ▶ [Quadrotor Kinematics and Dynamics](#) by Elkaim, Pradipta Lie, and Gebre-Egziabher presents two easily reconfigurable system architectures for guidance, navigation, and control of small UAVs. The presented system architectures integrate a low-cost inertial measurement unit, a GPS receiver, and a triad of magnetometers to generate a navigation solution which, in turn, is used in the guidance and control algorithms. The full system architecture – the hardware, software, and algorithms – is included for completeness. Hardware-in-the-loop simulation and flight-test results documenting the performance of these two systems are given.

2.3.3 UAV Sensors and Sensing Strategies

Section ▶ [UAV Sensors and Sensing Strategies](#) includes chapters ▶ [Sensors for Missions](#), ▶ [Inertial Sensor-Based Simultaneous Localization and Mapping for UAVs](#), ▶ [UAV Localization Using Inertial Sensors and Satellite Positioning Systems](#), and ▶ [Data Fusion and Tracking with Multiple UAVs](#).

Chapter ▶ [Sensors for Missions](#) by Mejias, Lai, and Bruggemann sets the tone for sensors used on UAVs that are assigned complex missions. The sensor suite onboard a UAV is tightly coupled with payload capabilities, as payload dictates UAV usability and market value. However, advances in miniaturization of electronics are enabling replacement of multiprocessing, power-hungry general-purpose processors with more integrated and compact electronics that contribute to more onboard

sensors. Several common payload sensors are described along with their usefulness to solve real-world problems.

Chapter ▶ [Inertial Sensor-Based Simultaneous Localisation and Mapping for UAVs](#) by Bryson and Sukkarieh provides an overview of algorithms for inertial sensor-based simultaneous localization and mapping (SLAM) within the context of UAVs, using the extended Kalman filter (EKF) and the extended information filter (EIF) due to their ease of understanding, applicability to online implementation, and prevalence in airborne localization applications outside of SLAM.

Chapter ▶ [UAV Localisation Using Inertial Sensors and Satellite Positioning Systems](#) by Bryson and Sukkarieh provides an overview of UAV localization with a focus on aided inertial localization, that is, algorithms for fusing data from, for example, satellite positioning systems, barometric sensors, and magnetometers with inertial sensors to provide real-time position and orientation. An example implementation of aided inertial localization on a UAV is presented as a tutorial to understand key concepts in airborne localization and as a basic guide toward more complicated implementations.

Chapter ▶ [Data Fusion and Tracking with Multiple UAVs](#) by Ridley, Upcroft, and Sukkarieh describes decentralized data fusion (DDF) algorithms for a team of multiple autonomous platforms. It is shown how through the DDF algorithms, each platform can maintain a consistent global solution from which decisions may be made. The overall system design is detailed, providing insight into the overall complexity of implementing a robust DDF system for use in information gathering tasks in outdoor UAV applications.

2.3.4 UAV Propulsion

Section ▶ [UAV Propulsion](#) includes chapter ▶ [Power Managements of a Hybrid Electric Propulsion System Powered by Solar Cells, Fuel Cells, and Batteries for UAVs](#).

Chapter ▶ [Power Managements of a Hybrid Electric Propulsion System Powered by Solar Cells, Fuel Cells, and Batteries for UAVs](#) by Lee, Park, and Kim provides a very comprehensive description of the power management of a UAV hybrid electric propulsion system. It considers three electric propulsion systems with solar cells, fuel cells, and battery power sources, which are designed and constructed to share the same operation voltage range and connect to the power bus without the need for additional converters or controllers. MATLAB/Simulink-based modeling is followed for each power source, and the component models are verified with published data from the manufacturers as well as flight-test data. The component models are integrated into one power system model that is used to simulate the UAV electric propulsion system. For fuel cells and batteries, the simulation process is verified via comparison between simulation results and available UAV flight-test results. Two types of power control logic are investigated, passive and active. The passive power management simulation shows that the behavior of each power source and its integrated system are adequate for the overall UAV flight envelope. The active power management simulation yields more efficient power distribution

and better system safety than passive power management. Additional simulations of a hybrid electric power system allow for estimation of the output behavior of the power source.

2.3.5 UAV Control

Section ▶UAV Control includes chapters ▶Linear Flight Control Techniques for Unmanned Aerial Vehicles, ▶Nonlinear Flight Control Techniques for Unmanned Aerial Vehicles, ▶Adaptive Control of Unmanned Aerial Vehicles: Theory and Flight Tests, and ▶Robust and Adaptive Control Methods for Aerial Vehicles.

Chapter ▶Linear Flight Control Techniques for Unmanned Aerial Vehicles by How, Frazzoli, and Chowdhary presents an overview of linear flight control and guidance methods for UAVs, starting with a discussion of rotation matrices and UAV kinematic equations and followed by derivation of the 6 DOF UAV equations of motion. Equations of motion are then linearized, and several linear multi-loop closure techniques for UAV guidance and control are discussed.

Chapter ▶Nonlinear Flight Control Techniques for Unmanned Aerial Vehicles by Chowdhary, Frazzoli, How, and Liu discusses nonlinear and adaptive control techniques that are often used to improve UAV performance and reliability. Such techniques are actively being studied to handle nonlinear aerodynamic and kinematic effects, actuator saturations and rate limitations, modeling uncertainty, and time-varying dynamics. An overview of tools and techniques used for designing nonlinear flight controllers is presented along with a summary of Lyapunov stability theory. In detail, the nonlinear control techniques that are considered include gain scheduling, model predictive control, backstepping, dynamic inversion-based control, model reference adaptive control, and model-based fault-tolerant control.

Chapter ▶Adaptive Control of Unmanned Aerial Vehicles: Theory and Flight Tests by Kannan, Chowdhary, and Johnson focuses on adaptive control of unmanned aircraft that are underactuated systems. A 6 DOF flight control algorithm is derived that can track both position and attitude trajectories. Approximate inverse models for vehicle attitude and position dynamics are used for feedback linearization leading to an inner loop that tracks attitude and angular rate and an outer loop that tracks position and velocity commands. A single adaptive element is used to compensate for inversion errors (uncertainty) in both loops. A key challenge in realizing an adaptive control design on real aircraft is dealing with actuator magnitude and rate saturation. Such saturation elements cannot be easily captured in inverse models and leads to incorrect learning in the adaptive element during periods of saturation. A mechanism to exactly remove such incorrect learning is provided. Additionally, nonlinear reference models are introduced to mitigate the risks of the closed-loop system entering regions of the flight envelope that result in loss of controllability. The resulting adaptive controller accepts trajectory commands comprising of desired position, velocity, attitude, and angular velocity and produces normalized actuator signals required for flight control. A modification to the baseline adaptive control system is also provided that enables long-term retention

of the uncertainty approximation within the adaptive element. This architecture is validated through flight tests on several fixed-wing and rotorcraft UAVs.

Chapter ▶[Robust and Adaptive Control Methods for Aerial Vehicles](#) by Lavretsky includes a collection of reliable, efficient, robust, and adaptive control methods for aerial vehicles. It begins with a brief overview of flight dynamics models suitable for flight control design. The first control design method represents the well-understood and now-classical linear quadratic regulator (LQR) command tracker, with proportional-integral (PI) feedback connections, serving as the backbone of all other subsequent methods. The main intent is to demonstrate the design of predictable, formally justified, yet numerically efficient flight controllers, with an LQR PI baseline and with a direct model reference adaptive control (MRAC), as an augmentation to the baseline. Through extensive simulation, analysis, and actual flight testing, it is shown that (LQR PI + adaptive) – controllers provide robust stability and maintain tracking performance, when operated in the presence of “unknown unknowns” in the vehicle dynamics and in often “unfriendly” operational environment. All presented control methods are flight tested and validated on a wide range of aerial vehicles.

2.3.6 UAV Communication Issues

Section ▶[UAV Communication Issues](#) includes chapters ▶[Problem of UAV Communications](#), ▶[Cognitive Networking for UAV Swarms](#), ▶[Layered Approach to Networked Command and Control of Complex UAS](#), and ▶[Cognitive Radio Architectures for Unmanned Aircraft Systems](#).

Chapter ▶[Problem of UAV Communications](#) by Heppe summarizes the current consensus view (as of the end of 2012) regarding critical data flows for UAS, control link performance requirements, potential frequency bands that can satisfy the relevant technical as well as regulatory constraints, challenges that must be overcome to ensure reliable operation, and possible data link design principles that could lead to a safe and workable implementation. Both line-of-sight and beyond-line-of-sight data links are addressed. It is shown that the challenges to be faced and overcome are significant, but a safe and workable implementation appears to be achievable through data link diversity and other error correction and error recovery techniques.

Chapter ▶[Cognitive Networking for UAV Swarms](#) by Brown, McHenry, and Jaroonvanichkul examines the enabling role of cognitive radio technologies for UAS to access more spectrum needed for flight operations. After requirements are set, different architecture choices available to the UAS cognitive radio designer are presented, including the communication architecture, the spectrum awareness techniques for assessing what spectrum is available, and the spectrum access techniques for deciding which available spectrum to use. Information in this chapter is relevant for the development of future UAS rules and standards.

Chapter ▶[Layered Approach to Networked Command and Control of Complex UAS](#) by Elston, Stachura, Dixon, Agrow, and Frew discusses different networking hardware, protocols, and sensors that, when combined, create a diverse and complex

UAS through a layered design approach with modular supporting software. It is shown that critical software components, such as service discovery, simplify the inclusion of a diverse set of subsystems and sensors. Maintaining the modularity of these software components ensures that the system can be expanded while requiring minimal software changes. A detailed description of a system is presented, which enabled flight operations of a multi-vehicle unmanned aircraft system for performing targeted, in situ sampling of supercell thunderstorms during the 2010 VORTEX2 field campaign.

Chapter ▶ [Cognitive Radio Architectures for Unmanned Aircraft Systems](#) by Wietfeld and Daniel discusses challenges and solution approaches with respect to self-organized and robust multi-UAV systems. The focus is on designing novel service-oriented system architecture to achieve a flexible deployment of UAS. The design aspects of mobility control algorithms addressing the competing requirements of communication reliability and spatial distribution of UAV swarms are demonstrated using aerial sensor networks and ad hoc aerial relay networks. Solution approaches rely on agent-based control of UAV swarms operating autonomously in dynamically changing environments. Different communication-aware algorithms for microscopic as well as macroscopic mobility control are presented, such as Cluster Breathing, Smart Cube, Potential Fields, and Role-Based Connectivity Management. The chapter also discusses how the network and application task specific performance requirements are met with the proposed mobility control algorithms even in the cases of temporarily unavailable communication links. The self-healing capabilities therefore allow for reliable networking and control of aerial robot swarms in diverse use cases, such as emergency response, environmental monitoring, and ad hoc network provisioning.

2.3.7 UAV Architectures

Section ▶ [UAV Architectures](#) includes chapters ▶ [HDRC3: A Distributed Hybrid Deliberative/Reactive Architecture for Unmanned Aircraft Systems](#), ▶ [Classification of Multi-UAV Architectures](#), and ▶ [Operator Interaction with Centralized Versus Decentralized UAV Architectures](#).

Chapter ▶ [HDRC3: A Distributed Hybrid Deliberative/Reactive Architecture for Unmanned Aircraft Systems](#) by Doherty, Kvarnstrom, Wzorek, Rudol, Heintz, and Conte presents a distributed UAS architecture, also extendable for use with multi-platform systems, providing full integration of both low and high autonomy. It covers the full spectrum of functionalities required for operation in missions requiring high autonomy. Specific interfaces and languages are introduced, which provide seamless transition between deliberative and reactive capability and reactive and control capability. Hierarchical concurrent state machines are introduced as a real-time mechanism for specifying and executing low-level reactive control. Task specification trees are introduced as both a declarative and procedural mechanism for specification of high-level tasks. Task planners and motion planners are described which are tightly integrated into the architecture. Generic middleware

capability for specifying data and knowledge flow within the architecture based on a stream abstraction is also described. Emphasis is placed on the robust integration and interaction between these diverse functionalities using a principled architectural framework. The architecture has been empirically tested in several complex missions, some of which are also described in this chapter.

Chapter ►[Classification of Multi-UAV Architectures](#) by Maza, Ollero, Casado, and Scarlatti presents a classification of different schemes for multiple UAV cooperation considering the coupling between the vehicles and the type of cooperation. It also considers UAVs that are networked with other elements in the environment to support their navigation and, in general, their operation. The chapter provides a theoretical framework but also emphasizes practical field demonstrations involving aerial vehicles.

Chapter ►[Operator Interaction with Centralized Versus Decentralized UAV Architectures](#) by Cummings starts from the fact that there are major attempts to streamline UAV operations and reduce staffing in order to invert the current many-to-one ratio of operators to vehicles. It then introduces architectural schemes in the context of optimizing operator workload and efficiency. In centralized multiple UAV architectures, a single operator, who requires significant cognitive resources, interacts with and oversees every UAV in the network. In decentralized multiple UAV architectures, an operator interacts with an automated mission and payload manager, which coordinates a set of tasks for a group of highly autonomous vehicles. While a single operator can maintain effective control of a relatively small network of centralized UAVs, decentralized architectures are more scalable, particularly in terms of operator workload, and more robust to single points of failure. However, in terms of operator workload, the ultimate success of either a centralized or decentralized UAV architecture is not how many vehicles are in the network per se but rather how many tasks the group of vehicles generates for the operator and how much autonomy is onboard these vehicles. Task-based control of UAV architectures with higher degrees of autonomy (i.e., decentralized networks) can mitigate cognitive overload and reduce workload. Mutually exclusive boundaries for humans and computers in multiple UAV systems should not be the goal of designers for either centralized or decentralized architectures, but rather more effort needs to be spent in defining mutually supportive roles such that humans and computers complement one another.

2.3.8 UAV Health Management Issues

Section ►[UAV Health Management Issues](#) includes chapters ►[Integrated Vehicle Health and Fault Contingency Management for UAVs](#), ►[Automated Failure Effect Analysis for PHM of UAV](#), ►[Prognostics Applied to Electric Propulsion UAV](#), ►[Actuator Fault Detection in UAVs](#), ►[Experimental Validation of Fault Detection and Diagnosis for Unmanned Aerial Vehicles](#), ►[Fault Detection and Diagnosis for NASA GTM UAV with Dual Unscented Kalman Filter](#), and ►[Fault Diagnosis of Skew-Configured Inertial Sensor System for Unmanned Aerial Vehicles](#).

Chapter ► [Integrated Vehicle Health and Fault Contingency Management for UAVs](#) by Roemer and Tang presents various concepts for integrating real-time vehicle health assessment and fault contingency management technologies for UAVs. The presented Integrated Vehicle Health Management (IVHM) and Automated Contingency Management (ACM) system architecture is shown to support real-time, onboard health state assessment and fault management so that UAVs can enjoy greater autonomy and survivability during anomalous operating conditions. Selected real-time system identification and automated health assessment algorithms are presented that can readily identify the dynamics and performance limitations of degraded UAV systems. Additionally, a high-level mission adaptation approach is presented to estimate the safe flight operating envelope after the occurrence of faults. Reconfigurable fault-tolerant control techniques that directly utilize the identified UAV subsystem dynamic models have been developed and tested in simulation. Finally, proof-of-concept demonstrations are presented using NASA engine and aircraft dynamic models with simulated engine and actuator faults.

Chapter ► [Automated Failure Effect Analysis for PHM of UAV](#) by Snooke describes how model-based simulation can be employed to automatically generate the system-level effects for comprehensive sets of component failures on systems within the aircraft. The results of the simulation can be used in several ways. They can be used to produce a system-level failure modes and effects analysis (FMEA) for aircraft systems. They can be used to identify the sensors necessary to discriminate remotely between different failures on the aircraft. Once a set of sensors have been chosen for placement on the vehicle, the simulation results can also be used to generate diagnostic and prognostic software for deployment on the vehicle. Using automated FMEA, safety analysis software is more efficient than doing the same work without software and also provides a guaranteed level of performance. Using the results of this analysis can provide sensor selection and diagnostic capability while retaining some of the benefits of rule-based diagnostic systems. Alternative model-based techniques have been widely used to create diagnostic systems in a variety of domains, and these approaches are compared with the diagnostic capability provided by a failure effect-oriented technique from the perspective of the UAV application.

Chapter ► [Prognostics Applied to Electric Propulsion UAV](#) by Goebel and Saha explores the technical underpinnings of how to perform prognostics and shows an implementation on the propulsion of an electric UAV. An accurate run-time battery life prediction algorithm is of critical importance to ensure the safe operation of the vehicle if one wants to maximize in-air time. Current reliability-based techniques turn out to be insufficient to manage the use of such batteries where loads vary frequently in uncertain environments. A particle filter is shown as the method of choice in performing state assessment and predicting future degradation. The method is then applied to the batteries that provide power to the propeller motors.

Chapter ► [Actuator Fault Detection in UAVs](#) by Ducard is dedicated to actuator fault detection systems for UAVs, with two main requirements: real-time capability and modularity. After defining the terminology employed in this field, it first reviews some commonly used techniques in FDI systems, followed by presenting briefly the mathematical model of a UAV that serves as a basis for the design of two actuator

FDI systems. The first method presents and illustrates the multiple-model approach, whereas the second method presents an FDI system, which is based on a single model. Both methods are enhanced by a mechanism that actively tests actuators in order to efficiently detect and isolate actuator faults and failures. Advantages and drawbacks of each method are stated issues of robustness are discussed against model uncertainties and external perturbation. In addition, aspects of computational load are addressed. The FDI systems applied to a realistic model of an unmanned aircraft, and the performance of the methods is shown in simulation.

Chapter ► [Experimental Validation of Fault Detection and Diagnosis for Unmanned Aerial Vehicles](#) by Chamseddine, Hadi Amoozgar, and Zhang investigates the problems of fault detection, diagnosis, and fault-tolerant control for UAVs. It first presents a detailed overview of existing experimental research focusing on fixed-wing as well as rotorcraft UAVs including single-rotor and multi-rotor helicopters. It then discusses three Kalman filters employed for actuator fault detection and diagnosis, namely, the unscented Kalman filter, the two-stage Kalman filter, and the adaptive two-stage Kalman filter. The three filters are experimentally applied to a quadrotor helicopter UAV test bed, and results are shown, compared, and discussed.

Chapter ► [Fault Detection and Diagnosis for NASA GTM UAV with Dual Unscented Kalman Filter](#) by Zhang investigates a simultaneous state and parameter estimation-based fault detection and diagnosis (FDD) scheme applied to a realistic nonlinear six degree-of-freedom fixed-wing unmanned aerial vehicle (UAV) model, the NASA GTM (generic transport model). By introducing partial loss faults in actuators into the NASA GTM, a dual unscented Kalman filter (DUKF) algorithm is applied for the purpose of online estimation of both flight states and fault parameters. A Bayesian rule is then used for detection and isolation decision making. The developed FDD scheme is implemented in both the nonlinear GTM and the linear parameter-varying (LPV) representation of the nonlinear GTM. Simulation results show satisfactory results for detecting and diagnosing the control effectors faults.

Chapter ► [Fault Diagnosis of Skew-Configured Inertial Sensor System for Unmanned Aerial Vehicles](#) by Yoon, Kim, Bae, Kim, and Kim presents fault detection and isolation scheme to handle three successive faults in the skew-configured inertial sensors of an unmanned aerial vehicle. The skew-configured inertial sensors are composed of the primary inertial measurement unit and the redundant secondary inertial measurement unit. Since small unmanned aerial vehicles are restricted by cost and payload space, the secondary small and low-cost inertial measurement unit is installed with a skewed angle in addition to the primary inertial measurement unit. In the hybrid fault detection and isolation scheme, a parity space method and an in-lane monitoring method are combined to increase system tolerance to the occurrence of multiple successive faults during flight. The first and second faults are detected and isolated by the parity space method. The third fault is detected by the parity space method and isolated by the in-lane monitoring method based on the discrete wavelet transform. Hardware-in-the loop tests and flight experiments with a fixed-wing unmanned aerial vehicle are performed to verify the performance of the proposed fault diagnosis scheme.

2.3.9 UAV Modeling, Simulation, Estimation, and Identification

Section ► [UAV Modeling, Simulation, Estimation, and Identification](#) includes chapters ► [Flight Dynamics Modeling of Coaxial Rotorcraft UAVs](#), ► [Modeling of a Micro UAV with Slung Payload](#), and ► [Command and Control of Autonomous Unmanned Vehicles](#).

Chapter ► [Flight Dynamics Modeling of Coaxial Rotorcraft UAVs](#) by Wang, Cui, Chen, and Lee aims at presenting a thorough approach related to systematic modeling of UAV flight dynamics by talking about the UAV model formulation, parameter identification, and model verification. The presented methodology of UAV model formulation and parameter identification is based on modeling two kinds of coaxial helicopters. This is a challenging problem as modeling of coaxial helicopters, despite the common governing kinematic and dynamic principles, deserves special attention due to their distinctive mechanical structure and aerodynamics behavior. The modeling procedures and parameter identification technique presented in this chapter may also serve as a guideline for modeling other types of aerial vehicles.

Chapter ► [Modeling of a Micro UAV with Slung Payload](#) by Feng, Rabbath, and Su derives a mathematical and simulation model of a micro UAV carrying a payload. When the load is slung underneath a UAV by cable, the flight dynamics of the UAV are altered, which makes the stability of the UAV disturbed. The unstable oscillation degrades UAV performance, and the accurate placement of the load will be affected. Unlike external disturbances, the negative effects are related to the characteristics of the UAV and the payload. In order for the UAV to be able to adopt the change of the system dynamics and reduce the effects caused by the swing of the load, one modeling method of a micro UAV with single slung payload is addressed. The slung payload is treated as a pendulum-like mass point, and the coupling factors between the UAV and the payload are considered. The derived model may be used to estimate the negative effects acting on the UAV, and it may also be used to estimate the trajectory of the load, which allows for improving the accuracy of placement of the loads.

Chapter ► [Command and Control of Autonomous Unmanned Vehicles](#) by Scheidt describes a series of experiments, including 2011 experiments in which 16 fully autonomous unmanned vehicles, including 9 unmanned air vehicles, were used to simultaneously support mounted, dismounted, and maritime users. During these experiments, users provided abstract mission-level ISR needs to the “vehicle cloud.” These needs were interpreted by the vehicles, which self-organized and efficiently achieved the user’s objectives. The starting point is using information theory to examine UAV command and control (C2). The information-theoretic analysis provides a justification and use cases for *autonomous* UAVs. An autonomous unmanned vehicle system “organic persistent intelligence, surveillance, and reconnaissance” (OPISR) is introduced. OPISR is an autonomous unmanned vehicle system that combines the immediate response to tactical ISR needs provided by organic assets with the time-on-station, minimal logistics provided by persistent unmanned systems. OPISR autonomous vehicles collectively interpret real-time tactical intelligence, surveillance, and reconnaissance (ISR) objectives submitted by any number of disadvantaged users, gather the required ISR data, and return the

needed intelligence directly to the affected user. OPISR is an ad hoc, decentralized system that requires no central base or authority and is capable of functioning in communications-denied environment.

2.3.10 MAVs and Bio-inspired UAVs

Section ▶[MAVs and Bio-inspired UAVs](#) includes chapters ▶[Micro Air Vehicles](#), ▶[Survey of the Human-Centered Approach to Micro Air Vehicles](#), ▶[Development of Insect-Sized MAVs](#), ▶[Flapping-Wing-Propelled Micro Air Vehicles](#), ▶[Inventing a Biologically Inspired, Energy-Efficient Micro Aerial Vehicle](#), and ▶[Issues Surrounding Communications with Micro Aerial Vehicles](#).

Chapter ▶[Micro Air Vehicles](#) by R. C. Michelson addresses challenges related to the design of MAVs. Such challenges span across aerospace, electrical, mechanical, and computer engineering because of flight regime in which these tiny aircrafts operate. Aerospace designers must contend with issues surrounding low Reynolds number flight, while electrical and mechanical designers are concerned with issues of energy storage, behavior of materials at small scales, and non-scaling items. The missions at which MAVs excel demand increased levels of autonomy, forcing computer engineers to create innate onboard intelligence exhibiting high bandwidth and superior abilities to interpret obstacle-rich environments not usually encountered by larger flying machines.

Chapter ▶[Survey of the Human-Centered Approach to Micro Air Vehicles](#) by S. Michelson presents a detailed overview of some of the Human Systems Integration (HSI) and Human Factors Engineering (HFE) issues involved with MAVs. The importance of a total systems engineering approach to MAV design, how MAVs fit into commonly accepted Human Systems Integration domains, and an exposure of some emerging issues with MAVs that require further research are discussed. The unique attributes of MAVs in terms of their size and control methods, combined with the challenges of the dynamic operational environments where they are deployed, represent HFE issues exclusive to the MAV platform that require special consideration. The importance of designing for the human operator is paramount for successful outcomes with MAV platforms. Specifically highlighted are some areas where currently researched HFE issues are particularly applicable to MAVs as opposed to large-scale systems.

Chapter ▶[Development of Insect-Sized MAVs](#) by Sunada, Liu, Tokutake, and Kubo describes a prototype bio-inspired flapping MAV with flexible wings, with a specific focus on the flexible-wing aerodynamics. The flapping-wing MAV has a weight of 2.4–3.0 g and a wingspan of 10–12 cm, which is comparable to hawk moths and hummingbirds. The MAV's flexible-wing aerodynamics is analyzed by combining an *in-house* computational fluid dynamics (CFD) method and wind tunnel experiments (EXP). In addition, fixed-wing and rotary-wing MAVs with elements that enable the miniaturization of an aerial vehicle are introduced.

Chapter ▶[Flapping-Wing-Propelled Micro Air Vehicles](#) by Jones and Platzer presents a brief history of the major discoveries in the scientific exploration of

flapping-wing flight. This is followed by a short review of the basic concepts of lift generation on wings in low-speed, steady flight, which leads into a discussion of the generation of thrust due to the flapping of wings. The aerodynamics of single flapping wings in forward and hovering flight, of flapping tandem and biplane wings, and of dual wings using the clap-and-fling effects are discussed. The chapter concludes with an overview of the major characteristics of five representative flapping-wing-propelled MAVs developed to date, including models developed at the AeroVironment Company, Naval Postgraduate School, Wright State University, and Delft University.

Chapter ►[Inventing a Biologically Inspired, Energy-Efficient Micro Aerial Vehicle](#) by Ratti and Vachtsevanos introduces a novel framework for the design and control of an MAV, where the conceptual design is based on biologically inspired principles and emulates a dragonfly. The chapter addresses the design and control features of the proposed design and gives an overview on the developmental efforts toward the prototyping of the flyer. The potential applications for such a high-endurance vehicle are numerous, including air deployable mass surveillance in cluster and swarm formations. The disposability of the vehicle helps in battlefield deployment as well, where such an MAV is made available to soldiers for proximity sensing and threat level assessment. Other applications include search and rescue operations and civilian law enforcement.

Chapter ►[Issues Surrounding Communications with Micro Aerial Vehicles](#) by C. Michelson seeks to answer many of the communications link questions that MAV designers have and gives a high-level overview of the factors that affect MAV data and control links. Challenges related to communications with MAVs are because of their size and very limited payload capabilities. Limited payload capacity leads to considerable constraints on power sources, sensors, and communication systems. Power sources are by far the most weight-inefficient components on an MAV. MAV designers are forced to look elsewhere to optimize their designs. The best way to do so in lieu of focusing on improving battery technology is to optimize the systems that draw power, thereby increasing endurance. Motors, onboard processing, and communications transceivers are the largest three power consumers on MAVs today. While motors and embedded processing are important to optimize, the sheer number of available communications options may leave MAV designers unsure how to proceed. By building an MAV around its onboard communications system, designers increase reliability, endurance, and capability with little or no added cost. Care must be taken to ensure that the end result meets the power, aerodynamic, and electromagnetic requirements for the particular MAV and its particular mission.

2.3.11 UAV Mission and Path Planning

Section ►[UAV Mission and Path Planning](#) includes chapters ►[Cooperative Mission Planning for Multi-UAV Teams](#), ►[Multi-team Consensus Bundle Algorithm](#), ►[Cooperative Mission and Path Planning for a Team of UAVs](#), ►[Cooperative Task Assignment and Path Planning for Multiple UAVs](#), ►[On the Decentralized](#)

Cooperative Control of Multiple Autonomous Vehicles, ►Innovative Collaborative Task Allocation for UAVs, ►Control of Communication Networks for Teams of UAVs, ►Information-Theoretic Exploration of Unmanned Aerial Vehicle in Unknown Cluttered Environment, ►Implementing Dubins Airplane Paths on Fixed-Wing UAVs, and ►Health Monitoring of a Drone Formation Affected by a Corrupted Control System.

Chapter ►Cooperative Mission Planning for Multi-UAV Teams by Ponda, Johnson, Geramifard, and How provides an overview of three of the most common planning frameworks: integer programming, Markov decision processes, and game theory. It also considers various architectural decisions that must be addressed when implementing online planning systems for multi-agent teams, providing insights on when centralized, distributed, and decentralized architectures might be good choices for a given application and how to organize the communication and computation to achieve desired mission performance. Algorithms that can be utilized within the various architectures are identified and discussed, and future directions for research are suggested.

Chapter ►Multi-team Consensus Bundle Algorithm by Argyle, Beard, and Casbeer focuses on how the consensus-based bundle algorithm (CBBA) is incorporated into a hierarchical concept of operation, where agents are divided into teams and each team plans for its agents to service a set of tasks. This team planning is carried out in a distributed manner using the traditional CBBA. An “outer-loop” team CBBA strategy coordinates teams’ plans. The hierarchical structure of the team CBBA facilitates a manageable architecture for large numbers of unmanned agents through human-centered operations. This is because each team is managed by a human operator with the team CBBA aiding coordination between teams.

Chapter ►Cooperative Mission and Path Planning for a Team of UAVs by Oh, Shin, Kim, Tsourdos, and White addresses the cooperative mission and path-planning problem of multiple UAVs in the context of the vehicle-routing problem. Since the conventional vehicle routing algorithms approximate their path to straight lines to reduce computational load, the physical constraints imposed on the vehicle are not to be taken into account. In order to mitigate this issue, a framework is described allowing integrated mission and path planning for coordinating UAVs using the Dubins theory based on the differential geometry concepts which can consider non-straight path segments. The main advantage of this approach is that the number of design parameters can be significantly reduced while providing the shortest, safe, and feasible path, which leads to a fast design process and more lightweight algorithms. In order to validate the integrated framework, cooperative mission and path-planning algorithms for two missions are developed: (1) road-network search route-planning patrolling every road segment of interest efficiently based on the optimization and approximation algorithm using nearest insertion and auction negotiation and (2) communication-relay route planning between a ground control station and the friendly fleet satisfying the constraints on the UAV speed and the avoidance of nonflying zones.

Chapter ►Cooperative Task Assignment and Path Planning for Multiple UAVs by Moon, Shim, and Oh presents a hierarchical framework for path planning and task assignment for multiple UAVs in a dynamic environment. The discussed

path-planning algorithm is based on the visibility and shortest path principles in Euclidean space, with the A* algorithm adopted to find an admissible path in a “best-first” approach during the search process. The path planner is augmented with a potential field-based trajectory planner, which solves for a detouring trajectory around other agents or pop-up obstacles. Task assignment is achieved by a negotiation-based algorithm, which assigns a task with the lowest cost to each agent after comparing all task costs of all participating agents. These algorithms are implemented on MATLAB/Simulink, which can run with simulated vehicle models or actual UAVs through a communication network. In the simulations, the algorithms are validated to perform task assignment and path planning flawlessly. In actual flight tests, the proposed algorithms were tested with a number of fixed wing UAVs in a fully realistic situation under various reality factors such as communication loss or tracking errors. The flight test shows, even in the presence of such uncertainties and logistic factors, the algorithms were able to perform all of the given tasks without any collision with other agents or obstacles.

Chapter ► [On the Decentralized Cooperative Control of Multiple Autonomous Vehicles](#) by Hirsch and Schroeder is concerned with dynamically determining appropriate flight patterns for a set of autonomous UAVs in an urban environment, with multiple mission goals. The UAVs are tasked with searching the urban region for targets of interest and tracking those targets that have been detected. It is assumed that there are limited communication capabilities between the UAVs and that there exist possible line-of-sight constraints between the UAVs and the targets. Each UAV operates its own dynamic feedback loop, in a receding-horizon framework, incorporating local information as well as remote information to determine the task to perform and the optimal flight path of UAV over the planning horizon. This results in a decentralized and more realistic model of the real-world situation. As the coupled task assignment and flight route optimization formulation is NP-hard, a hybrid heuristic for continuous global optimization is developed to solve for the flight plan and tasking over the planning horizon. Experiments are considered as communication range between UAVs varies.

Chapter ► [Innovative Collaborative Task Allocation for UAVs](#) by Karaman, Koyuncu, and Inalhan is devoted to a large-scale distributed task/target assignment problem for a fleet of autonomous UAVs, deriving an algorithm that uses the delayed column generation approach on a non-convex supply-demand formulation for the problem. The algorithm exploits a computationally tractable distributed coordination structure, i.e., a market for tasks and targets created by the UAV fleet. The resulting structure is solved via a fleet-optimal dual simplex ascent in which each UAV updates its respective flight plan costs with a linear update of waypoint task values as evaluated by the market. Synchronized and asynchronous distributed implementations of this approximation algorithm are demonstrated in a thorough experimental study involving dynamically changing scenarios with random pop-up targets.

Chapter ► [Control of Communication Networks for Teams of UAVs](#) by Kopeikin, Ponda, and How studies the communication network that is a fundamental component of a multi-UAV system, as it enables exchanges in command and control messages and allows for remotely sensed mission data to be sent to processing

centers. Network control is critical for the system to function properly. Challenges in network communication control are presented, followed by a background discussion in wireless networking including system architecture, wireless channel performance, topology models, and information routing, as well as bounds and limitations in cooperative control and decision making because of network limitations. Several network control strategies for multi-UAV systems are discussed, including motion planning methods to control the topology and relay deployment techniques to extend the performance of the network.

Chapter ► [Information-Theoretic Exploration of Unmanned Aerial Vehicle in Unknown Cluttered Environment](#) by Yang, Gan, and Sukkarieh proposes an information-theoretic path-planning method for exploration mission in unknown environments. Instead of using traditional grid-based occupancy maps, the Gaussian process (GP) is used to build an environmental map. The GP map performs inference directly on the collected sensor datasets, which allows it to infer the probability of collision for any query point in continuous 3-D space, removing the need for maintaining a full discrete map. This GP map is fused with the rapidly exploring random tree (RRT) path planner to plan a safe path and acquire information about the unknown environments. Using mutual information as an information measure, the most informative path is chosen as the path for exploration. Simulation results show that GP map combined with RRT planner achieves exploration task successfully in unknown complex environment and present their potential implementation in UAV missions.

Chapter ► [Implementing Dubins Airplane Paths on Fixed-Wing UAVs](#) by Owen, Beard, and McLain presents a 3-D Dubins airplane model, deriving a complete architecture for implementing Dubins airplane paths on small fixed-wing UAVs. A vector-field method is then used to design a guidance law that causes the Dubins airplane model to follow straight-line and helical paths. Dubins airplane paths are more complicated than Dubins car paths because of the altitude component. Based on the difference between the altitude of the start and end configurations, Dubins airplane paths are classified as low-, medium-, or high-altitude gain. While for medium- and high-altitude gain there are many different Dubins airplane paths, it is proposed to select the path that maximizes the average altitude throughout the maneuver. The proposed architecture is implemented on a six degree-of-freedom MATLAB/Simulink simulation of an Aerosonde UAV, and results from this simulation demonstrate the effectiveness of the technique.

Chapter ► [Health Monitoring of a Drone Formation Affected by a Corrupted Control System](#) by Lechevin, Rabbath, and Maupin proposes a dynamic feature that is instrumental in achieving vulnerability assessment of a network of UAVs, whose control system is possibly affected by the diffusion of malware. The feature consists of the characterization of the transition from stability to instability with probability one. The stability of the networked UAVs can be indirectly affected by malicious attacks targeting the communication units or the control systems. The network is modeled as a discrete-time, jump, linear system whose state space variables represent the probabilities that each node receives a malware and is infected by it. The stability analysis is obtained by means of a stochastic Lyapunov function argument and yields a sufficient condition expressed as a linear matrix

inequality (LMI). This LMI involves the networked asset state space matrices and the probability that each UAV's control system is infected. An approximation to the sufficient condition is proposed so that convergence of the system trajectories could be monitored online.

2.3.12 UAV Autonomy

Section ▶[UAV Autonomy](#) includes chapters ▶[Integrated Hardware/Software Architectures to Enable UAVs for Autonomous Flight](#), ▶[Distributed Optimization of Autonomous UAVs with Event-Driven Communication](#), and ▶[UAV Guidance Algorithms via Partially Observable Markov Decision Processes](#).

Chapter ▶[Integrated Hardware/Software Architectures to Enable UAVs for Autonomous Flight](#) by Pippin describes hardware and software architecture components that enable autonomous flight operation, also presenting some recommended architectural approaches and best practices. This is deemed essential as UAVs become increasingly more autonomous and ubiquitous and system hardware and software designers need to consider system requirements that contribute to increased levels of autonomy. Autonomous UAV architectures need to be modular, open, and provide visibility for operators and testers, also embracing open and extensible architectures that can be configured and deployed for robust and safe autonomous operation. Future UAVS will operate with varying levels of human interaction and will require the ability to process sensor data onboard and to operate using high-level, autonomous behaviors. The chapter concludes with a case study of the hardware and software architecture for an autonomous UAV research platform.

Chapter ▶[Distributed Optimization of Autonomous UAVs with Event-Driven Communication](#) by Zhong and Cassandras considers problems where multiple autonomous UAVs cooperate to control their individual state so as to optimize a common objective while communicating with each other to exchange state information. Since communication costs can be significant, especially when the UAVs operate with limited energy, conditions are sought under which communication of state information among nodes can be restricted while still ensuring that the optimization process converges. An asynchronous, event-driven scheme is described which limits communication to instants when some state estimation error function at a node exceeds a threshold. This scheme guarantees convergence to an optimal even in the presence of communication delays as long as they are bounded. This approach is applied to a UAV network coverage control problem where the objective is to maximize the probability of detecting events occurring in a given region, and it is shown that it may significantly reduce communication costs, hence also prolonging the system's lifetime, without any performance degradation.

Chapter ▶[UAV Guidance Algorithms via Partially Observable Markov Decision Processes](#) by Ragi and Chong presents a path-planning algorithm to guide UAVs to track multiple ground targets based on the theory of *partially observable Markov decision processes* (POMDPs). This method shows how to exploit the generality and flexibility of the POMDP framework by incorporating a variety of features of

interest naturally into the framework, which is accomplished by plugging in the appropriate models. Specifically, this study shows how to incorporate the following features by appropriately formulating the POMDP action space, state-transition law, and objective function: (1) control UAVs with both forward acceleration and bank angle subject to constraints, (2) account for the effect of wind disturbance on UAVs, (3) avoid collisions between UAVs and obstacles and among UAVs, (4) track targets while evading threats, (5) track evasive targets, and (6) mitigate track swaps.

2.3.13 UAV Sense, Detect, and Avoid Systems

Section ►UAV Sense, Detect, and Avoid Systems includes chapters ►Development of a Regulatory Safety Baseline for UAS Sense and Avoid, ►Achieving Sense and Avoid for Unmanned Aircraft Systems: Assessing the Gaps for Science and Research, ►Automatic Traffic Alert and Collision Avoidance System (TCAS) Onboard UAS, ►Test Flights to Demonstrate Effectiveness of a Ground-Based Detect and Avoid Integration Concept, ►Scalable RADAR-Based Sense and Avoid System for Unmanned Aircraft, and ►Assessment of Detect and Avoid Solutions for Use of Unmanned Aircraft Systems in Nonsegregated Airspace.

Chapter ►Development of a Regulatory Safety Baseline for UAS Sense and Avoid by Oztekin and Wever presents a systems level approach to analyze the safety impact of introducing UAS into the NAS. Utilizing Safety Management Systems (SMS) principles and the existing regulatory structure, a methodology is outlined to determine a regulatory safety baseline for a specific area of interest regarding a new aviation technology, such as UAS Sense and Avoid (SAA). The presented methodology is then employed to determine a baseline set of hazards and causal factors for the UAS Sense and Avoid problem domain and associated regulatory risk controls.

Chapter ►Achieving Sense and Avoid for Unmanned Aircraft Systems: Assessing the Gaps for Science and Research by Davis and Cook focuses on the efforts by the Office of the Under Secretary of Defense (OUSD) for Acquisition, Technology, and Logistics (AT&L) to make progress in solving the SAA problem by the establishment of the SAA Science and Research Panel (SARP) in February 2011. The SARP consists of a panel of experts in technologies necessary to provide UAS with the ability to sense and avoid other aircraft. The panel's primary purpose is to promote partnerships between the U.S. DoD and the broader academic and scientific community on UAS NAS Integration science and research initiatives in order to identify open questions and challenges in research and science efforts that must be addressed to provide UAS with an effectual SAA capability. Further, this chapter describes the methods of identifying and closing the science and research gaps that have been identified to date.

Chapter ►Automatic Traffic Alert and Collision Avoidance System (TCAS) Onboard UAS by Meyer, Gottken, Vernaleken, and Scharer reports on the SAA capabilities of the Barracuda UAS demonstrator, on which Cassidian installed a co-operative collision avoidance system based on Traffic Alert and Collision Avoidance

System (TCAS). The demonstration is intended as a risk mitigation measure to support future UAS development efforts. The demonstration steps involve laboratory tests with real equipment in a closed-loop demonstration and the automatic execution of a collision avoidance maneuver in flight. The in-flight demonstration takes place in segregated air space involving the Barracuda demonstrator platform and a real intruder. The chapter outlines the setup of the cooperative collision avoidance system demonstrator, including the interface with the flight control system of the Barracuda and the control authority granted to the cooperative collision avoidance system demonstrator. It summarizes the Human-Machine-Interface (HMI) layout and situation awareness provided to the UAS operator and illustrates how the potential loss of data link connection is covered by the system design. The development process is detailed, including requirements definition, validation, and verification steps as well as hardware-in-the-loop demonstration in support of the in-flight demonstration. It illustrates the demonstration scenarios utilized in the flight demonstration and the results achieved. Conclusions are drawn regarding the potential of such cooperative collision avoidance systems based on TCAS, the operational implications, and the certification aspects to be solved.

Chapter ► [Test Flights to Demonstrate Effectiveness of a Ground-Based Detect and Avoid Integration Concept](#) by Udovic, de Jong, and Vielhauer presents and reports on the VUSIL program (*Validierung von UAS zur Integration in den Luftraum*) that has developed a concept for integrating UAS into uncontrolled nonsegregated airspace, which is also used by manned civil aviation. The surrounding traffic is indicated on a display in the pilot ground control station (GCS), based on radar data provided by the Air Navigation Service Provider (ANSP). In addition, the pilot is supported by means of a “detect and avoid” tool in detecting potential conflicts. This tool shows conflicts and possible avoidance maneuvers on a separate display. To validate the integration concept, two flight campaigns with two different UAS (helicopter and fixed-wing UAS) and several intruders were conducted. In the first flight campaign, the intruders for the real flying UAS were simulated. In the second flight campaign, the intruder was a manned helicopter. The concept has been validated by the results of both flight campaigns and by a safety analysis. The latter has addressed demonstrating the equivalent level of safety (ELOS) of “see and avoid” in manned aviation and “detect and avoid” as developed in the VUSIL program.

Chapter ► [Scalable RADAR-Based Sense and Avoid System for Unmanned Aircraft](#) by Moses, Rutherford, and Valavanis presents one possible solution for addressing the midair collision problem in addition to increasing the levels of autonomy of UAS beyond waypoint navigation to include preemptive sensor-based collision avoidance. The proposed solution goes beyond the current state of the art by demonstrating the feasibility and providing an example of a scalable, self-contained, RADAR-based, collision avoidance system. The RADAR hardware and collision avoidance algorithms are presented in detail. The technology described herein can be made suitable for use on a miniature (maximum take-off weight <10 kg) UAS platform. This is of paramount importance as the miniature UAS field has the lowest barriers to entry (acquisition and operating costs) and consequently represents the most rapidly increasing class of UAS.

Chapter ▶ [Assessment of Detect and Avoid Solutions for Use of Unmanned Aircraft Systems in Nonsegregated Airspace](#) by Verstraeten, Stuip, and Birgelen summarizes and assesses the most promising candidate solutions for detect and avoid (DAA) for use of UAS in nonsegregated airspace against a set of DAA requirements. A DAA solution is the combination of the sensor suite, the avoidance algorithms, and the method of operation. The functions of a DAA solution are collision avoidance and, in uncontrolled airspace, separation provision. The chapter focuses on the detection of conflicting traffic by the sensor suite. The sensor suite needs to be able to detect different classes of conflicting traffic in varying environments. Requirements for DAA solutions have to be set, and DAA systems must then be developed to meet these requirements. ATM requirements for use of UAS in nonsegregated airspace have been drafted by EUROCONTROL, including a subset of requirements that are directly or indirectly of influence on the sensor suite used to DAA other traffic. This subset is used as baseline for the establishment of DAA requirements and expanded by development of five additional generic requirements based on the main tasks of a DAA solution: (1) detection of other traffic; (2) tracking of other traffic and (3) assessing if there is a conflict; (4) if there is a conflict, determining which evasive maneuver is to be executed; and (5) executing the selected maneuver. Five candidate solutions are assessed against the requirements: a noncooperative solution, a cooperative solution, and three solutions mixing cooperative and noncooperative sensors. Overall it is concluded that it is a great challenge to develop a collision avoidance solution for UAS with a satisfactory level of safety. It is even more difficult to develop a DAA system that is capable of both collision avoidance and separation provision.

2.3.14 Networked UAVs and UAV Swarms

Section ▶ [Networked UAVs and UAV Swarms](#) includes chapters ▶ [UAV Swarms: Models and Effective Interfaces](#), ▶ [Decentralized Multi-UAV Coalition Formation with Limited Communication Ranges](#), ▶ [Coordinated Convoy Protection Among Teams of Unmanned Aerial Vehicles](#), and ▶ [UAV Routing and Coordination in Stochastic, Dynamic Environments](#).

Chapter ▶ [UAV Swarms: Models and Effective Interfaces](#) by Chapman and Mesbahi examines the modeling and design of effective control interfaces for human operators of UAV swarms. The swarm is modeled as a two-component hierarchical system consisting of the interaction dynamics among the UAVs in the swarm, referred to as the *network dynamics*, and the *UAV dynamics* itself. Human operators are assumed to be able to interface with the swarm via the network dynamics, which in turn has adopted a *leader-follower consensus model*. The system-theoretic and topological features of the network dynamics are then examined in order to design effective mechanisms for interfacing with the swarm. A performance metric is selected for reasoning about effective human swarm interaction. The role of topological features of the network is highlighted in the context of the chosen metric and is related through the effective resistance of the corresponding electrical

network. This is then followed by exploiting such topological features for designing a network rewiring protocol to maximize the metric. These topology design tools are applied to wind-gust rejection in disturbed swarming scenarios, demonstrating the viability of topology-assisted design for improved swarm performance. A network-based model reduction is also proposed to form a lower-order model of the network which is easier for the human operators to conceptualize and manage. The reduction process involves a novel partitioning scheme, dubbed *leader partition*, in order to fuse “similar” states in the UAV network and to form a graph-theoretic method for model reduction. This model reduction technique is then applied to derive improved swarming performance in the presence of wind gusts.

Chapter ► [Decentralized Multi-UAV Coalition Formation with Limited Communication Ranges](#) by Sujit, Manathara, Ghose, and Sousa discusses a communication protocol derived to search for potential coalition members over a dynamic UAV network and a strategy for a UAV coalition to track and destroy moving targets. The effects of communication ranges and delays as well as the scalability of the proposed schemes with change in number of targets and UAVs are studied. The results show that it is beneficial to search for potential coalition members over a wide diameter in the UAV network when the communication delay is less, while it is more advantageous to determine a coalition from among the immediate neighbors in the presence of significant communication delay.

Chapter ► [Coordinated Convoy Protection Among Teams of Unmanned Aerial Vehicles](#) by Egerstedt, Rahmani, and Young investigates how to control and coordinate teams of UAVs to provide protection to convoys of ground vehicles. This is a rich yet canonical problem when coordinating multiple UAVs in that coordinated movements, task assignments, and resource balancing must all be performed for a successful completion of the mission. Time optimal paths for providing convoy protection to stationary ground vehicles are presented, and these algorithms are extended to moving ground vehicles. The assignment problems, associated with dispatching UAVs from the convoy to inspect and clear potential threats, are also discussed.

Chapter ► [UAV Routing and Coordination in Stochastic, Dynamic Environments](#) by Enright, Frazzoli, Pavone, and Savla focuses on a technical approach that relies upon methods from queuing theory, combinatorial optimization, and stochastic geometry. The main advantage of this approach is its ability to provide analytical estimates of the UAV system performance on a given problem, thus, providing insight into how performance is affected by design and environmental parameters, such as the number of UAVs and the target distribution. This approach also provides provable guarantees on the system’s performance with respect to an ideal optimum. To illustrate this approach, a variety of scenarios are considered, ranging from the simplest case where one UAV moves along continuous paths and has unlimited sensing capabilities, to the case where the motion of the UAV is subject to curvature constraints, and finally to the case where the UAV has a finite sensor footprint. Finally, the problem of cooperative routing algorithms for multiple UAVs is considered, within the same queuing-theoretical framework, and with a focus on control decentralization.

2.3.15 UAV Integration into the National Airspace

Section ►UAV Integration into the National Airspace includes chapters ►Aviation Regulation, ►Human Factors of Unmanned Aircraft System Integration in the National Airspace System, ►Methodologies for Regulatory Compliance and Harmonization, ►A Certification Strategy for Small Unmanned Aircraft Performing Nomadic Missions in the US National Airspace System, ►Hazard and Safety Risk Modeling, ►Safety Risk Management of Unmanned Aircraft Systems, ►Certification of Small UAS, ►Technology Surveys and Regulatory Gap Analyses of UAS Subsystems Toward Access to the NAS, ►Concept of Operations of Small Unmanned Aerial Systems: Basis for Airworthiness Toward Personal Remote Sensing, and ►Standards and Certification of a UAS Sense and Avoid Capability.

Chapter ►Aviation Regulation by Dalamagkidis presents a brief introduction to aviation regulation. Key terms are defined, and an overview of current manned aviation regulations is provided using the U.S. Federal Aviation Regulation as an example. This includes airworthiness certification, operation rules, and airspace classes.

Chapter ►Human Factors of Unmanned Aircraft System Integration in the National Airspace System by Kaliardos and Lyall focuses on identifying human factor challenges to integrating UAS in the National Airspace System (NAS) for both pilots and air traffic controllers. The method for identifying these challenges is primarily based on the differences or “gaps” between manned aircraft in the NAS today and the unique aspects of UAS. The goal is not to generate a comprehensive list of human factors issues, but to focus on those that are traceable to fundamental characteristics of UAS and that are also considered challenging with respect to the current NAS and its regulatory framework. It is assumed that for integration into the NAS, future UAS will be much more standardized in many respects than in the past – closer to that of today’s civil manned aircraft, which are subject to rigorous design, operational, manufacturing, and training approvals by the FAA. Under such assumptions, human factors not only are central to the very definition of UAS but are also central to some of the most important challenges facing the integration of UAS in the NAS.

Chapter ►Methodologies for Regulatory Compliance and Harmonization by Marshall proposes a methodology for analysis of current regulations for applicability to UAS activities. Where the rules are in development, or merely being contemplated, a structure for harmonization with international standards is proposed. The focus is on the USA as the nation that has the most comprehensive aviation regulations, while also supporting major efforts to promulgate regulations and standards to supplement those regulations with UAS specific requirements and criteria. To provide global context, the International Civil Aviation Organization’s (ICAO’s) structure and procedures are reviewed in detail, and contrasted with State sponsored regulatory processes, with an analysis of the applicability of ICAO’s standards to UAS operations.

Chapter ►A Certification Strategy for Small Unmanned Aircraft Performing Nomadic Missions in the US National Airspace System by Stachura, Elston, Argrow, Frew, and Dixon discusses the specifics of the Certificates of Authorization (COA)

obtained for the second Verification of the Origin of Rotation in Tornadoes Experiment (VORTEX2) project and how the operations are conducted to satisfy the COA requirements. A strategy is outlined for operating these nomadic missions with small UAS within the confines of FAA regulations. This includes information on getting FAA COAs for a large area, specifically focusing on area selection, airworthiness, and emergency procedures, which are the keys to these applications.

Chapter ►[Hazard and Safety Risk Modeling](#) by Dalamagkidis presents aspects of risk modeling with a focus on UAS. It provides an overview of the current level of safety of manned aviation in terms of accident statistics. These are then mapped as target levels for UAS under the “Equivalent Level of Safety” principle to provide a glimpse at what that may entail for UAS regulations. Different methodologies are presented for estimating the risk of ground impact and midair collision accidents and how these estimates can be translated to system requirements. Guidelines are provided on the use of different risk models followed by applying a selection of them to five different UAS in two distinct scenarios, to compare the results of different choices.

Chapter ►[Safety Risk Management of Unmanned Aircraft Systems](#) by Clothier and Walker provides existing risk practitioners with a high-level introduction to some of the unique issues and challenges in the application of the safety risk management process to UAS. The scope is limited to safety risks associated with the operation of unmanned aircraft in the civil airspace system and over inhabited areas. This chapter notes the unique aspects associated with the application of the safety risk management process to UAS compared to that of conventionally piloted aircraft. Key challenges discussed include the specification of high-level safety criteria; the identification, analysis, and evaluation of the risks; and the effectiveness of available technical and operational mitigation strategies. Some solutions to these challenges are examined including those currently in practice and those still under research and development.

Chapter ►[Certification of Small UAS](#) by Leijgraaf describes certification procedures for (small) UAS. It focuses on the certification process, the requirements for the safe design of a UAS, and the organizational requirements for the company designing the UAS.

Chapter ►[Technology Surveys and Regulatory Gap Analyses of UAS Subsystems Toward Access to the NAS](#) by Stansbury and Wilson provides the necessary details on how to conduct a technology survey and regulatory gap analysis of UAS technology subsystems. Four past studies performed by Embry-Riddle Aeronautical University for the FAA’s William J. Hughes Technology Center are discussed. These studies address UAS propulsion systems, sense and avoid technologies and procedures, command control and communication, and emergency recovery and flight termination systems. A recommended process for future studies is provided.

Chapter ►[Concept of Operations of Small Unmanned Aerial Systems: Basis for Airworthiness Toward Personal Remote Sensing](#) by Stark, Coopmans, and Chen discusses the challenges of UAS integration into the NAS for a class of small UAS for personal remote sensing (PRS). This approach is centered on the three pillared foundations for NAS integration presented by the U.S. DoD Unmanned Aircraft System Airspace Integration Plan and focuses on the specific challenges that are

unique to the PRS UAS platform. This chapter presents a concept of operations for these unmanned aircrafts along with an application scenario example and concludes with a discussion of the future use of UAS in the NAS and how it is achievable through adequate regulations and standards.

Chapter ►[Standards and Certification of a UAS Sense and Avoid Capability](#) by Zeitlin centers on “certifiable” and “standardized” UAV sense and avoid (SAA) capabilities that are needed to mitigate for the lack of a remote pilot’s ability to “see and avoid” other aircraft, which is an operational requirement. Regulators certify the airworthiness of aircraft, assuring their compliance with applicable regulations. Approvals of SAA implementations constitute part of that process. Each applicant needs to develop a Project Specific Certification Plan in close coordination with the regulator. Various tools for safety analysis and configuration control support this effort. Specification of the certification basis for SAA needs close attention, since the system addresses functions traditionally allocated to an onboard pilot. Algorithms and software will receive scrutiny due to their safety roles. Standards are developed to capture common requirements in support of systems that may use some degree of unique design innovation. A standard should suggest means of demonstrating compliance to its requirements, and so doing will greatly simplify the burden for both applicant and regulator. The closest existing standard to SAA is that for the Traffic Alert and Collision Avoidance System II (TCAS II), but SAA includes the additional function of self-separation. SAA can be implemented with various technologies in a variety of architectures. SAA should provide two basic functions, each performing prescribed subfunctions. Considerable modeling and simulation will be required to validate system performance and support the safety case. The regulator may offer guidance to applicants through publication of an Advisory Circular.

2.3.16 UAV-Human Interfaces and Decision Support Systems

Section ►[UAV-Human Interfaces and Decision Support Systems](#) includes chapters ►[Human Interfaces in Micro and Small Unmanned Aerial Systems](#), ►[Human Factors Perspective on Next Generation Unmanned Aerial Systems](#), ►[Cognitive Task Analysis for UAV Design](#), ►[Display and Control Concepts for Multi-UAV Applications](#), and ►[UAV Operators Workload Assessment](#).

Chapter ►[Human Interfaces in Micro and Small Unmanned Aerial Systems](#) by Peschel and Murphy surveys the various aspects of user interfaces for a Mission Specialist role on micro and small UAS human-robot teams. Three formal human team member roles are presented, this of Flight Operations Director, Pilot and Navigator, and the Mission Specialist, in order to identify distinct team member role differences. For each category of UAV, the Mission Specialist role is evaluated to determine what type of user interface technologies are present and/or available, how the Mission Specialist currently or could interact with the user interface technology, and what are the perceived consequences of this user interface technology in the context of the three identified micro and small UAS human-robot team roles. The findings of this survey suggest that current Mission Specialist performance in micro

and small UAS may be suboptimal due to the sharing of a single Pilot and Navigator-oriented user interface or a reuse of the Pilot and Navigator user interface.

Chapter ► [Human Factors Perspective on Next Generation Unmanned Aerial Systems](#) by Goodrich and Cummings presents a comprehensive view on UAS autonomy and user interface design, motivating emerging themes in near-term and far-term UAS developments. Issues include user interface design, UAS autonomy, UAS teaming, operator workload, and payload management.

Chapter ► [Cognitive Task Analysis for UAV Design](#) by Adams provides an overview of cognitive analysis methods that can be integrated into the early system design process to account for the human element. It specifically provides an overview of task analysis, work analysis, and information flow analysis methods along with an overview of how individual methods from the different analysis classes have been combined. It is argued, and rightly so, that although UAS are complex tools requiring thoughtful designs that account for the platform itself, payloads, and human users as a holistic system, often the focus is first placed on designing the platform or payload, while the human element is considered at a later stage. As such, system design approaches do not properly consider the human cognitive limitations and do not design the system to support the human's tasks and decision making. Specific examples of applying these analyses methods to unmanned aerial systems, ranging from potential futuristic systems to research systems to deployed systems, are also reviewed.

Chapter ► [Display and Control Concepts for Multi-UAV Applications](#) by Calhoun and Draper introduces a variety of display and control concepts that may be especially applicable to multi-UAV applications. Many such technologies are being investigated at the U.S. Air Force Research Laboratory and include multimodal interfaces, temporal displays, and integrated visualization concepts. The thesis is that for any candidate technology, rigorous user-centered design and evaluation needs to be conducted, which focuses on the tasks and requirements of the specific multi-UAV application being targeted. It is also important to ensure that the operator has adequate means to first observe and then direct the automation's functioning in order to be responsive to changes in the mission, vehicle status, or operational environment. What is important to capture is that advances in automation technology are leading to the development of UAV concepts in which a single pilot will be responsible for multiple UAVs. Thus, the operator's role will become more supervisory in nature, resulting in a new interface paradigm required for effective supervisory control of multiple UAVs by a single operator.

Chapter ► [UAV Operators Workload Assessment by Optical Brain Imaging Technology \(fNIR\)](#) by Izzetoglu, Ayaz, Hing, Shewokis, Bunce, Oh, and Onaral discusses the utilization of near-infrared-based functional brain imaging systems, fNIRs, in the monitoring of a cognitive workload during UAV operation and as an objective measure of expertise development, that is, the transition from novice to expert during operator training. The challenge relates to the fact that UAV ground operators are required to acquire skills quickly and completely, with a level of expertise that builds the operator's confidence in his/her ability to control the UAV under adverse conditions. As UAVs are held to increasingly higher standards of

efficiency and safety, operators are routinely required to perform more information-dense and cognitively demanding tasks, resulting in increased cognitive workloads during operation. Functional brain monitoring offers the potential to help UAV operators meet these challenges, and research has demonstrated the utility of fNIRs for the purpose of monitoring frontal cortical areas that support executive functions (attention, working memory, response monitoring). fNIR technology allows for continuous monitoring of operators during training as they develop expertise, as well as the capacity to monitor their cognitive workload under operational conditions while controlling UAVs in critical missions.

2.3.17 Human Factors and Training

Section ►[Human Factors and Training](#) includes chapters ►[Using Best Practices as a Way Forward for Remotely Piloted Aircraft Operators: Integrated Combat Operations Training-Research Testbed](#) and ►[From Research to Operations: The PITVANT UAS Training Experience](#).

Chapter ►[Using Best Practices as a Way Forward for Remotely Piloted Aircraft Operators: Integrated Combat Operations Training-Research Testbed](#) by Rowe, Conwell, Morris, and Schill centers on work undertaken at the U.S. Air Force Research Laboratory (AFRL) in the Integrated Combat Operations Training-Research Testbed (ICOTT), where training gaps in the RPA community are extensively researched. This is the aftermath of the massive growth and increase of medium-altitude, long-endurance (MALE) remotely piloted aircraft combat air patrols, which has enforced the need to train RPA operators quickly and effectively. Using a competency-based approach, researchers, engineers, subject matter experts, and warfighters are developing a training research testbed to evaluate curriculum, training methodologies, and best practices in training simulation. The chapter addresses the evolution of training requirements for the RPA community as well as targeted solutions to support RPA training, operational readiness needs, and an exploration into the existing methods and common tools used to understand and evaluate the relative trade-off in training utility associated with alternative training systems. The overarching discussion focuses on methods for providing more rapid and efficient knowledge and skill development for RPA operators.

Chapter ►[From Research to Operations: The PITVANT UAS Training Experience](#) by Madruga Matos, Vieira Caetano, Morgado, and Borges de Sousa presents the PITVANT UAS R&D program training experience, including the different crew positions and responsibilities, the several training phases, and the systems engineering methodology behind all developments carried by the joint team of the Portuguese Air Force Academy and Porto University. The training program is described including theoretical classes, written exams, and practical instruction and evaluation. The process of developing, testing, and validating concepts of operations and the correspondent operational procedures and their training with the involvement of end users is reported. The current operational capabilities of the systems are explained, showing that the PITVANT program has achieved a level of

maturity that enables testing and validation in near real scenarios. This leads to the next step in the systems spiral development that should include, in the near future, the possibility of technology transfer to the industry.

2.3.18 UAV Logistics Support

Section ▶UAV Logistics Support includes chapters ▶UAV Logistic Support Definition and ▶UAV Logistics for Life-Cycle Management.

Chapter ▶UAV Logistic Support Definition by Chiesa and Fioriti presents considerations and hypotheses about RAMS characteristics and logistic support options for operational fleets of UAS. At first, an outline of why logistic support is relevant for UAS in comparison with other complex systems is presented, followed by considerations why reliability, safety, and maintainability are relevant aspects for UAS, explaining how such characteristics can be achieved by design. Synthetic considerations regarding transportability, a characteristic strictly connected to safety, reliability, maintainability, and logistic operations, are discussed. It is stated that considering (in addition to technical features) targets, requirements, constraints at the origin of a fleet of UAS, fleet sizing, and related system support (elements and strategies), a useful tool to face such complex problems is stochastic simulation and in particular a Monte Carlo methodology, which is also discussed.

Chapter ▶UAV Logistics for Life-Cycle Management by Karaagac, Pakfiliz, Quagliotti, and Alemdaroglu provides the reader with general knowledge on UAV Logistics for Life-Cycle Management, focusing on current logistics challenges and possible future UAV logistics trends that may improve UAV deployment. Although UAVs do not have a pilot onboard, they require nearly the same logistics support as most manned aircraft. That is, logistics support covers support for all components including the unmanned aircraft and the ground control station. The objective is to design a system with a reduced logistic footprint, enabling fast deployment and high mobility.

2.3.19 UAV Applications

Section ▶UAV Applications includes chapters ▶Survey of Unmanned Aerial Vehicles (UAVs) for Traffic Monitoring, ▶Measurement and Exploration in Volcanic Environments, ▶Cooperative Unmanned Aerial Systems for Fire Detection, Monitoring, and Extinguishing, ▶Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States, ▶Unmanned Aerial Systems Physically Interacting with the Environment: Load Transportation, Deployment, and Aerial Manipulation, ▶Unmanned Aircraft Systems for Maritime Operations, ▶Autonomous Remote Sensing of Invasive Species from Robotic Aircraft, and ▶Cyber-Physical Systems Enabled by Small Unmanned Aerial Vehicles.

Chapter ▶Survey of Unmanned Aerial Vehicles (UAVs) for Traffic Monitoring by Kanistras, Martins, Rutherford, and Valavanis focuses on surveying UAV-based

systems for traffic monitoring and management. Although there is voluminous research on the subject, UAVs are proven to be a viable and less time consuming alternative to real-time traffic monitoring and management as they provide the dynamic “eye-in-the-sky” solution to the problem.

Chapter ► [Measurement and Exploration in Volcanic Environments](#) by Melita, Longo, Muscato, and Giudice presents a challenging application for UAVs in volcanic environments, as they may be used to collect typical aerial measurements and data. The main forms of measurements concern the collection of visual/thermal images and gas analysis and sampling. An overview of the major worldwide projects carried out in the last few years by several research organizations is summarized and discussed.

Chapter ► [Cooperative Unmanned Aerial Systems for Fire Detection, Monitoring, and Extinguishing](#) by Merino, Martinez-de Dios and Ollero deals with the application of cooperative UAVs to forest fires. It presents a decision and control architecture for multi-UAS teams that are equipped with diverse sensors (e.g., infrared and visual cameras) and details the perception techniques (fire segmentation, geo-localization, and data fusion) that are used toward fire extinguishing.

Chapter ► [Selection of Appropriate Class UAS/Sensors to Support Fire Monitoring: Experiences in the United States](#) by Ambrosia and Zajkowski describes some of the UAS lessons learned by both the U.S. Forest Service (USFS) and the National Aeronautics and Space Administration (NASA) during their more than 10-year efforts on identifying appropriate UAS wildfire observation capabilities. The agencies, along with the UAS community, have demonstrated the use of both low-altitude, short-endurance (LASE) and medium-altitude, long-endurance (MALE) platforms for wildfire sensor intelligence gathering. Those experiences are identified along with an examination of the future direction of UAS for supporting the wildfire management community.

Chapter ► [Unmanned Aerial Systems Physically Interacting with the Environment: Load Transportation, Deployment, and Aerial Manipulation](#) by Kondak, Ollero, Maza, Krieger, Albu-Schaeffer, Schwarzbach, and Laiacker discusses the novel and very challenging applications of using UAVs for aerial manipulation and load transportation. A specific application of using autonomous helicopters equipped with robotic arms for aerial manipulation is detailed, along with field experiments demonstrating joint load transportation with multiple autonomous helicopters.

Chapter ► [Unmanned Aircraft Systems for Maritime Operations](#) by Borges de Sousa, McGuillivary, Bento, Morgado, Matos, Gomes Bencatel, and de Oliveira discusses current practices and major UAS trends for maritime operations, along with projections of future UAS maritime applications. Various aspects of UAS program management, including organization, operator responsibilities, program operation, and overall program costs are reviewed, followed by maritime aircraft missions and required capabilities. Technological trends are highlighted focusing on developments relevant to maritime UAS operations. Trends including miniaturization of sensors and computer systems, high energy density of power sources, and increased subsystem standardization and modularity will have important effects in the future, including increased system autonomy via new command and control frameworks.

Chapter ▶ [Autonomous Remote Sensing of Invasive Species from Robotic Aircraft](#) by Goktogan and Sukkarieh presents an ensemble system consisting of a helicopter, a fixed-wing UAV, and their supporting infrastructure that is used in a number of environmental research experiments focused on autonomous remote sensing, detection, classification, and management of invasive species, weeds, in Australia. In these experiments, three distinct families of weeds on three different terrains are investigated. In the first group of experiments, a helicopter UAV equipped with a high-resolution imaging payload is flown over difficult to reach water channels and wetlands for detection of aquatic weeds. The second set of experiments is performed in relatively flat rangelands to map woody infestations. The third set of experiments is focused on the airborne detection of wheel cacti on remote mountainous terrain using fixed-wing aircrafts. Successful results of these experiments suggest that robotic aircrafts in a properly designed UAS can play an important role in environmental robotic science.

Chapter ▶ [Cyber-Physical Systems Enabled by Small Unmanned Aerial Vehicles](#) by Coopmans, Stark, Jensen, Chen, and McKee provides several examples of unmanned aircraft sensing-enabled cyber-physical system (CPS) scenarios, enabling adaptive management and effective control of complex physical systems such as water distribution based on measurement of soil moisture and crop evapotranspiration, radio tag-based tracking of fish, alternative energy harvesting, mapping of invasive plant species, and airborne plume (pollution) tracking. This chapter serves as a motivator for potential widespread UAS applications where UAS are used as mobile sensors and/or mobile actuators in large-scale, closed-loop CPS.

2.3.20 Social and Ethical Implications

Section ▶ [Social and Ethical Implications](#) includes chapters ▶ [Ethics and UAVs](#), ▶ [International Governance of Autonomous Military Robots](#), ▶ [The Moral Case Against Autonomous and Semiautonomous UAVs](#), ▶ [The Moral Case for Autonomy in Unmanned Systems](#), ▶ [Moral Predators: The Duty to Employ Uninhabited Aerial Vehicles](#), ▶ [Killer Robots: Ethical Issues in the Design of Unmanned Systems for Military Applications](#), ▶ [Conclusion: Testimony on Ethical Issues of UAVs for National Academy](#), and ▶ [Future of Unmanned Aviation](#).

Chapter ▶ [Ethics and UAVs](#) by Lucas provides an overview of ethical, legal, and “robot morality” challenges arising from the military and security uses of robotics and other unmanned vehicles in a number of relevant conflict environments, including the increased domestic uses of both remotely controlled and fully autonomous unmanned aerial, maritime, and ground systems for immigration control, border surveillance, drug interdiction, and domestic law enforcement.

Chapter ▶ [International Governance of Autonomous Military Robots](#) by Marchant, Allenby, Arkin, Borenstein, Gaudet, Kittrie, Lin, Lucas, O’Meara, and Silberman aims at providing a background of some of the principal legal issues that may motivate and initiate a much-needed legal and ethical dialogue related to the use of lethal autonomous robotic technologies in the military context.

Chapter ► [The Moral Case Against Autonomous and Semiautonomous UAVs](#) by Sharkey focuses on ethical concerns about the application of armed robots in areas with mixed combatant and civilian populations, making the claim that one must scrutinize the mapping between the applications of the new technology and the current laws to ensure that those laws are preserved and followed.

Chapter ► [The Moral Case for Autonomy in Unmanned Systems](#) by Arkin centers on the need to restrain the technology itself above and beyond the human limits of the warfighters themselves, making the case for the use of ethical autonomy in unmanned systems, which is deemed necessary since warfare will continue and autonomous robots will ultimately be deployed in its conduct. In this way, one may hope that battlefield atrocities will not become progressively worse given the progression of standoff weapons and increasing use of technology.

Chapter ► [Moral Predators: The Duty to Employ Uninhabited Aerial Vehicles](#) by Strawser focuses on the supposed objections to the use of UAVs in principle, defending the view that society has a duty to protect an agent engaged in a justified act from harm to the greatest extent possible so long as that protection does not interfere with the agent's ability to act justly. Since UAVs do afford such protection an argument is made that a nation is obligated to employ UAV weapon systems if it can be shown that their use does not significantly reduce a warfighter's operational capability.

Chapter ► [Killer Robots: Ethical Issues in the Design of Unmanned Systems for Military Applications](#) by Sparrow argues that designers of unmanned systems used for military applications must consider ethical, operational, requirements and limits of such systems. This chapter identifies and discusses a number of issues and offers some analysis of the implications of each issue and how it might be addressed.

The concluding chapter in this section ► [Conclusion: Testimony on Ethical Issues of UAVs for National Academy of Sciences](#) contains a transcript of testimony presented by Lucas to a select ad hoc committee convened by the National Academy of Sciences (USA) in response to a request from the U.S. Defense Advanced Research Projects Agency (DARPA) to evaluate the "Ethical and Societal Implications of Advances in Militarily Significant Technologies That Are Rapidly Changing and Increasingly Globally Accessible." This testimony was delivered at the inaugural meeting of the committee on 31 August 2011 at the NAS Beckman Center, on the campus of the University of California – Irvine.

Chapter ► [Future of Unmanned Aviation](#), brings closure to the handbook.

2.4 Remarks

The rest of this Introduction section includes chapters related to ► [Aviation History and Unmanned Flight](#), ► [Definitions and Terminology](#), ► [Classification of UAVs](#), and ► [Military and Civilian Unmanned Aircraft](#). After going through the Introduction section, the reader will be ready to proceed to technical aspects of unmanned aviation and aircraft.

Abstract

The field of UAVs has been plagued with different terms to describe the same thing. Even the term UAV or unmanned aerial vehicle is controversial, and it has been replaced in many places with UAS or Unmanned Aircraft System. The different terms often came from the different requirements and concepts between military and civilian systems or have regulatory/legal importance. This chapter provides definitions for some of the most used terms in the field.

3.1 Introduction

Since many names have been to describe unmanned aircraft, this chapter begins with an overview of these terms and their *raison d’être*. It then continues with some other commonly used terms and expressions, concluding with a list of acronyms that are in use in the field and throughout this handbook.

3.2 UAV or UAS?

Several names have already been used to describe unmanned aircraft. UAVs became UAS, the preferred term used by the Federal Aviation Administration (FAA). Other names included Remotely Piloted Vehicles (RPVs), a term that was used in the Vietnam War. Today the USAF has mainly substituted RPV for Remotely Piloted Aircraft or RPA, a term used to include both the aircraft and the pilot, while the United Kingdom has designated them as Remotely Piloted Air System (RPAS), to demonstrate the presence of the man in the loop to control them; see Herlik (2010) and Fishpool (2010), respectively.

An unmanned aerial vehicle (also known as a drone) refers to a pilotless aircraft, a flying machine without an onboard human pilot or passengers. As such, “unmanned” implies total absence of a human who directs and actively pilots the aircraft. Control functions for unmanned aircraft may be either onboard or off-board (remote control).

The term UAV or unmanned aerial vehicle has been used for several years to describe unmanned aerial systems. Various definitions have been proposed for this term, like

A reusable aircraft designed to operate without an onboard pilot. It does not carry passengers and can be either remotely piloted or preprogrammed to fly autonomously.
Joint Capability Group on Unmanned Aerial Vehicles (2007)

In the definition above, the characterization *reusable* is used to differentiate unmanned aircraft from guided weapons and other munition delivery systems.

A few years ago, the U.S. Department of Defense (DoD), followed by the FAA and the European Aviation Safety Agency (EASA), adopted the term UAS or Unmanned Aircraft System. This was meant to signify that UAS are aircraft and as such airworthiness will need to be demonstrated, and they are also systems consisting of ground control stations, communication links, and launch and retrieval systems in addition to the aircraft itself.

The FAA has defined an *Unmanned Aircraft* or UA as

A device used or intended to be used for flight in the air that has no onboard pilot. This includes all classes of airplanes, helicopters, airships, and translational lift aircraft that have no onboard pilot. Unmanned aircraft are understood to include only those aircraft controllable in three axes and therefore, exclude traditional balloons.

Federal Aviation Administration (2008)

As a comparison, the definition of *Unmanned Vehicle* given in the 2007–2012 Unmanned systems roadmap is also provided:

A powered vehicle that does not carry a human operator, can be operated autonomously or remotely, can be expendable or recoverable, and can carry a lethal or nonlethal payload. Ballistic or semi-ballistic vehicles, cruise missiles, artillery projectiles, torpedoes, mines, satellites, and unattended sensors (with no form of propulsion) are not considered unmanned vehicles. Unmanned vehicles are the primary component of unmanned systems.

U.S. Department of Defense. Office of the Secretary of Defense (2007)

Similarly, EASA defines UAS as

An Unmanned Aircraft System (UAS) comprises individual system elements consisting of an “unmanned aircraft”, the “control station” and any other system elements necessary to enable flight, i.e. “command and control link” and “launch and recovery elements”. There may be multiple control stations, command & control links and launch and recovery elements within a UAS.

European Aviation Safety Agency (2009)

In practice, UAS and UAV are often used interchangeably, and only when the system aspect is important (mainly for legal/regulatory reasons) does UAS have preference.

3.3 Important Terms

Accident An unplanned event or series of events that results in damages. The term mishap is often used to refer to an accident, as well. Accidents that do not occur directly, but rather as a result of other accidents, are referred to as secondary accidents. Note that the National Transportation Safety Board (NTSB) defines an accident as an occurrence incidental to flight in which, as a result of the operation of an aircraft, any person (occupant or non-occupant) receives fatal or serious injury or any aircraft receives substantial damage.

Federal Aviation Administration (2000)

Accident Probability Levels An arbitrary categorization that provides a qualitative measure of the most reasonable likelihood of occurrence of an accident resulting from personnel error, environmental conditions, design inadequacies, procedural deficiencies, or system, subsystem, or component failure or malfunction.

U.S. Department of Defense (2000)

Accident Risk Categories An arbitrary categorization of accident risk assessment values often used to generate specific actions such as mandatory reporting of certain hazards to management for action or formal acceptance of the associated accident risk.

U.S. Department of Defense (2000)

Accident Severity An assessment of the consequences of the most reasonable credible mishap that could be caused by a specific hazard.

U.S. Department of Defense (2000)

Air Traffic Control (ATC) ATC is a service provided under appropriate authority to promote the safe, orderly, and expeditious flow of air traffic.

Air Transport Association (ATA) (2008)

Air Traffic Management (ATM) ATM refers to the dynamic, integrated management of air traffic and airspace – safely, economically, and efficiently – through

the provision of facilities and seamless services in collaboration with all involved parties.

Air Transport Association (ATA) (2008)

Air Vehicle There are certain types of aircraft like moored balloons, unmanned balloons, unmanned rockets, and ultralights that are considered “vehicles” and, thus, are allowed to fly without an airworthiness certificate. More specifically most requirements regarding pilot certification, operating and flight rules, vehicle registration and marking, and maintenance certification that are normally applicable to aircraft do not apply for this category Schultz (2006), although operational restrictions are in place. For example, the following pertain to the operation of ultralight vehicles (FAR Part 103): (i) single occupant, (ii) daylight operations, (iii) recreation or sport purposes only, and (iv) no flight over congested areas in cities, towns, or open areas when crowds are present.

Aircraft An aircraft is defined in the United States Code (USC) as *any contrivance invented, used, or designed to navigate, or fly in, the air* (49 USC §40102). In general, aircraft exist in a variety of possible configurations: fixed-wing, rotary-wing or rotorcraft, helicopters, vertical takeoff and landing (VTOL) vehicles, or short takeoff and landing (STOL) ones. An aircraft may also be either heavier or lighter than air, with balloons and airships belonging to the latter category.

Airman Airman as defined in (49 USC 40102) is an individual:

1. In command, or as pilot, mechanic, or member of the crew, who navigates aircraft when under way
2. Except to the extent the Administrator of the Federal Aviation Administration may provide otherwise for individuals employed outside the U.S., who is directly in charge of inspecting, maintaining, overhauling, or repairing aircraft, aircraft engines, propellers, or appliances
3. Who serves as an aircraft dispatcher or air traffic control-tower operator

Airport The airport is defined as a landing area used regularly by aircraft for receiving or discharging passengers or cargo (49 USC 40102).

Background Risk Risks voluntarily accepted in the course of normal activities.
Range Safety Group, Range Commanders Council (2007)

Collision Avoidance Considered a last resort maneuver of an aircraft to avoid an imminent collision. Without the maneuver a collision might occur.

Small Unmanned Aircraft System Aviation Rulemaking Committee (2009)

Compounding Conservatism An analysis approach that results in extremely conservative results by making a series of conservative assumptions.

Range Safety Group, Range Commanders Council (2007)

Conflict Avoidance Activity which seeks to ensure that aircraft remain safely separated and well clear of each other as to not present a collision hazard.

Small Unmanned Aircraft System Aviation Rulemaking Committee (2009)

Conservatism As used in risk analysis modeling, conservatism is a set of modeling assumptions that exaggerates the risk by overstating event probabilities, hazard probabilities, or consequences.

Range Safety Group, Range Commanders Council (2007)

Damage An undesired outcome that may include injury, fatality, as well as physical, functional, and/or monetary loss.

Expected Fatalities The mean number of fatalities predicted to occur as a result of an operation if the operation were to be repeated many times.

Range Safety Group, Range Commanders Council (2007)

Exposure The number of personnel or resources affected by a given event or, over time, by repeated events. This can be expressed in terms of time, proximity, volume, or repetition. This parameter may be included in the estimation of severity or probability, or considered separately.

United States Air Force (1998)

Fail-Safe A design feature that ensures the system remains safe, or in the event of a failure, causes the system to revert to a state that will not cause a mishap.

U.S. Department of Defense (2000)

Fixed-Wing Aircraft Aircraft with immovable wings that require a runway to take off and land or alternatively can be catapult launched. Nevertheless, fixed-wing configurations that require very short runways (STOL) or can take off vertically (VTOL) are also available.

Flight Termination System (FTS) A flight termination system ends the flight of a vehicle and consists of the entire system on an airborne vehicle used to receive, decode, and execute a flight termination command.

Range Safety Group, Range Commanders Council (2007)

Fragmentation The breakup of an in-flight vehicle into fragments (components of the vehicle, pieces of the structure, chunks of solid propellant, miscellaneous hardware, etc.) due to explosive loads, aerodynamic and inertial loads, activation of a flight termination system, intercept with another vehicle, or impact on a surface.

Range Safety Group, Range Commanders Council (2007)

General Aviation General aviation is a term used to describe all nonmilitary and non-airline flying, encompassing everything from recreational aircraft to experimental aircraft to privately owned and operated business jets.

Air Transport Association (ATA) (2008)

Hazard Any real or potential condition that can cause injury, illness, or death of personnel, or damage to or loss of equipment or property. Hazards can be further distinguished as initiating, contributory, and primary. Initiating hazards include events and conditions that start an adverse chain of events that can lead to an accident. Primary hazards are events that directly and immediately cause an accident. Finally contributory hazards are the hazards that are not initiating or primary, although in this term is defined equivalently with hazard.

Range Safety Group, Range Commanders Council (2007)

Federal Aviation Administration (2000)

Hazard Threshold The lowest level at which adverse outcomes are expected to appear.

Range Safety Group, Range Commanders Council (2007)

Hazardous Operation Those activities which, by their nature, expose personnel or property to dangers not normally experienced in day-to-day actions.

Range Safety Group, Range Commanders Council (2007)

Helicopter A helicopter refers to an aircraft that takes off and lands vertically; it is also known as a rotary-wing aircraft with the ability to hover, to fly in very low altitudes, to rotate in the air, and to move backwards and sideways. It is capable of performing nonaggressive or aggressive flights. A helicopter may have different configurations, with a main and a tail rotor (most common), with only a main rotor, with tandem configuration, with coaxial but opposite rotary rotors, as well as with one, two, or four rotors.

Individual Risk Individual risk is the risk that a person will suffer a consequence. Unless otherwise noted, individual risk is expressed as the probability that an individual will become a casualty due to all hazards from an operation at a specific location.

Range Safety Group, Range Commanders Council (2007)

Involuntary Activity No choice was made by the person affected which placed them in a position of increased risk, or the activity participated in or the item used was one that is generally done or used by more than 99 % of the population.

Range Safety Group, Range Commanders Council (2007)

Model Aircraft A small UAS used by hobbyists and flown within visual line of sight under direct control from the pilot, which can navigate the airspace and which

is manufactured or assembled and operated for the purposes of sport, recreation, and/or competition.

Small Unmanned Aircraft System Aviation Rulemaking Committee (2009)

Mishap See *Accident*.

Mission A flight test or operation. It may include multiple vehicles or all phases of the flight beginning with lift-off/launch.

Range Safety Group, Range Commanders Council (2007)

National Airspace System (NAS) The National Airspace System refers to the common network of U.S. airspace, air navigation facilities, equipment and services, and airports or landing areas.

Air Transport Association (ATA) (2008)

Outrage Factor The components of outrage regarding public perception of imposed risk. Such components may include the source of the risk, the transparency/clarity of the risk presentation by the responsible party, the familiarity of the public with the risk, and the level of the perceived risk.

Range Safety Group, Range Commanders Council (2007)

Risk An expression of consequences in terms of the probability of an event occurring, the severity of the event, and the exposure of personnel or resources to potential loss or harm.

United States Air Force (1998)

Risk Analysis A study of potential risk under a given set of conditions. Risk analysis is an activity that includes the complete array of tasks from data gathering, identification of hazards, estimation of associated risks, and verification of results.

Range Safety Group, Range Commanders Council (2007)

Risk Assessment The process of detecting hazards and their causes and systematically assessing the associated risks.

United States Air Force (1998)

Risk Control An action designed to reduce risk by lowering the probability of occurrence and/or decreasing the severity of an identified hazard.

United States Air Force (1998)

Risk Management See *Risk Control*.

Risk Profile A plot that shows the probability of an accident causing a given number of casualties (vertical axis) vs. the number of casualties (horizontal axis). The area under the plot is a measure of the casualty expectation.

Range Safety Group, Range Commanders Council (2007)

Safety Critical A term applied to any condition, event, operation, process, or item whose proper recognition, control, performance, or tolerance is essential to safe system operation and support.

U.S. Department of Defense (2000)

Sensitivity Analysis The computation of the effect of changes in input values or assumptions (including boundaries and model function form) on the outputs. The study of how uncertainty in a model output can be systematically apportioned to different sources of uncertainty in the model input.

Range Safety Group, Range Commanders Council (2007)

By investigating the “relative sensitivity” of model parameters, a user can become knowledgeable of the relative importance of parameters in the model.

Transponder A transponder is an electronic device that “responds” to interrogation by ground-based radar with a special four-digit code that air traffic control specifically assigns to the aircraft on which it is located. Certain transponders have the ability to transmit automatically the altitude of the aircraft in addition to the special code.

Air Transport Association (ATA) (2008)

Uncertainty The absence of perfectly detailed knowledge. Uncertainty includes incertitude (the exact value is unknown) and variability (the value is changing). Uncertainty may also include other forms such as vagueness, ambiguity, and fuzziness (in the sense of borderline cases).

Range Safety Group, Range Commanders Council (2007)

Visual Line of Sight Unaided (corrective lenses and/or sunglasses exempted) visual contact with aircraft sufficient to be able to maintain operational control of the aircraft, know its location, and be able to scan the airspace in which it is operating to decisively see and avoid other air traffic or objects.

Small Unmanned Aircraft System Aviation Rulemaking Committee (2009)

Visual Observer An sUAS flight crew member who assists the sUAS PIC in the duties associated with collision avoidance. This includes, but is not limited to, avoidance of other traffic, airborne objects, clouds, obstructions, and terrain.

Small Unmanned Aircraft System Aviation Rulemaking Committee (2009)

Voluntary Activity The person affected made a choice, which placed them in an increased position of risk compared to the rest of the population. This can be occupation-related (e.g., being a UAS crew member) or not (e.g., doing recreational paragliding).

Range Safety Group, Range Commanders Council (2007)

Waiver Granted use or acceptance of an article that does not meet the specified requirement,

Range Safety Group, Range Commanders Council (1999)

Worst-Case A semiquantitative term referring to the maximum possible exposure, dose, or risk that can conceivably occur, whether or not this exposure, dose, or risk actually occurs in a specific population.

Range Safety Group, Range Commanders Council (2007)

Abstract

Although there are many who believe that UAVs are a recent invention going back at most two or three decades, unmanned flight has a rich history that goes back all the way to ancient times. Of course, the first systems that can qualify with the modern definition of UAVs are quite recent and mainly involve the reconnaissance drones developed and deployed during the cold war. Today, UAV systems have evolved and expanded into widely different designs like quadrotors, ducted fan, and blimps in addition to the classic fixed-wing and helicopter approaches. They have also acquired new roles beyond reconnaissance and have also found applications beyond the military domain, for example, in weather monitoring or infrastructure inspection. This chapter provides a short overview of this history.

4.1 Introduction

This section presents a historical perspective on unmanned flight starting from the ancient times and reaching modern times. The purpose is not to provide a detailed historical account of manned or unmanned aviation, but an insight on how UAVs have evolved to be what they are today. The section is subdivided based on the different time periods. This division is not completely arbitrary, but it reflects the evolution of what an unmanned aircraft is, from the first ideas on flying machines in the ancient times up to the industrial revolution, to target drones and missiles, to airborne reconnaissance systems, and to the multirole systems of today.

4.2 Precursors of Flight and Unmanned Aircraft

In modern times, manned aviation appeared in the late 1700s, and it took another century for heavier than air machines to take to the skies. Unmanned aircraft followed soon after the advent of the airplane, appearing around the time of the First World War (1916). However, the idea of building “flying machines” was first conceived close to 2,500 years ago, in ancient Greece and China!

Pythagoras, Archimedes, and others studied the use of autonomous mechanisms for a variety of applications. The first known autonomous flying machine has been credited to Archytas from the city of Tarantas or Tarentum in South Italy, known as Archytas the Tarantine. Archytas has been referred to as Leonardo da Vinci of the Ancient World and was also the father of number one in number theory (Valavanis et al. 2007) and the solution for doubling the cube. He was also possibly the first engineer, designing and building various mechanisms. In 425 BC he built a mechanical bird, which he called “the pigeon,” shown in Fig. 4.1. According to Cornelius Gellius in his *Noctes Atticae*, the bird was made of wood, nicely balanced with weights, and flew using air (most likely steam) enclosed in its stomach (Gellius 1927). It is alleged that Archytas’ pigeon flew about 200 m before falling to the ground, once all energy was used. The pigeon could not fly again, unless the mechanism was reset (Guedj 1998).

During the same era in a different part of the Ancient World – China – at about 400 BC, the Chinese were the first to document the idea of a vertical flight aircraft. The earliest version of the Chinese top consisted of feathers at the end of a stick. The stick was spun between the hands to generate enough lift before released into free flight.

Over the years, the Chinese experimented with other types of flying machines such as hot air balloons, rockets, or kites. It is noteworthy that although some of these machines were used for entertainment, some of the applications were military in nature. In fact there are historical records of a “wooden hawk” that was used for reconnaissance around 450 BC, as well as a kite in the shape of a crow, which was employed during the Ming Dynasty to bomb enemy positions (Yinke 2005).

Fig. 4.1 An artist's depiction of the flying pigeon, the first documented UAV in history. It is reported that it flew for about 200 m

Several centuries later, Leonardo Da Vinci, in 1483, designed an aircraft capable of hovering, called aerial screw or air gyroscope, shown in Fig. 4.2. It had a 5 m diameter and the idea was to make the shaft turn, and if enough force were applied, the machine could spin and fly. This machine is considered by some experts as the ancestor of today's helicopter Hiller Aviation Museum (2004). Da Vinci also devised a mechanical bird in 1508 that would flap its wings by means of a double crank mechanism as it descended along a cable.

The first widely recognized manned flight took place in 1783 using a hot air balloon designed by the Montgolfier brothers and commemorated in Fig. 4.3. Soon after, similar attempts took place in England, and for several years ballooning dominated manned flights, until the first helicopters in the 1860s and later fixed-wing aircraft.

Many flying machines were designed between 1860 and 1909, initially focusing on vertical takeoff and landing aircraft because of the limitations of the steam-powered engines that were in use at the time. As the power to weight ratio of engines improved, these early machines were transformed to the helicopter and airplane designs that are in use today.

The main drive behind aircraft development has always been the fast and safe transportation of people and cargo. Nevertheless, the military soon realized the

Fig. 4.2 Leonardo Da Vinci's air screw, a forerunner of modern helicopter designs (Public domain photo)

potential benefits of unmanned aircraft and efforts to adapt flying machines to operate without a pilot onboard started. Such systems were initially unmanned ordinance delivery systems, what would now be referred to as “missiles” or “smart bombs.” Another use for such systems was to operate as “target drones” that assisted in the training of antiaircraft gun operators. Today UAVs have been defined as those systems that are designed to be recovered after each mission, and although they may carry weapons, the weapon is not by itself an integral component of the airframe (Newcome 2004). Nevertheless, in the early days of unmanned flight, these distinctions were not that important since the technological obstacles were the same and were even shared by manned aircraft as well.

4.3 1916–1944

In 1916, less than 15 years after the Wright brothers historical flight, the first modern unmanned aircraft was demonstrated. It was the Hewitt–Sperry Automatic Airplane, named after the two inventors that designed it. This aircraft could not have become a reality without the previous work of Sperry on gyroscopic devices that were needed to provide flight stabilization. Sperry managed to attract the interest of the U.S. Navy resulting in the development of the Curtiss–Sperry Aerial Torpedo, while at the same time the U.S. Army Air Force sponsored the Liberty Eagle Aerial Torpedo of Charles Kettering shown in Fig. 4.4 (Zaloga 2008). Due to technical problems and lack of accuracy, interest on “automatic” planes was lost, but the potential for use of remotely operated drones for target practice was soon realized.

In Britain, experiments with unmanned aircraft took place throughout the 1920s with the RAE 1921 Target. In 1933, the Royal Navy used the Queen Bee target drone (Fig. 4.5) for the first time (Newcome 2004). It was a modified version of the DeHavilland Tiger Moth biplane and was successfully employed for gunnery practice.

Fig. 4.3 The first manned flight using a hot air balloon took place in 1783 in France (Photo Credit: Bildarchiv Preussischer Kulturbesitz, Berlin)

Remote operation required the perfection of radio control, a concept proposed and demonstrated in 1895 and 1898, respectively, by Tesla (Newcome 2004). Yet again private industry spurred developments, when actor Reginald Denny opened his “Reginald Denny Hobby Shops” in 1934 and started selling radio-controlled airplanes. A few years later, he demonstrated his work for the U.S. Army that led to the development of a very successful target drone used extensively during WWII.

4.4 The Machines of the Cold War

Soon after the end of WWII, interest in reconnaissance missions increased. The descendants of Reginald Denny’s target drones became the basis of the first reconnaissance drone, the SD-1 (Newcome 2004). Also known as the MQM-57

Fig. 4.4 The USAF Liberty Eagle Aerial Torpedo, also known as the Kettering Bug after its creator Charles Kettering (Photo Credit: National Museum of the USAF)

Falconer, it was developed in the mid-1950s, and by the end of its career, close to 1,500 had been built (National Museum of the USAF 2009). The SD-1 (Fig. 4.6) was remotely operated, carried a camera, and after a 30 min flight returned to base and was recovered with parachute (Zaloga 2008).

The loss of the U-2 spy plane over the Soviet Union in 1960 gave a new push towards unmanned reconnaissance drones, and the loss of a second U-2 over Cuba 2 years later helped circumvent any doubts and funding problems (Zaloga 2008). The USAF supported the Ryan Model 147 drone that evolved into a series of models with different capabilities. Two variations of the more than two dozen available are shown in Figs. 4.7 and 4.8. They were also based on a drone design and were used for reconnaissance missions by the USA over China, Vietnam, and other countries in the 1960s and 1970s (Zaloga 2008; Newcome 2004). During this time, close to 3,500 Lightning Bugs were launched, and close to 84 % returned (Wagner 1982). It is noteworthy that these drones were credited with kills that occurred when fighters tried to shoot them down and one drone was given ace status after being responsible for the loss of five North Vietnamese MIGs (Zaloga 2008).

The Ryan Model 147, which became known as the Lightning Bug, was probably the first unmanned aircraft that can withstand today's definition of a UAV aircraft.

Fig. 4.6 The SD-1, also known as the MQM-57 Falconer, was the first reconnaissance drone of the US Army and remained in service until the 1970s (Photo Credit: National Museum of the USAF)

In fact, modernized versions of this drone are still being built and used to carry out missions to this day.

Meanwhile, the US Navy acquired a helicopter drone from the Gyrodine Company called the QH-50 DASH (Fig. 4.9) (Zaloga 2008). This design was preferred because it could be launched from smaller vessels. Its main mission was to launch antisubmarine torpedoes; nevertheless, it was also used for surveillance, cargo transport, and other applications. This was despite reliability issues with its electrical system that led to large number of peacetime losses (Zaloga 2008).

Fig. 4.7 The AQM-34Q, one of several variations of the Ryan Model 147 unmanned reconnaissance drone, used in the 1960s and 1970s (Photo Credit: National Museum of the USAF)

Fig. 4.8 The BGM-34C was another member of the Ryan Model 147 family. It was a multi-role drone capable of performing reconnaissance, electronic countermeasure and strike missions (Photo Credit: US Air Force)

In the late 1960s, the CIA was involved in its own hypersonic, long-range reconnaissance drone, designed to be launched from another “mother” aircraft. The D-21 Tagboard (Fig. 4.10) program was mired with technical problems, accidents, and failed missions that led to its ultimate cancellation in the early 1970s (Zaloga 2008).

Fig. 4.9 A QH-50 DASH-drone armed with torpedoes over the flight deck of the USS Hazelwood (Photo Credit: US Navy)

Fig. 4.10 The Lockheed D-21B Tagboard (Photo Credit: National Museum of the USAF)

Fig. 4.11 The DBR-1 also known as the Tupolev Tu-123 Yastreb (Photo Credit: Tupolev)

In parallel with US efforts, the Soviet Air Force developed its own reconnaissance drones. The first system was the TBR-1 based on a popular target drone, and it was soon followed by the DBR-1 (Fig. 4.11) that allowed for higher range and capabilities (Zaloga 2008). The DBR-1 was not designed to be fully recovered; instead when it reached the recovery area, it dumped fuel, ejected the nose containing the sensor package, and the rest of the airframe crashed. As a result, the DBR-1 involved high operational costs which led to its replacement in the mid-1970s by the Tu-141/143 (Fig. 4.12), a mid- and short-range, respectively, reconnaissance drones that were fitted with parachutes for recovery.

In Europe the unmanned system of choice of the time was funded by Canada and the UK and was developed by Canadair (Zaloga 2008). This resulted in the CL-89 Midge (Fig. 4.13) that was also acquired by the French and German armies. It was designed to follow a preprogrammed course, take photographs (day or night), and return to be recovered by parachute (Zaloga 2008). A more sophisticated version, the CL-289, that also featured better range was developed in the late 1970s with major funding coming now from Germany (Zaloga 2008).

Another major player in the area of unmanned aircraft was the Israeli Air Force that acquired and operated a squadron of American drones for reconnaissance purposes during the Yom Kippur War (Zaloga 2008). Later, the Israeli Aircraft Industries and Tadiran developed their own aircraft, the Scout (Fig. 4.14) and Mastiff, respectively (Zaloga 2008). The Mastiff was the basis of the very popular Pioneer system, and the Israeli designs have also influenced the construction of the Predator and Shadow UAV (Newcome 2004).

4.5 Modern Systems

Modern systems are much more diverse than their precursors. Although one can readily identify the heritage of the reconnaissance drones in the popular Pioneer (Fig. 4.15) of the 1980s or the French-built SPERWER (Fig. 4.16), we have moved towards larger, more capable, and higher endurance systems like the RQ-4 Global Hawk (Fig. 4.17). Systems that can take multiple roles are also available like the MQ-9 Reaper (Fig. 4.18), which besides reconnaissance can also be used as a hunter-killer, and the Neptune (Fig. 4.19) that is used for water operations.

Although some of the aforementioned UAVs like the MQ-9 Reaper can be armed, there is now an entire class of systems being developed with combat operations as their primary mission, known as Unmanned Combat Aircraft Systems (UCAS). Although many of these systems are still in experimental stages, there are several that are already operational. Examples of UCAS include the Neuron (Fig. 4.20), the Barracuda, the Italian Sky-X (Fig. 4.21), the MiG Skat, and the BAE Mantis.

Almost all of the aforementioned systems utilize a fixed-wing design. However, there is a number of helicopter UAVs available, several of which are currently operational in military and civil applications. Some examples of helicopter UAVs

Fig. 4.23 The MQ-8 Fire Scout is being developed by Northrop Grumman Corporation to support US Army and Navy requirements (Public domain photo)

Fig. 4.24 The Aerosonde Laima was the first UAV to make a transatlantic crossing (Newcome 2004) (Public domain photo)

Fig. 4.25 The Helios UAV developed by NASA and AeroVironment. During its second high-altitude flight, it reached 96,863 ft, shattering the existing world altitude record for sustained level flight for both propeller and jet-powered aircraft (Photo Credit: NASA)

include the A-160 Hummingbird (Fig. 4.22), the APID55, the Schiebel S-100, and the MQ-8 Fire Scout (Fig. 4.23).

In recent years there is an increasing interest for long-endurance UAVs that can fly for several days. The Aerosonde Laima (Fig. 4.24) is one such system and was the first to do the transatlantic crossing. The record though is held by the QinetiQ Zephyr which managed to remain airborne for a little over 2 weeks, taking into advantage its lightweight design and solar power. A large number of long-endurance systems are also used for civilian applications. For example, NASA employs the Helios, Altair, and Ikhana UAVs primarily for Earth science missions (Figs. 4.25 and 4.26).

Small UAVs have also garnered significant interest, especially since they are considered by many as entry points to the civilian market. Although their smaller sizes invariably leads to reduced payload capacities, a large number of small and miniature UAVs are in operation or active development. This is because they are versatile, portable, and easy to maintain; they can be employed for the same applications as larger UAVs on a smaller scale and at a lower cost. In fact several of these systems are considered expendable, and no recovery is attempted especially if there is any risk perceived (Fig. 4.26).

Examples of small UAVs include the Skylark, the Evolution, the Puma, and the Aerocon Inspector. In the miniature category, there exist systems that weigh less than 1–3 kg and are easily backpackable (some are even foldable). Such systems include the Cyberbug, Raven (Fig. 4.27), WASP (Fig. 4.28), BATCAM, Nighthawk (Fig. 4.29), and the Dragon Eye.

Fig. 4.26 The Ikhana is a Predator B UAV acquired by NASA and retrofitted for Earth science missions (Photo Credit: NASA)

Fig. 4.27 The Raven is a backpackable UAV for “over the hill” and route reconnaissance that evolved from the Pointer UAV. In the photo paratroopers are training with an RQ-11 Raven (Photo Credit: US Army, Sgt. Amanda Jackson)

Another UAV design concerns the lighter-than-air systems or airships, a distinct UAV category with significantly higher endurance than other systems that makes them ideal for a variety of operations. The main advantage of such systems is that they provide an airborne sensor platform that can be used for persistent area surveillance. Such systems include the Joint Land Attack Elevated Netted Sensor (Fig. 4.30), the Persistent Threat Detection System (Fig. 4.31), and the Rapid Aerostat Initial Deployment system (Fig. 4.32). The High-Altitude Airship (Fig. 4.33) is an untethered platform concept that will be able of providing satellite-like services to ground forces.

Fig. 4.28 The WASP is a MAV that can carry an EO payload and has an endurance of over 1 h (Photo Credit: NIST)

Fig. 4.29 The Nighthawk is the evolution of the BATCAM foldable UAV (Photo Credit: NIST)

In addition to the popular fixed-wing and helicopter systems, other designs are also used for UAVs (Figs. 4.34 and 4.35). These include duct-fan design (e.g., the iStar MAV, the Sikorsky Cypher, and the SELEX Galileo Spyball), counterrotating rotors (e.g., the IT-180 and the KOAX X-240), as well as mixed designs like the Eagle Eye (Fig. 4.36) and X-50 (Fig. 4.37) that combine some of the advantages of fixed-wing and helicopter designs. Finally, the CyberQuad and the AirRobot AR 100-B (Fig. 4.38) are both examples of the quad-rotor design that is especially popular in academic environments.

Abstract

Different UAV classification schemes have been proposed to help differentiate existing systems based on their operational characteristics and their capabilities. Several of these schemes are also of regulatory importance since the metrics used directly correlate with risk from ground impact or midair collision accidents. This chapter provides characteristic UAV classifications from a variety of sources, both civilian and military.

5.1 Introduction

This section aims to present different UAV classification schemes that have been proposed and/or are currently in use. UAV classification is not only used to help differentiate existing systems but has regulatory importance. This is because it is unlikely that rules will be developed that can fit all UAVs and as a result different requirements may be imposed on different UAV categories based on their

K. Dalamagkidis
Institut für Informatik I6, Technische Universität München, Garching bei München, Germany
e-mail: dalamagkidis@tum.de

characteristics. This is also true in manned aviation where, for example, AC 23.1309 already divides FAR Part 23 aircraft into four classes based on MTOW and engine type with different target levels of safety for each one.

There is a large number of metrics that have been used for UAV classification, including mean takeoff weight (MTOW), size, operating conditions, capabilities, or any combination of these and other characteristics. It should be noted that while some of these metrics have minimal effect on the safety performance requirements of the system, they are still important from an operational, commercial, legal, and possibly other points of view. Rather than an exhaustive list which would be of little value, this section presents characteristic examples of different types of classifications from the literature.

A comprehensive classification of UAV demonstrating both the wide variety of UAV systems and capabilities as well as the multiple dimensions of differentiation is presented in Table 5.1.

5.1.1 Classification Based on MTOW and Ground Impact Risk

MTOW is a good metric to classify aircraft for regulatory purposes since it correlates well with the expected kinetic energy imparted at impact, which in turn is considered to be the primary factor affecting safety of operations, as discussed in Weibel and Hansman (2004), Range Safety Group, Range Commanders Council (2007, 1999), Haddon and Whittaker (2002), Joint JAA/Eurocontrol Initiative on UAVs (2004), European Aviation Safety Agency (EASA) (2005), and Dalamagkidis et al. (2012). Of course the broad categories defined in AC 23.1309, do not cover the full spectrum of UAVs that extends down to just a few grams.

In Dalamagkidis et al. (2012), a model was used to estimate the expected number of fatalities after a ground impact. The model was based on the kinetic energy, which was in turn estimated from the MTOW of the UAV. Based on a requirement to maintain an expected number of fatalities of less than 10^{-7} h^{-1} , the classification presented in Table 5.2 was derived. It should be noted that the reliability targets in Table 5.2 were derived based on certain assumptions like a standard population density of 200 ppl/km². For operation over metropolitan areas, this number can be significantly higher and even prohibitive for large systems. On the other hand, the Micro and Mini class UAV, as defined in Table 5.2, are so light that it is almost impossible for a fatality or serious injury to occur after a ground impact. They are also unlikely to cause problems to other aviation, provided that they operate with sufficient clearance from airports, due to their typically low operating altitudes.

A similar classification, but directly based on the kinetic energy, is shown in Table 5.3. In this case the proposed classification scheme directly correlates each UAV class with certification requirements for the aircraft, its pilot, and its operator.

Another simple classification scheme based on MTOW is presented in Table 5.4. This scheme also shows the expected range and maximum operating altitude of the UAVs of each class which are also a function of MTOW.

Table 5.1 UAV categorization for differentiation of existing systems (Source: van Blyenburgh (2006))

| | Mass (kg) | Range (km) | Flight alt. (m) | Endurance (h) |
|---------------------------------------|----------------------------|------------|-----------------|---------------|
| Micro | <5 | <10 | 250 | 1 |
| Mini | <20/25/30/150 ^a | <10 | 150/250/300 | <2 |
| Tactical | | | | |
| Close range (CR) | 25–150 | 10–30 | 3,000 | 2–4 |
| Short range (SR) | 50–250 | 30–70 | 3,000 | 3–6 |
| Medium range (MR) | 150–500 | 70–200 | 5,000 | 6–10 |
| MR endurance (MRE) | 500–1,500 | >500 | 8,000 | 10–18 |
| Low altitude deep penetration (LADP) | 250–2,500 | >250 | 50–9,000 | 0.5–1 |
| Low altitude long endurance (LALE) | 15–25 | >500 | 3,000 | >24 |
| Medium altitude long endurance (MALE) | 1,000–1,500 | >500 | 3,000 | 24–48 |
| Strategic | | | | |
| High altitude long endurance (HALE) | 2,500–5,000 | >2,000 | 20,000 | 24–48 |
| Stratospheric (Strato) | >2,500 | >2,000 | >20,000 | >48 |
| Exo-stratospheric (EXO) | TBD | TBD | >30,500 | TBD |
| Special task | | | | |
| Unmanned combat AV (UCAV) | >1,000 | 1,500 | 12,000 | 2 |
| Lethal (LET) | TBD | 300 | 4,000 | 3–4 |
| Decoys (DEC) | 150–250 | 0–500 | 50–5,000 | <4 |

^aVaries with national legal restrictions

5.1.2 Classification Based on Operational Altitude and Midair Collision Risk

Although MTOW provides a good basis to classify aircraft based on the risk they present to people and property after a ground impact, UAV classes based on altitude may also be of interest since they will dictate to a degree collision avoidance requirements (see Zeitlin 2009). A simple classification was proposed in Dalamagkidis et al. (2012) and is outlined below and presented in Table 5.5:

1. *Very low altitude (VLA/LOS)* operating in Class G airspace and typically in altitudes less than 400–500 ft with the operator always in visual contact with the aircraft
2. *Very low altitude (VLA/BLOS)* as above but with the possibility that the aircraft is flown beyond the line of sight of the operator

Table 5.2 Proposed UAV classification based on MTOW and ground impact risk. T_{GI} is the minimum time between ground impact accidents (Source: Dalamagkidis et al. (2012))

| Category | | | | |
|----------|----------|----------------|------------------|--|
| Number | T_{GI} | MTOW | Name | Notes |
| 0 | 10^2 | Less than 1 kg | Micro | Most countries donot regulate this category since these vehicles pose minimal threat to human life or property |
| 1 | 10^3 | Up to 1 kg | Mini | These two categories roughly correspond to R/C model aircraft |
| 2 | 10^4 | Up to 13.5 kg | Small | |
| 3 | 10^5 | Up to 242 kg | Light/ultralight | Airworthiness certification for this category may be based either on ultralights (FAR Part 103), LSA (Order 8130), or even normal aircraft (FAR Part 23) |
| 4 | 10^6 | Up to 4,332 kg | Normal | Based on MTOW these vehicles correspond to normal aircraft (FAR Part 23) |
| 5 | 10^7 | Over 4,332 kg | Large | These vehicles best correspond to the transport category (FAR Part 25) |

Table 5.3 Proposed classification of UAVs based on MTOW by the CAA of New Zealand (Source: Civil Aviation Authority of New Zealand (2007))

| Class | Maximum energy | UAV | Requirements | |
|-------|----------------|---|------------------------------|--|
| | | | Operator | UAV pilot |
| 1 | Up to 10 kJ | No certification requirement | Regulated by UAV association | Must have pilot license when flying beyond line of sight or in controlled airspace |
| 2 | Up to 1 MJ | Flight permit required | Certificated by CAA | Pilot license, type rating and in some cases instrument rating |
| 3 | Over 1 MJ | Type and airworthiness certificates, maintenance release and continuing airworthiness | Certificated by CAA | Pilot license, type rating and in some cases instrument rating |

3. *Medium altitude (MA)* operating in Class A through E airspace

4. *Very high altitude (VHA)* operating in Class E airspace above FL600

Another proposed classification that can be considered to be indirectly correlated with the midair collision risk is presented in Table 5.6. This classification uses the maximum deviation from the commanded flight path and its duration as the key

Table 5.4 Classification of UAVs based on MTOW (Source: Industrianlagen-Betriebsgesellschaft mbH (2001))

| Class | MTOW (kg) | Range category | Typical max altitude (ft) |
|-------|-----------|----------------|---------------------------|
| 0 | ≤25 | Close range | 1,000 ft |
| 1 | 25–500 | Short range | 15,000 ft |
| 2 | 501–2,000 | Medium range | 30,000 ft |
| 3 | >2,000 | Long range | Above 30,000 ft |

Table 5.5 Proposed classification based on class of airspace used

| Class | Airspace class | S&A | Transponder | 2-way ATC communication |
|----------|----------------|-----------------------|-----------------------|---------------------------|
| VLA/LOS | Class G | Not required | Not required | Not required ^a |
| VLA/BLOS | Class G | Required ^b | Required ^b | Not required ^a |
| MA | Class A–E | Required | Required | Required |
| MA/A | Class A | Required ^b | Required | Required |
| VHA | Above FL600 | Required ^b | Required | Required ^b |

^aCommunication with ATC before operation may still be required^bMay be waived for certain types of operations or under certain conditions**Table 5.6** Source: Industrianlagen-Betriebsgesellschaft mbH (2001)

| Category | Grade of deviation from planned/required flight path | Explanation/definition |
|----------|--|--|
| I | No deviations | |
| II | Minor deviations | Deviations in altitude of not more than 100 ft. Lateral deviations of not more than a nautical mile. UAV is able to correct deviation within 10 s. |
| III | Remarkable/considerable deviations | Deviations in altitude of not more than 500 ft. Lateral deviations of not more than one nautical mile. UAV is able to correct deviation within 30 s. |
| IV | Extreme deviations | Deviations in altitude of more than 500 ft. Lateral deviations of more than one nautical mile. UAV is not able to correct deviation within 30 s. |

differentiation parameters. Of course, the different categories presented can also impose different requirements on pilot certification, onboard control systems, etc.

5.1.3 Classification Based on Autonomy

Another way to categorize UAVs that is also of interest for certification purposes is based on their level of autonomy. Already UAVs are exhibiting autonomy in certain functions, and this trend is expected to increase, especially if one pilot is to control

Table 5.7 Autonomous control levels
(Source: Clough (2002a))

| ACL | Level descriptor |
|-----|--|
| 0 | Remotely piloted vehicle |
| 1 | Execute preplanned mission |
| 2 | Changeable mission |
| 3 | Robust response to real-time faults/events |
| 4 | Fault/event adaptive vehicle |
| 5 | Real-time multi-vehicle coordination |
| 6 | Real-time multi-vehicle cooperation |
| 7 | Battlespace knowledge |
| 8 | Battlespace cognizance |
| 9 | Battlespace swarm cognizance |
| 10 | Fully autonomous |

more than one aircraft at the same time, a possibility discussed in Protti and Barzan (2007). In 2005 the autonomous control levels (ACL) were proposed to measure autonomy. More specifically, ten (10) such levels were proposed in Clough (2002a) that were based on requirements like situational awareness, analysis, coordination, decision making, and operational capability. A list of the ACL is presented in Table 5.7.

Each ACL is based on three aspects characterizing autonomy, namely, the level of independence from human involvement, the complexity of the mission, and the complexity of the environment (Huang 2007). Of course, some of the distinctions between the ACL defined in Table 5.7 may not be of value for regulatory purposes, and some of them are not applicable for civil UAV. A simpler classification that takes into account only the level of human involvement and is compatible with the four operational modes proposed in Federal Agencies Ad Hoc Autonomy Levels for Unmanned Systems (ALFUS) Working Group (WG) (2004) is provided below:

- Remotely piloted: A certified pilot remotely controls the system either within LOS or with feedback from the UA sensors.
- Remotely operated (semiautonomous): The UA is given high-level commands (waypoints, objects to track, etc.), and its performance is monitored by a trained operator. In this case the flying is performed by the UA itself, but all the decision making is delegated to a human.
- Fully autonomous: The UA is given general tasks and is capable of determining how to accomplish them, even at the face of unforeseen events. It can also monitor its health and take remedial action after the occurrence of faults.

It should be noted that as autonomy increases, new regulatory issues will arise. For example, Clough (2002b) and Protti and Barzan (2007) mention that highly autonomous systems may exhibit non-deterministic behavior, something that will be likely prohibited based on current regulatory approaches. It is also evident that issues of liability for highly autonomous systems may also pose questions that will need to be addressed.

Table 5.8 NATO UAV classification guide from the Sep. 2009 JCGUAV meeting (Source: The Joint Air Force Competence Centre (2010))

| Class | Category | Normal operating altitude | Normal mission radius | Example platforms |
|----------------------------|---------------|---------------------------|-----------------------|---|
| Class I (less than 150 kg) | Small >20 kg | Up to 5,000 ft AGL | 50 km (LOS) | Luna, Hermes 90 |
| | Mini 2–20 kg | Up to 3,000 ft AGL | 25 km (LOS) | Scan Eagle, Skylark, Raven, DH3, Aladin, Strix |
| | Micro <2 kg | Up to 200 ft AGL | 5 km (LOS) | Black Widow |
| Class II (150–600 kg) | Tactical | Up to 10,000 ft AGL | 200 km (LOS) | Sperwer, Iview 250, Hermes 450, Aerostar, Ranger |
| Class III (>600 kg) | Strike combat | Up to 65,000 ft AGL | Unlimited (BLOS) | |
| | HALE | Up to 65,000 ft AGL | Unlimited (BLOS) | Global Hawk |
| | MALE | Up to 45,000 ft AGL | Unlimited (BLOS) | Predator B, Predator A, Heron, Heron TP, Hermes 900 |

5.1.4 Military Classifications

There are several military UAV classifications in use. The NATO JCGUAV presented in September of 2009 a classification guide based on MTOW; see Table 5.8. All UAVs are divided into three classes: Class I for those weighing less than 150 kg, Class II for those in the range 150–600 kg, and Class III for those over 600 kg. More information can be found in The Joint Air Force Competence Centre (2010). Class I is subdivided into small (20–150 kg), mini (2–20 kg), and micro. Class III is also subdivided but based on the operational role of the UAV.

The JUAV CoE has defined its own categories that depend on the operational characteristics and other UAV attributes. These categories include tactical, operational, and strategic UAV that have different scope and operate under different commands (U.S. Department of Defense, Office of the Secretary of Defense 2007). Also defined are six levels of domestic use as shown in Table 5.9. A different categorization based on airworthiness requirements is shown in Table 5.10. For all categories, airworthiness and operator qualifications will need to be demonstrated. In addition to that, Cat I aircraft is limited to LOS operations.

Table 5.9 Domestic use UAV levels and corresponding system attributes as defined by the JUAV CoE (Source: U.S. Department of Defense, Office of the Secretary of Defense (2007))

| Level | Airspeed (KIAS) | Weight (kg) | Operating altitude (ft) |
|-------|-----------------|-------------|-------------------------|
| 0 | ≤250 | ≤0.9 | ≤1,200 |
| 1 | ≤250 | 0.9–9 | ≤3,000 |
| 2 | ≤250 | 10–594 | ≤18,000 |
| 3 | ≤250 | 595–5,625 | ≤18,000 |
| 4 | ≥250 | ≤5,625 | ≤18,000 |
| 5 | Any | ≥5,625 | ≥18,000 |

Table 5.10 Military UAV categories and relevant UAV regulations (Source: U.S. Department of Defense, Office of the Secretary of Defense (2007))

| Category | FAA regulation | Airspace usage | Airspeed limit (KIAS) |
|-------------------------------|----------------------------|--------------------------------|-----------------------|
| Cat I – R/C model aircraft | None (AC 91-57) | Class G | 100 ^a |
| Cat II – Nonstandard aircraft | FAR Parts 91, 101, and 103 | Class E,G, and non-joint-use D | 250 ^a |
| Cat III – Certified aircraft | FAR Part 91 | All | None |

^aProposed

5.1.5 Classification Based on Ownership

Finally UAVs – like other aircrafts – can be categorized based on their ownership as *public* or *state* when they are owned and operated by public entities like federal agencies or local law enforcement and *civil* when they are owned by industry or private parties; see Hempe (2006).

Abstract

This chapter is based on information retrieved from the included references at the end of the chapter. It gives a brief overview of the global unmanned aircraft market, followed by a review of the military and civilian unmanned systems sectors. It aims at registering the current state of the art in the unmanned aviation arena projecting what lies ahead.

6.1 Introduction

The unmanned aircraft arena has seen unprecedented levels of growth over the past 20 years with military applications dominating the field. However, the 2013 year was the critical and the turning point year for using unmanned aircraft in civilian and public domain applications for the following three important reasons:

- On 20 June 2013, the European Remotely Piloted Aircraft Systems (RPAS) Steering Group, ERSR, which was set up by the European Commission in July 2012 and was composed by a group of stakeholders of the main organizations and experts interested in the integration of RPAS into the European aviation system, handed over to the European Commission the “*Roadmap for the Integration of Civil Remotely Piloted Aircraft Systems into the European Aviation System*.” This was the result of the mandate received by the ERSR to establish a roadmap for the safe integration of civil RPAS into the European aviation system, aiming at an initial RPAS integration by 2016. This roadmap aims at facilitating decisions taken by the involved organizations, providing transparency and efficiency in planning different initiatives, and supporting the coordination of related activities in Europe.
- On 7 November 2013, the U.S. Federal Aviation Administration (FAA) presented the “*Roadmap for Integration of Civil Unmanned Aircraft Systems (UAS) in the National Airspace System (NAS)*,” which was the result of the joint effort between the FAA and the UAS Aviation Rulemaking Committee (ARC). The purpose of this roadmap is to outline the tasks and considerations that need to be completed in order to enable UAS integration into the NAS. This roadmap is the aftermath of, and in accordance with, the Congressional mandate in the *FAA Modernization and Reform Act of 2012*, Pub. L. 112-95. It is expected that this roadmap will be updated accordingly in subsequent publications, incorporating lessons learned and findings and also revising target dates toward efficient integration of UAS into the NAS.
- On 30 December 2013, the FAA announced the selection of six UAS research and test site operators across the USA that are tasked to study a broad range of issues and challenges related to unmanned aircraft. The six test sites can operate until 13 February 2017, with Congress expected to consider extending the test sites beyond that date. This announcement was followed by the statement that “The FAA is committed to the safe and efficient integration of UAS into the NAS, thus enabling this emerging technology to safely achieve its full potential.”

Further, the International Civil Aviation Organization (ICAO), which is a special agency of the United Nations (UN), has long been committed to “the safe and orderly development of international civil aviation throughout the world,” being the organization that also sets standards and regulations necessary for aviation safety, security, efficiency, and regularity, as well as aviation environmental protection.

The above actions from the ERSR and the FAA along with the backing of ICAO have cautiously opened the door to utilizing unmanned aircraft in civilian and public domain applications. A “domino effect” is expected to accelerate research

and development; increase funding; create new jobs; generate provable novel and cutting-edge technologies for increased safety and security of unmanned aircraft; contribute to developing functional and operational “standards” for unmanned aviation; enforce closer collaboration and coordination among national and international interested parties; bring closer academia, government, industry, and the private sector; and engage interested parties to discussing and eventually resolving ethical, legal, and privacy issues, to say the least and name but a few opportunities.

It has been estimated that the international UAV market will be worth up to \$80 billion by 2020. The USA is the world’s largest operator of unmanned aircraft and the front runner in producing and using technology in military services since the 1950s, also expected to continue to represent the biggest market as a result of requirements, spending on the systems, and research and development funding into the technology. The USA was the highest spender on UAVs in 2009 with the North American region (including Canada) spending \$2.7 billion. The results from the continued deployment of UAS in Afghanistan and the surrounding area as well as Iraq have also contributed to their increased use and procurement. The U.S. Department of Defense spent more than \$17 billion up to 2013 for new UAV systems and technology with \$5.0 billion on UAV research and development. The international market for UAVs/UAS has also grown in recent years with other countries worldwide, recognizing the capabilities and widespread utility of unmanned systems and investing heavily in these new technologies. It is anticipated that, as a result of the previous announcements, spending and investment will increase and the market numbers will shortly be revised.

Before continuing with a review of the military and civilian use of unmanned aircraft, and since several terms are used to describe such systems, a brief explanation is provided to clarify the context in which such names are used.

The terms UAVs and UAS have distinct definitions and it should be clear why, at first, UAVs became UAS: A UAV refers to a pilotless aircraft, a flying machine without an onboard human pilot or passengers. As such, “unmanned” implies total absence of a human who directs and actively pilots the aircraft. Control functions for unmanned aircraft may be either onboard or offboard (remote control). The term UAS was introduced by the U.S. Department of Defense, followed by the FAA and the European Aviation Safety Agency (EASA). This term was meant to signify that UAS are aircraft and as such airworthiness will need to be demonstrated and they are also systems consisting of ground control stations, communication links, and launch and retrieval systems in addition to the aircraft itself. Similar distinctions are true for RPA versus RPAS. Other names include remotely piloted vehicles (RPVs), a term that was used in the Vietnam War, while the U.S. military also calls them RPA a term used to include both the aircraft and the pilot, while the UK and ICAO have designated them as RPAS, to demonstrate the presence of the man in the loop to control them. The ICAO recommended definition for RPAS is “A set of configurable elements consisting of a remotely-piloted aircraft, its associated remote pilot station(s), the required command and control links and any other system elements as may be required, at any point during flight operation.”

6.2 Military Unmanned Systems

There exist many different types of unmanned aircraft depending on size, payload, and endurance. There is increased interest for Mini UAVs (MUAVs) and Micro Air Vehicles (MAVs) mostly used for short-range close reconnaissance tasks (mostly by Special Forces) and in urban environments, usually operated at company or battalion level. Lightweight MUAVs/MAVs are basically launched by hand or by a bungee catapult. MUAVs/MAVs can usually be disassembled and be carried in a backpack. Power is mostly provided by lithium polymer, lithium sulfide, or zinc-air batteries, with range typically being no more than 20 km and endurance of up to 2 h. Application wise, the MUAV/MAV and the ground control station (GCS) usually have line-of-sight (LOS) air-to-ground radio relay or microwave links due to the short-range limitation. Although MUAVs/MAVs have extensively been used by the military deployed in Iraq and Afghanistan, they are also suitable for civilian use being relatively inexpensive to purchase and operate. As such, using swarms or multiple MAVs is projected to be a key area in future UAV development that will enable more effective intelligence, surveillance, and reconnaissance (ISR) due to the increased availability of multiple sensors during a mission.

Larger UAVs/UAS operated in Afghanistan and Iraq have demonstrated their usefulness in Counter-Improvised Explosive Device (C-IED) tasks. Vertical Take-Off and Landing UAVs (VTOL UAVs) are particularly seen as suitable for C-IED with the air vehicle capable of hovering at a distance to find and locate Improvised Explosive Devices (IEDs). VTOL UAVs are additionally seen as useful in urban environments, for maritime ISR tasks from naval vessels, and in areas where normal fixed-wing UAV operations might be difficult due to terrain, threats, or insufficient support personnel deployed at forward bases to recover the UAV. Militaries have largely procured Tactical UAVs (TUAVs) to provide ISR support to ground forces with ranges typically up to 250 km and an endurance of up to 15 h. TUAVs either are catapult launched or have automatic takeoff and landing (ATOL) capabilities. The USA also uses and refers to a class of UAV systems smaller than the TUAV but larger than the MUAV as the small UAS (SUAS or sUAS).

Medium-altitude long-endurance (MALE) and high-altitude long-endurance (HALE) unmanned aircraft offer low-cost alternatives to manned aircraft for strategic reconnaissance tasks, with some having an armed capability to undertake close air support (CAS). GCS operators use beyond-line-of-sight (BLOS) satellite data links, typically Ku-band, to control and receive data from these MALE/HALE UAVs and C-band LOS data links for shorter-range missions, takeoff, and landings. MALE/HALE UAVs provide persistent ISR at long ranges being equipped with electro-optical/infrared (EO/IR) sensors and ground surveillance radar systems without the limitations of manned aircraft, particularly the physiological effect on aircrew flying long endurance missions. Combined solar/electric or hydrogen-powered HALE UAVs could have an endurance of months or years. Some unmanned HALE platforms like solar-powered stratosphere UAVs and lighter-than-air (LTA) airships are likely to be more cost-effective alternatives to manned weather aircraft, satellites, and other space-based platforms. LTA platforms are particularly cheaper

alternatives to conventional MALE/HALE UAVs. The average LTA airship unit cost is estimated to be \$3.0 million with flying operating costs about \$50 per hour, compared to up to \$10,700 for the MQ-9 Reaper or the Heron 1 UAV that includes the costs of fuel, maintenance, and deployment of personnel.

Unmanned combat aerial vehicles (UCAVs) are expected to replace and complement manned strike aircraft in the future, providing an intelligence, surveillance, target acquisition, and reconnaissance (ISTAR), Suppression of Enemy Air Defenses (SEAD), and deep penetration strike in environments where there is a high threat from enemy air defenses. However, at this stage, technologies have not matured to the point to enable UCAVs to replace manned air superiority fighter aircraft. Very low-observable (VLO) or low-observable (LO) stealth characteristics must be incorporated into the UCAV's airframe to reduce its radar cross section (RCS), infrared (IR) signature, and radio frequency (RF). Weapons and sensors are carried internally to further reduce the UCAV's RCS. In comparison to their manned aircraft equivalents, UCAVs promise to be much cheaper to develop and procure, although support costs might be high to maintain airframe coatings and materials that give the aircraft its stealth capabilities.

A potential future UAV application is for delivering cargo and supplies to frontline troops or in a humanitarian aid operation, as well as for casualty or medical evacuation in areas considered too risky to operate manned land vehicles or helicopters. The USA and Israel are currently investigating UAV technologies in these roles, which may as well transfer to the civilian domains.

Another type of military UAV is the so-called attack UAV. This type of UAVs is fitted with a high-explosive warhead that is flown by a GCS operator and then loiters over a target area using their onboard sensors to identify and then attack a target. The main attack UAV is the Harop manufactured by Israel Aerospace Industries (IAI). The delta-wing Harop carries a 23 kg warhead. The European missile company MBDA has also developed an attack MAV designated the Tactical Grenade Extended Range (Tiger) that carries a warhead less than 0.5 kg.

The U.S. Army has experienced a significant rise in the use of UAVs with nearly 4,000 air vehicles now in service compared to 54 a decade ago. The U.S. Army's Aviation Center at Fort Rucker, Alabama, is now home to the U.S. Army Unmanned Aircraft Systems Center of Excellence (UAS CoE), which is tasked with integrating and coordinating Army UAV use as well as defining current and future UAV concepts for the service. The "U.S. Army Roadmap for UAS 2010–2035," published by UAS CoE in April 2010, defines the service's long-term UAV procurement plans and how these will be integrated and operated. At battalion level, the U.S. Army operates the RQ-11B Raven MUAV manufactured by AeroVironment located at Monrovia in California.

The electrically powered 1.9 kg Raven entered U.S. Army service in 2006. It has a length of 0.9 m and a 1.37 m wingspan. The Raven can carry a 0.18 kg payload comprising a 5× zoom EO camera and IR camera equipped with a laser rangefinder that can designate targets at a range of 25 km. It has a maximum speed of 83 km/h, a range of up to 10 km, and an endurance of 90 min. U.S. Army Raven training is undertaken by the 2nd Battalion, 29th Infantry Regiment, and 197th Infantry Training

Brigade at Fort Benning in Georgia. Preliminary UAV training is undertaken at the UAS Training Battalion (UASTB) at Fort Huachuca, Arizona. The Raven is also operated by the Netherlands, Italy, and Spain, and it has also been leased in the past by the UK. The U.S. Army has spent some \$232 million on R&T and the procurement of the Raven, totaling more than 2,000 air vehicles with a total requirement for 3,000. About \$37.6 million was spent on 312 air vehicles in 2011 with orders to continue through to 2014. The Raven is also in service with the U.S. Marine Corps (USMC) with more than 1,020 acquired since 2008 at a cost of about \$71 million, with 16 more air vehicles procured in 2011 at a cost of \$32.5 million. The U.S. Army's SUAS Product Improvement Program (SUAS PIP) plans upgrades to the existing Raven UAS, such as new modular sensor suites for enhanced C-IED and CBRN tasks, an increased range of 15 km, and interoperability with unmanned ground vehicles (UGVs) and unmanned ground systems (UGS).

After canceling the Future Combat Systems (FCS) program and the acquisition of further MUAVs/MAVs, the US Army now focuses its efforts on acquiring systems like the AeroVironment Wasp and the larger Puma AE (All Environment) as well as the gMAV (Gasoline Micro Air Vehicle) VTOL MAV. Nano-UAVs and other MAVs are also planned with the U.S. Army previously testing in 2004 the 0.8 lb Tactical Mini UAV (Tacmav) manufactured by Applied Research Associates (ARA). The Tacmav is now marketed by ARA as the Nighthawk. The electric-powered 0.43 kg Wasp has a 0.72 m wingspan, an endurance of 45 min, and a 5 km range. It was developed by AeroVironment with the Defense Advanced Research Projects Agency (DARPA) with more than 200 air vehicles acquired by the USAF Special Operations Command (AFSOC) as part of its Battlefield Air Targeting Micro Air Vehicle (BATMAV) program in 2006. Full rate production of an unspecified number of Wasp IIIs was approved by AFSOC in 2008. The USMC also ordered the MAV in 2007 at a cost of \$19.3 million being assigned to units at platoon level. The Puma AE is a hand-launched electric 5.9 kg MUAV with a wingspan of 2.8 m. It has an endurance of 2 h and a range of 15 km. It shares a GCS with the Raven and the Wasp. It was selected by U.S. Special Operations Command (USSOCOM) in 2008 to meet its \$35 million All Environment Capable Variant (AECV) requirement for a cost-effective shipborne UAV. It entered service in 2009 replacing an earlier version of the Puma. The gMAV is manufactured by Honeywell Defense & Space at Albuquerque, New Mexico, as the T-Hawk (Tarantula-Hawk) and is largely used for C-IED tasks with the US Army and joint EOD units. It is designed to operate in urban environments, and 90 systems (180 air vehicles) have been acquired by the U.S. Navy. The 11 kg ducted fan gMAV is 0.38 m in length and has a 0.33 m diameter. It can carry a 0.9 kg payload of interchangeable gimballed EO or IR sensors as well as avionics and RF radio pods. The gMAV is powered by a 4.4 hp (3 kW) heavy fuel boxer twin engine, providing a maximum speed of about 74 km/h and the ability to fly in a 37 km/h wind. It has an endurance of 50 min, a range of 10 km, and a maximum service ceiling of 10,000 ft. About 83 gMAV Block I have been delivered since 2007 with plans for up to 166 to be acquired. Block II/III featuring a gimballed sensor payload has since been fielded by units in Afghanistan with the type due to equip Infantry Brigade Combat Teams (IBCT) from 2011. A larger 18 kg

version powered by a heavy fuel engine has also been developed for the U.S. Army's Brigade Combat Team Modernization (BCTM) Increment two program with first flight in 2012. The U.S. Army operates at brigade level the AAI RQ-7B Shadow 200 TUAV, which was delivered in 2004–2008. Some \$350 million has been spent on the acquisition of the Shadow for the U.S. Army since 2007. The 208 kg Shadow 200 features a twin-boom and inverted V-tail. It is 3.6 m in length with a height of 1.0 m and a wingspan of 6.2 m if equipped with an enhancement kit. It can carry a payload of up to 36 kg that includes a 35 lb IAI Tamam Plug-in Optronic Payload (POP) POP-300 IR/EO sensor with laser pointer/rangefinder that is capable of detecting targets up to 10 km. The Shadow is powered by a single 38 hp (28 kW) UEL AR741 Wankel engine that provides a maximum speed of 203 km/h or a cruise speed of 166 km/h. Range is 110 km with an endurance of up to 9 h and maximum altitude of 15,000 ft. The Shadow has a Tactical Automatic Landing System (TALS) or can be launched from a hydraulic catapult launcher. The complete Shadow UAS comprises four air vehicles, two GCS and ground data terminals, one portable GCS, and four RVTs. Three air vehicles are transportable by an air vehicle transporter (AVT). The fourth is used as a spare. Some 48 Shadow UAVs were ordered in 2007 by the USMC to replace the RQ-2 Pioneer with deliveries being completed in 2009. In January 2010, AAI was awarded a \$39 million contract for the supply of two air vehicles for the U.S. Army and one for the USMC with deliveries in March 2011.

Growing military UAV use has mostly been driven by the USA's operational experience of using these platforms in most theaters, Israel's adoption of the systems for intelligence and reconnaissance tasks, as well as usage in the Kosovo War, in Afghanistan, and Iraq. UAV technology has now much improved and become more reliable, although there do still remain some problems. Nevertheless, it has been forecast that a large percentage of manned military aircraft missions will be undertaken by UAVs in the near future. It is also projected that the military UAS market will remain of higher value than the civilian market for the foreseeable future due to a higher allocation of funding drawn from national government defense budgets, although tightened spending could have an effect on some programs and procurement. Industry has provided additional funding toward research and development costs of national UAV programs or has developed their own systems with the hope of attracting of domestic and international orders.

6.3 Civilian Unmanned Systems

Possible civilian UAV applications include scientific research, search and rescue, emergency response, traffic control tasks, infrastructure support, aerial photography, forest protection and wildfire monitoring, environmental monitoring, energy and electrical facility monitoring, pipeline inspection, and coast guard support, to name but a few possible applications. Further, UAVs may also be used for crisis management operations during and after natural disasters like hurricane Katrina and Sandy, or after terrorist attacks, to survey disaster zones or to look for survivors. The use of UAVs to transport civilian air cargo could be a lucrative area in the future.

In the short term, earth observation and surveillance are expected to account for the biggest share of the civilian UAV market.

Increasing opportunities within this market has led to the establishment of numerous small and medium enterprises (SMEs) developing low-cost systems for civilian applications. However, there remains the danger of duplication as too many companies are formed offering similar systems. Europe in particular now offers the most diverse choice of UAVs compared to any other region in the world, but may struggle to find sufficient demand worldwide to guarantee that they will be able to focus on UAV technology in the long term. The development of low-cost systems will be a major factor in sales. To ensure low-cost UAV development, some major companies have opted to convert off-the-shelf manned platforms into UAVs. The BAE Systems Herti, for example, is based on the J6 Fregata motor glider developed by Poland's J&AS Aero Design. The company has additionally used the MT-03 autogyro, which is produced by RotorSport, UK, in partnership with Germany's AutoGyro, as a basis for its Ampersand UAV. France's Sagem has converted the German Stemme S15-VT powered glider into the patroller. The USA's Aurora Flight Services, Russia's Irkut, and Israel's Aeronautics Defense Systems have all opted to convert the Austrian Diamond DA42 Twin Star twin-engine aircraft into a UAV or optionally piloted vehicle (OPV) that can be flown manned or unmanned. Italy's Selex Galileo, meanwhile, has been working with the Italian UAV company Unmanned Technologies Research Institute (UTRI) to develop the Short Take-Off and Landing OPV (STOL OPV) surveillance platform based on the two-seat Xenon gyroplane produced by Poland's Celier Aviation.

The level and the degree of use of some VTOL UAVs, TUAVs, and MALE UAVs for law enforcement and ground and border surveillance will basically be determined by funding from national governments with a leased fee-for-service arrangement more likely in an effort to keep costs down. An outright UAV purchase might not be seen as financially viable if taking into account that a complete UAS like the BAE Systems Herti will not cost much less to buy than a single Eurocopter EC145 – a platform being regularly chosen for police air support tasks. A manned platform like a helicopter is likely to remain the preferred choice as it provides more versatility, although a UAV has longer endurance time, lower operating costs, and a smaller logistics footprint. Outsourcing where a private contractor provides UAV services is already a growing trend among cash-strapped European militaries.

Focusing on law enforcement tasks and in addition to the surveillance role, some UAVs could be fitted with a Long Range Acoustic Device (LRAD) loudspeaker and lightweight nonlethal weapons to reduce the risk to police officers on the ground. France's Tecknisolar Seni test flew its Bourdon MUAV in 2004 fitted with a 1.1 kg Verney-Carron Flash-Ball nonlethal defense weapon that fires 44 mm rubber balls, plastic rounds, tear gas, or dye-ball markers. France's SMP Technologies plans to incorporate a 0.5 kg taser stun gun, which it manufactures into an I-Drone quadrotor UAV for law enforcement tasks. Austria's Schiebel has already flown its Camcopter S-100 VTOL UAV with a LRAD in a military test.

There is currently a wide array of UAV applications in the civilian world, and many more are envisioned for the future. Among them, UAVs monitoring the Arctic,

deployed to survey areas affected by earthquakes, monitoring marine mammals, use for civilian scientific research or environmental monitoring, weather/atmospheric data collection, oceanographic data collection, agricultural monitoring, and high-altitude geological mapping of magnetic, radiological, and gravimetric data and more, among many others.

6.4 Discussion

There is no doubt that the international market for UAVs or UAS or RPA or RPAS has grown in recent years. The use of these systems instead of manned platforms has particular benefits for an operator, namely, lower procurement costs than for manned aircraft and a small logistics footprint. There is additionally a low risk to human life. Military use is currently the biggest market for UAVs and likely to do so for the foreseeable future, despite growing interest in the systems for civilian uses. Europe and the rest of the world were initially fairly slow to adopt UAVs with the USA and Israel using systems operationally from the 1970s. Earlier UAV technology was unreliable with flight control systems and sensor technology, endurance, and weather conditions limiting usage. UAV technology has now much improved and become more reliable, although there do still remain some problems.

Military UAVs are generally operated in restricted airspace away from civilian air traffic, but serious problems are posed when both military and civilian operators start to use the systems in congested airspace, including possible midair collision. Current major efforts are trying to put in place general harmonization rules for UAV operations within civilian or controlled airspace with each state responsible for its own air regulations. Several regional efforts have been launched to draw up guidelines for UAV use in controlled airspace.

Despite progress, there is still need for new technology to ensure that UAVs can operate safely in civilian airspace. One important area is the development of sense and avoid (S&A) technology that will enable the UAV to autonomously identify a manned aircraft and then make corrections to its flight path to avoid a midair collision. Integrating UAVs into congested airspace remains one of the main areas of current studies that will draw on existing and future UAV technology.

There are still other problems to overcome, particularly for the military, to ensure that UAVs can remain operable, such as the need to develop secure data links to prevent possible hostile jamming and data sent from the UAV's sensors from getting into the wrong hands. The USA and Israel have already had problems with enemy forces intercepting unsecure data broadcast from UAVs. There is additionally the problem of nations and hostile forces developing and gaining anti-UAV technology. The USA's Raytheon has already successfully used its Laser Phalanx naval close-in weapon system to shoot down a UAV in tests. There is additionally the problem of the loss of data links between the GCS and the UAV, which has been the most common cause of crashes for the past decade. There is particularly a need to allocate sufficient satellite bandwidth to control UAVs and to provide a means of transmitting communications and real-time data from sensors to ground control stations and

other receiving facilities. The USA has had problems with the allocation of enough bandwidth that has led it to use commercial satellite operators in addition to its own military satellite systems. The London Satellite Exchange (LSE), for example, is one commercial operator that has been providing Ku-band links for UAVs for several countries, including France. Research is being undertaken to address some of these issues. In Europe, for example, a study is being conducted by the European Space Agency (ESA) on European and Canadian satellite technologies. The Advanced Research on Telecommunication Satellite Systems (ARTES) program also includes planned studies into satellite communications (satcom) systems for civilian UAVs. A separate study dubbed SIGAT has also worked on identifying appropriate military radio spectrum for UAV integration into general air traffic in Europe. UAVs featuring autonomous flight capabilities could lower bandwidth use with the operator just responsible for guidance to the target area or making the decision to release weapons.

Some of these potential roles for UAVs could, however, be controversial, and their use by law enforcement agencies might not be fully supported by the public. There are also issues about the export and proliferation of UAVs. The informal Missile Technology Control Regime (MTCR) prevents the proliferation of certain UAVs, particularly systems that could be used to deliver weapons of mass destruction. It has restricted the sale of MALE systems, as has the USA's own export laws. Several UAV manufacturing nations, such as China, are not part of the MTCR that has led to concerns that the technology could end up in the hands of terrorist organizations. MTCR has, however, restricted sales of UAVs to nations outside Europe. The USA's General Atomics Aeronautical Systems Inc (GA-ASI) has been keen to export of an unarmed version of the Predator MALE UAV, dubbed the Predator XP.

6.5 Conclusions

Although UAVs have been and are a familiar presence in war zones, the picture is changing and roadmaps have been produced to integrate UAVs into the global airspace. The civilian sector is attracting, of course, the interest of UAV OEMs and users, worldwide. In some cases, the civilian market is driven by specific needs such as border patrol, forest fire monitoring, rescue operations, etc. In other cases, the need is more generic and the UAVs may find multiple application domains, like traffic monitoring, police surveillance, etc. UAV applications are set to explode in the commercial market once airspace regulations are clearly defined and published. The Association for Unmanned Systems International (AUUSI) and UVS International hold annual shows and conferences lobbying governments for greater access to civilian skies.

The airspace that belongs to manned systems still presents a controversial barrier to the civilian UAV market segment as regulatory agencies had limited significantly UAV access to the national airspace. For example, the FAA's line-of-sight restriction and other certification requirements have been a major roadblock. However, the

2013 year is a turning point year as roadmaps for integrating UAS into the national airspace have been published both in the USA and Europe.

Regardless, we are witnessing a growing role of relatively low-cost, nearly expendable UAVs in military and civilian operations. The use of these systems, instead of manned platforms, is providing particular benefits to the operator, namely, lower procurement costs and a small logistics footprint. UAVs are currently a growth industry in the aviation sector, with scores of new companies competing for a slice of the market. We are about to witness major changes as UAV technologies are becoming more reliable and safer, and their utility is expanding rapidly, accompanied by demand and the rapid growth of the industry. Reliability is likely to be a key issue for UAVs aimed at civilian use as the industry continues to lobby aviation regulators to gain access to skies that for the most part remained off-limits. A major challenge that needs to be addressed and solved before widespread use of UAVs relates to privacy, legal, and ethical issues.

Section II

UAV Design Principles

Daniel J. Pack and Graham Drozeski

Kimon P. Valavanis and George J. Vachtsevanos

UAV Design Principles presents the basic design principles of UAVs and the components that comprise a complete unmanned aircraft system, avoiding in depth technical details. It aims at creating the “overall picture” with respect to UAV functionality and, consequently, to indirectly motivate the reader about the challenges that need to be overcome in order to make UAVs fully operational, reliable, and safe.

► **Computational and Experimental Design of a Fixed-Wing UAV** by Ryaciotaki-Boussalis and Guillaume presents a comprehensive methodology for the design and manufacture of all aspects of a prototype fixed wing UAV, which also allows for utilizing multi-segmented flight control surfaces on the wings of such UAVs. Adding multiple segments to UAV wings creates smaller control surfaces; thus, refined adjustments to UAV performance while airborne may be accomplished.

► **UAV Handbook: Payload Design of Small UAVs** by Gruber, Kwon, Hager, Sharma, Yoder, and Pack discusses payload design issues for small UAVs, which are essential to overcome various small UAV constraints imposed by stringent weight, power, and volume. The efficacy of design principles is demonstrated with the help of the payloads for a fixed wing UAV developed by the Center for Unmanned Aircraft Systems Research at the U.S. Air Force Academy, and it is shown that the system requirements for specific applications are closely related to those for other small UAV applications.

► **Small UAV Design Development and Sizing** by Brandt describes a rationale for selecting a low-risk UAV configuration and a methodology for sizing and optimizing the shape of both fueled and electric-powered aircraft. Three examples of low-risk UAV configurations are shown to be essentially similar from the point of view of optimization and sizing. The sizing methodology for fueled aircraft is described in detail, and a similar one for electric-powered aircraft is described to the extent that it differs from that for fueled aircraft. Typical values of technology-related parameters used in sizing calculations are given, followed by an example of a small UAV designed using the proposed methodology.

► **Systematic Design Methodology and Construction of Micro Aerial Quadrotor Vehicles** by Phang, Li, Chen, and Lee presents guidelines to optimally and systematically design and construct an ultralight micro aerial quadrotor vehicle, including details of the steps to design a stable quadrotor with not more than 50 g take-off weight and flight duration of 8 min. The methodology covers, sequentially, structural analysis of the micro quadrotor air frame, design in a 3-D virtual simulator, design of the avionic system, controller implementation via simulation, and component fabrication and implementation. Finally, performance is evaluated, tested, and confirmed with real flight missions.

► **Dexterous UAVs for Precision Low-Altitude Flight** by Jiang and Voyles follows the concept of force closure (a term from the dexterous manipulation community) to introduce a new type of dexterous six degrees-of-freedom (6 DOF) UAV, which provides the unique capability of being able to resist any applied wrench, or generalized force-torque, providing more precise control during low-altitude flight. The major challenge that needs to be overcome in such designs is that low-altitude flight usually introduces ground-effect disturbances and other backwash issues, while in the new field of aerial mobile manipulation it often includes close to structures operations for inspection or manipulation purposes. The presented design differs considerably from typical helicopters or quadrotors, which cannot instantaneously resist or apply an arbitrary force in the plane perpendicular to the rotor axis, thus, making such designs inadequate for complex mobile manipulation tasks.

Collectively, the five chapters provide a plethora of ideas and design principles that prepare the reader to capture more advanced technical challenges.

Abstract

This chapter presents a detailed example for the design and manufacture of all aspects of a prototype unmanned aerial vehicle (UAV). It further allows for the utilization of multi-segmented flight control surfaces on the wings of these UAVs. Adding multiple segments to UAV wings creates smaller control surfaces. By introducing smaller control surfaces, a wing can make refined adjustments to UAV performance while airborne. This unique technique will (i) apply localized correcting forces to the UAV, (ii) reduce structural deformation, (iii) minimize drag contribution due to control surface actuation, (iv) suppress and control structural resonance due to lift forces and vibrational modes, (v) reduce the weight of the structure, and (vi) improve the endurance of flights.

8.1 Odyssey UAV Mission

8.1.1 Introduction

In recent years, UAVs have played a major role in the security of the nation and have gained popularity over traditional full-size piloted aircrafts. Further, the use of UAVs has become a favored solution for important tasks requiring air operations. Examples of areas for air operations include academic research, earth environmental studies, fire surveillance, and reconnaissance.

This chapter describes the thought process and techniques required to design and develop a fixed-wing UAV. It presents a case study for the design of a particular UAV underway at the Structures, Propulsion, And Control Engineering (SPACE) – a NASA-sponsored University Research Center (URC) of Excellence at the California State University, Los Angeles (CSULA).

The main objective was to develop a multi-mission UAV, named “Odyssey,” which could be adapted to different mission requirements. The Odyssey UAV (Fig. 8.1) incorporates a flight control system (FCS) into a twin boom aircraft configuration, which is designed to be capable of carrying a payload of up to 14 lb, remaining in flight for up to 3 h and operating at a maximum altitude of 10,000 ft above sea level. The design encompasses the major areas of aircraft design, which include aerodynamics, structures, avionics, and propulsion.

Three scale prototypes were constructed and flown by the SPACE Center team as part of the concept verification, allowing the team to experiment and learn from a

Fig. 8.1 Odyssey UAV

number of manufacturing techniques prior to the construction of the Odyssey UAV. This UAV was also used to develop and apply novel techniques for real-time structural health monitoring (SHM). The integration of a system for SHM of an aircraft allows for reduction of weight while maintaining a high level of confidence in UAV design. These SHM data are used for fault detection, while a control system is used to assure system reconfiguration.

8.1.2 Objective of the Design and Development of the UAV

During the previous years, the NASA University Research Center of Excellence (URC) has concentrated gaining the experience, skills, and manufacturing techniques for the development of small, lightweight UAVs that have excelled in the area of endurance. The Odyssey UAV project was focused on the design of a multi-mission/multipurpose air system that can operate autonomously with a maximum payload carrying capacity of 14 lb.

8.1.3 Mission Requirements of the UAV

The mission requirements were selected for the design of a multipurpose UAV that is capable of wide variety of missions with minimal structural modifications. The following are the specific requirements that have been used to design the Odyssey UAV:

Endurance: 3 h

Payload: 14 lb maximum

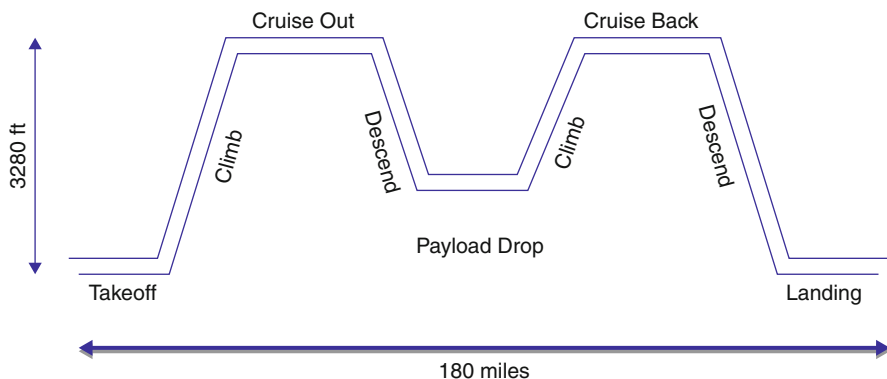

Fig. 8.2 Mission profile

Cruise speed: 81.4 ft/s

Cruising altitude: 3,000 ft (above sea level)

Max. altitude: 10,000 ft (above sea level)

The endurance capabilities of the air-frame were a trade-off between the payload weight and the mission. The mission profile shown in Fig. 8.2 was adopted for the development of the Odyssey UAV. However, the final mission will be determined by NASA once the UAV is developed.

As shown in Fig. 8.2, the UAV was designed to take off within a distance of about 300 ft, climb, reach cruise altitude, and maintain a speed of 81.4 ft/s. The UAV will then cruise for 3 h, covering 180 mi, and then finally will decent to a predetermined way point for a payload drop.

8.2 Odyssey UAV Design Specifications

8.2.1 Initial Sizing

The first step in designing Odyssey was to perform a feasibility study by identifying existing UAVs with similar geometry, size, and mission requirements. Using available data from existing UAVs, a parametric study was performed to determine an initial wingspan, power requirement, and UAV maximum speed. The following table shows the UAVs and corresponding parameters that were considered for this study (Table 8.1).

Figures 8.3–8.5 graphically show a comparison of the existing UAV's weight versus cruise speed, weight versus wingspan, and weight versus horsepower.

These figures were used to determine the first estimate of the UAV sizing including (1) gross weight, (2) wingspan, and (3) engine size. Specifically, the UAV gross weight was estimated to be between 100 and 150 lb, the wingspan estimated to be between 11 and 16 ft and the engine power estimated to be of at least 7 HP.

Table 8.1 UAV parametric study

| UAV | Weight (lb) | Wingspan (ft) | Cruise speed (mi/h) | HP | Ceiling (ft) |
|-------------|-------------|---------------|---------------------|------|--------------|
| Aerosonde | 28.8 | 5.6 | N/A | 1.7 | |

Fig. 8.3 Weight versus cruise speed

Fig. 8.4 Weight versus wing span

Fig. 8.5 Weight versus horsepower

8.2.2 Aerodynamic Design Process

The traditional aerodynamic analytical relationships were utilized for developing the aerodynamic UAV model by the following steps: Step 1: Make selections such as the airfoils used for the main wing and tail, the configuration of the plane such as pusher or puller, the span, location of wings relative to each other and chord length. Step 2: Perform analysis on the geometry of the airfoils selected for the aircraft. Once the geometry of the aircraft is selected, it is possible to estimate lift-to-drag ratios, static margin, and performance capabilities. The degree of refinement increases as the number of finalized parameters is increased. The increase in refinement begins to reveal the cost of construction and the types of manufacturing techniques that will be required. This is the approach that was used to design and manufacture the Odyssey UAV. Step 3: Use the Athena Vortex Lattice (AVL) computational fluid dynamics software package to model the aerodynamic characteristics of the proposed UAV

structure. Step 4: Compare chosen aerodynamic characteristics to actual flight data. These aerodynamic characteristics should provide baseline aerodynamic parameters for state-space model to be used in the development of an autonomous controller. Following the steps mentioned above allows for the completion of the UAV design.

For UAV design, a decision must be made between increased maneuverability and stability of the aircraft. For the aerodynamic design of the Odyssey UAV, priority was given to an increase in stability and payload rather than an increase in maneuverability. To achieve this, a twin boom pusher assembly with a rectangular wing was selected. Since the payload of the Odyssey UAV includes a forward-facing camera, the pusher configuration also facilitates undisturbed imaging.

8.2.3 Geometry and Configuration

The Odyssey UAV design has a rectangular main wing that has a 15 ft wingspan, a mean aerodynamic chord of 1.75 ft, and an aspect ratio of 8.57. In order to simplify the design and analysis, the main wing does not change geometry along its span nor is it swept. The aircraft is estimated to have a gross weight of 140 lb. The airfoil selected for the main wing is an Eppler214, and the airfoil for the horizontal tail and vertical stabilizers is NACA0012. These airfoil types were selected so that the UAV will exhibit a high lift at low speeds and provide adequate moments for stable pitch. Other aircraft specifications are shown in Tables 8.2–8.4 below.

The control surface sizing was based on the results of the stability studies conducted in AVL. Based on the results, the sizes of the control surfaces for the aircraft are shown in Table 8.5.

Figure 8.6 shows a representation of the UAV main geometry which includes the main wing and the horizontal and vertical tails. The yellow areas represent the control surfaces.

8.2.4 Airfoil Selection

This section describes the process in determining final geometry of the UAV based on CFD analysis and empirical calculations. As mentioned in the previous section, the airfoil types were selected so that the UAV will exhibit a high lift at low speeds and provide adequate moments for stable pitch.

Several experimental studies were performed in order to identify the final airfoil selection for the wing and horizontal tail/vertical tails. The airfoil types for these wing and tail combinations included in these studies were the Eppler214 and NACA0012, Clark Y and NACA2412, and Eppler214 and NACA2412. The Eppler12 and Clark Y were chosen for the main wing, while the NACA0012 and NACA2412 were chosen for the horizontal and vertical tails.

Since the interaction of the wing and tail is vital for the performance of the aircraft, the airfoil selection was based on the following design criteria:

- Lift/drag (L/D) must be greater than 15.

- Good trim conditions (which implies good pitch stability).

Table 8.2 Wing specifications

| | |
|---------------------------|--------------------------------|
| Wing (Eppler214 airfoil) | |
| Weight | $W = 140 \text{ lb}$ |
| Wing loading | $W/S = 5.33 \text{ lb/ft}^2$ |
| Aspect ratio | $AR = 8.57$ |
| Taper ratio | $C_t/C_r = 1$ |
| Wing area | $S = 26.25 \text{ ft}^2$ |
| Wingspan | $b = 15$ |
| Root chord | $C_r = 1.75 \text{ ft}$ |
| Tip chord | $C_t = 1.75 \text{ ft}$ |
| Average chord length | $C = 1.75 \text{ ft}$ |
| Quarter chord sweep angle | $L = 0^\circ$ |
| Leading-edge sweep | $L = 0^\circ$ |
| Span efficiency | $e = 0.505$ |
| Thickness ratio | $t/c = 0.137$ |
| Total surface area | $S_{surf} = 67.5 \text{ ft}^2$ |

Table 8.3 Vertical stabilizer specifications

| | |
|--|------------------------------|
| Horizontal stabilizer (NACA0012 airfoil) | |
| Span | $b = 6 \text{ ft}$ |
| Root chord | $C_r = 1 \text{ ft}$ |
| Tip chord | $C_t = 1 \text{ ft}$ |
| Planform area | $S = 6 \text{ ft}^2$ |
| Taper ratio | $l = 1$ |
| Aspect ratio | $AR = 6$ |
| Thickness ratio | $t/c = 0.12$ |
| Sweep angle | $L = 0^\circ$ |
| Total surface area | $S_{surf} = 12 \text{ ft}^2$ |

Table 8.4 Horizontal stabilizer specifications

| | |
|--|---------------------------------|
| Vertical stabilizer (NACA0012 Airfoil) | |
| Span | $b = 2.25 \text{ ft}$ |
| Root chord | $C_r = 1 \text{ ft}$ |
| Tip chord | $C_t = 0.675 \text{ ft}$ |
| Ave. chord | $C_a = 0.8375$ |
| Planform area | $S = 0.675 \text{ ft}^2$ |
| Taper ratio | $l = 0.675$ |
| Aspect ratio | $AR = 7.500$ |
| Sweep angle (LE) | $L = 15.52^\circ$ |
| Total surface area | $S_{surf} = 4.500 \text{ ft}^2$ |

Table 8.5 Control surface specification

| | Flaps | Aileron | Elevator | Rudder |
|-------------|-------|---------|----------|--------|
| Chord (in.) | 6.825 | 6.825 | 3.6 | 3.9 |
| Span (in.) | 30 | 20 | 64.8 | 27 |

Fig. 8.6 Representation of UAV geometry and control surfaces

Fig. 8.7 Angle of attack versus lift-to-drag ratio

Figure 8.7 shows the different lift-to-drag ratios for the selected airfoil combinations, and all performed with an L/D ratio greater than 15. Figure 8.8 shows the pitch stability of the aircraft with the different airfoil combinations. It can be seen that Clark Y and NACA2412 and E325 and NACA2012 have negative pitch stability. Since the objective of the Odyssey UAV is to be naturally stable during steady flight, this negative pitch stability is not desired. The selected airfoil combination that provided the most desired performance for the Odyssey UAV was the NACA00012 for the main wing and the Eppler214 for the tails.

The final set of experiments for this study was to evaluate the drag performance of the different airfoil combinations. Figure 8.9 demonstrates that the Eppler214 and NACA0012 combination has the lowest drag.

Fig. 8.8 Pitch stability

Fig. 8.9 Drag polar

Based on the analysis that was performed, the optimal airfoil combination selected for the Odyssey UAV was the Eppler214 and NACA0012 since this combination provides (1) optimal L/D, (2) the lowest drag polar, and (3) the most stable aircraft performance. The following Table 8.6 shows the aerodynamic data obtained from both empirical studies and CFD analysis.

Table 8.6 Aerodynamic coefficients from empirical studies

| | | | |
|-------------------------------------|---------------|--------|----------------------|
| Skin friction coefficient | C_{fe} | 0.0055 | |
| Zero lift parasite drag coefficient | $C_{D,O} =$ | 0.0184 | |
| Span efficiency | $e =$ | 0.5 | |
| Induced drag factors | $k_3 =$ | 0.0735 | |
| | $k_2 =$ | 0 | |
| | $k_1 =$ | 0.0245 | |
| | $K =$ | 0.0980 | |
| Air density (sea level) | $p =$ | 0.0024 | slug/ft ³ |
| Total engine power | $P =$ | 9.80 | HP |
| Prop efficiency | $H_{pr} =$ | 0.70 | |
| Total power available | $P =$ | 6.86 | HP |
| Speed | $V =$ | 81.40 | ft/s |
| Max curve slope | $Cl_{max} =$ | 1.06 | |
| Stall speed | $V_{stall} =$ | 57.20 | ft/s |
| Maximum lift-to-drag ratio | $L/D =$ | 18.8 | |

These coefficients are determined from both analytical studies and CFD analysis using AVL. The AVL software uses the vortex lattice method to estimate the lift and drag forces on the modeled aircraft. This software package was used during the design of the Odyssey UAV to ensure that the design provided adequate lift for both the UAV structure and the 14 lb payload. The software was also used to determine aircraft stability and to provide other necessary aerodynamic parameters.

The CFD study also determined that the wing and the horizontal tail must have an incidence angle of 2° . The necessary angles of attack for the main wing were found by optimizing the lift-to-drag ratios at cruising conditions. In addition to this, AVL was used to perform studies to investigate the overall performance of the aircraft at different speeds and altitudes. Optimizing an aircraft design minimizes fuel consumption, minimizes drag, and reduces the loads that the structure experiences.

By applying CFD to an aircraft design, performance of the UAV design can be simulated. The simulated performance can be used to determine if off-the-shelf components, such as an engine, can be used while maintaining design parameters of the aircraft. If off-the-shelf parts can be utilized rather than custom parts, both time and cost of manufacturing are reduced. For the Odyssey, the simulation showed that an off-the-shelf engine met the aircraft requirements and a Desert Aircraft model DA-120 engine was purchased.

Another important parameter in aircraft design is the static margin. This is the distance between the neutral point (i.e., the entire aircraft's aerodynamic center) and the center of gravity divided by the length of the chord. The static margin is used in determining the longitudinal stability of an aircraft. A positive static margin on an aircraft means that the center of gravity is in front of the neutral point, while a negative static margin on an aircraft means that the center of gravity is behind the neutral point. As the static margin increases, the longitudinally

stability increases. However, as the static margin increases, maneuverability decreases. As stated previously, the stability of the Odyssey UAV was determined to be more important than its maneuverability, so this UAV was designed with a static margin of 15 %.

8.2.5 Structural Requirements

The structural design of a UAV is based on the aerodynamic loads generated during each stage of the mission which include takeoff, climb, cruise, diving, and landing. These loads are determined from CFD and form the flight envelope of the Odyssey UAV as seen below in Fig. 8.10.

Based on the maneuverability requirements of the Odyssey UAV design, the maximum acceleration loading was set to 3.0 g. This is the largest acceleration that Odyssey UAV will experience in the flight envelope. Thus, the aircraft structure was designed to meet the 3.0 g loading condition while maintaining a factor of safety of 2.0. Initial weight estimates obtained from a finite element model (FEM) indicated that an aircraft structure designed to meet these loads would weigh approximately 140 lb.

8.2.6 Engine Selection

Once the aerodynamic analysis is complete, the propulsion system can be selected using the following considerations: (1) the size of the propulsion system must be able to meet the minimum thrust requirements necessary to overcome the drag of the aircraft and achieve lift with an estimated maximum headwind; (2) the type of propulsion system used for an aircraft, such as piston engines, turboprop, and turbofan, turbojet, will influence the performance characteristics of the aircraft; (3) the amount of thrust output by the engine compared to the weight of the engine needs to be maximized; and (4) the thrust-specific fuel consumption (TSFC) which compares the ratio of the rate of fuel consumed to the thrust produced needs to be minimized. The temperature air surrounding the aircraft affects the performance of the aircraft since decreased air density leads to decreased lift and thrust. An aircraft designed with high maneuverability and high-speed requirements will require high thrust requirements (low engine efficiency), while an aircraft designed with simple cruise requirements will have low fuel consumption (high engine efficiency). For UAV propulsion systems designed for a specific mission, trade-offs must be made between thrust and efficiency.

Piston engines are internal combustion engines that convert the reciprocating motion of pistons to rotational motion to spin a propeller. These engines are ideal for cruising speeds since they are built to operate at subsonic speeds and provide low thrust-specific fuel consumption. A propeller-driven engine has low maneuverability and cannot produce as much thrust as newer jet engines, but the low TSFC for

Fig. 8.10 V-n diagram:
operational

Fig. 8.11 Thrust required

propeller-driven engines is ideal for endurance missions. Alternatively, airbreathing jet engines, such as turbojet or turbofan, are another type of internal combustion engine which turbines instead of pistons to compress air. These airbreathing engines are capable of producing high thrust but are inefficient and heavy.

Since both stability of the aircraft and flight endurance were the main mission requirements of the Odyssey UAV, a piston-type engine was chosen. Figure 8.11 shows the thrust requirements of the piston engine at various speeds, while Fig. 8.12 shows the amount of power required at various speeds. The fuel tank for Odyssey UAV is custom made, and it is capable to hold a fuel capacity that would allow for a maximum 3 h of flight time.

Fig. 8.12 Power required

8.3 Odyssey UAV Software Analysis

8.3.1 Structural Analysis: Femap

A Nastran FEA model was developed to determine the allowable stresses within the aircraft skin and internal structures. For simplicity, only structural elements of the aircraft are modeled. All panels were modeled using 2-D orthotropic materials and laminate properties to determine membrane forces, bending moments, and transverse shear loads. The fuselage and wing skins are composed of sandwich panels made from composite materials. The material properties of the face materials were then defined within the FEM using core material properties specified by the manufacturer. Geometry for the finite element model was imported from Solid Works, and the imported surfaces were meshed with the laminate properties to simulate the sandwich panels.

8.3.2 Composite Stress Analysis

The structure's margin of safety was determined utilizing the Tsai-Hill Failure Index (FI) to predict the failure in composite materials. The FI is defined as

$$FI = \frac{\sigma_1^2}{X^2} - \left(\frac{1}{X^2} + \frac{1}{Y^2} - \frac{1}{Z^2} \right) \sigma_1 \sigma_2 + \frac{\sigma_2^2}{Y^2} + \frac{\tau_{12}^2}{S^2}$$

where

σ_1 = calculated plane stress of the sandwich panel in direction 1

σ_2 = calculated plane stress of the sandwich panel in direction 2

Fig. 8.13 Fuselage stress contours (Tsai-Wu failure index)

τ_{12} = calculated in-plane shear stress of the sandwich panel

X = normal allowable stress of the sandwich panel in the X direction

Y = normal allowable stress of the sandwich panel in the Y direction

S = in-plane shear allowable of the panel

8.3.3 Modeling

All internal loads were applied using mass elements when the laminate properties of the fuselage skin, bulkheads, and internal components were modeled. All mass elements are attached to the structure using interpolation elements (rigid RBE3) in the FEM model. The function of the RBE3 is to attach the force or mass of a single dependent node to the average independent node and will not increase the stiffness of the model. RBE3 can also be considered as a “force link,” which distributes the forces of the independent nodes to the dependent nodes by interpolation. The fuselage structure load was applied by specifying the aircraft accelerations in the FEA model as seen in Fig. 8.13. An engine thrust load of 60 lb was also applied to the engine assembly mass element, and the fuselage was constrained at the interface between the bulkheads and the main spar of the wing.

The structure of the wing-boom-tail assembly and all internal ribs were modeled with the use of laminate properties. For the wing-boom-tail assembly (Fig. 8.14), all lift loads were applied using nodal loads. A distributed lift load, which decreased toward the wing and tail tips, was calculated by incorporating a maximum gust load of 3.0 g and the aircraft accelerations obtained from the FEA model. The moments

Fig. 8.14 EA analysis of wing structure

Fig. 8.15 Composite wing structure

about the quarter chord of the main wing were also applied to the model by using nodal loads. The wing is constrained at the interface between the bulkheads of the fuselage and the main spar of the wing.

Figure 8.15 shows the main load-bearing structure within the wing which is a composite spar that has a box beam configuration.

The spar is composed of alternating layers of both bidirectional and unidirectional carbon fiber. The layers of unidirectional carbon fiber are orientated in the spanwise direction to maximize the tensile and compressive strength of the carbon fiber in bending. The bidirectional layers of carbon fiber are orientated in a 45° angle with respect to the spanwise direction to increase the strength of the spar under torsional loading. Regions where the spar experiences the least bending moments are manufactured with fewer layers of carbon fiber. The loading transferred from the tail through the booms add additional local stresses. To alleviate large stress concentrations, the spar and local sandwich panels were reinforced with additional layers of carbon fiber (Fig. 8.16).

The base main wing was optimized and reinforced by increasing the number of layers of carbon fiber to counteract the large bending moments experience near the root chord. As the bending moment decreases with distance from the root, the number of layers of carbon fiber is decreased to prevent the risk of peak stress concentrations. Based on previous structural analysis, additional reinforcement was required in regions where the central wing, the wing tip extensions, and the booms connect.

Fig. 8.16 Carbon fiber layers for spar

Fig. 8.17 Simulated deflections caused by in-flight loads

8.3.4 Deflections

The results of the FEM show that the aircraft in a 3.0 g maneuver is capable of withstanding an ultimate aerodynamic load of 720 lb and can have expected wing tip deflections up to 1.69 in. (Fig. 8.17).

8.3.5 Normal Mode Shapes and Mode Frequencies

A structure modal analysis must be performed since uncontrolled vibrations can be catastrophic for the aircraft. Based on the finite element modeling shown in Fig. 8.18, the first structural bending mode frequency of the Odyssey UAV main wing was determined to be 8.25 Hz.

Fig. 8.18 Analysis of the first structural bending mode frequency

8.3.6 Stress and Strain

The FEM of the Odyssey UAV wing-boom-tail was used to predict the stress and strain fields in the structure while under load. The greatest stress concentration occurs near the root of the wing, while the peak stress concentration occurs near where the fuselage attaches to the wing (Fig. 8.19).

The direction of composite material needs to be specified during manufacturing. The skin material used in the Odyssey UAV is a bidirection carbon fiber weave which has equal stiffness and strength in two directions. However, the spar is composed of unidirectional carbon fiber, which is stiffer and stronger in the tow direction. FEM allows the user to specify the tow direction of the composite material. Since the largest contribution to stress on the wing structure is due to bending, it is critical to analyze the strain contours in the wingspan direction (Fig. 8.20).

8.3.7 Computational Fluid Dynamics

The Athena Vortex Lattice was used as the CFD software to calculate the aerodynamic parameters and the flight dynamics of the Odyssey UAV. It is a free resource software package that is an effective tool to approximate and refine the flight-dynamic characteristics of a custom-built rigid-body UAV.

The two major approximations made by the Athena Vortex Lattice include the following: (1) the software treated the fuselage as a slender body and did not consider certain drag features (booms and the main landing gear) of the Odyssey UAV model, and (2) the software used an average skin friction drag coefficient. The actual skin friction drag coefficient requires extensive wind tunnel testing, and it typically makes a small contribution to the overall drag coefficient of the aircraft. Regardless of these approximations, the software can provide a reasonable aerodynamic model that can be refined from flight testing.

Fig. 8.19 Wing assembly stress contours (Tsai-Wu failure index)

Fig. 8.20 Strain contour in the span direction

Despite of its limitations, AVL is still a powerful tool in regard to designing and building custom aircraft and was crucial to the development of the Odyssey. The software can provide lift loading at varying angles of attack, flight stability characteristics, dynamic system matrices, and other parameters necessary to design, manufacture, and control a UAV (Fig. 8.21).

8.4 FOSS System Application to the Odyssey UAV

8.4.1 Introduction to Structural Health Monitoring

The integration of a system for structural health monitoring of an aircraft allows for reduction of weight while maintaining a high level of confidence in UAV design. In addition, a real-time SHM system with a novel robotic/UAV-to-human interface will reduce the risk of in-flight breakups by providing crucial flight data to the ground control station (GCS), including structural deformations, stresses, and loading. These SHM data will also be used for fault detection, while the proposed control system algorithms will assure system reconfiguration. Traditional sensing

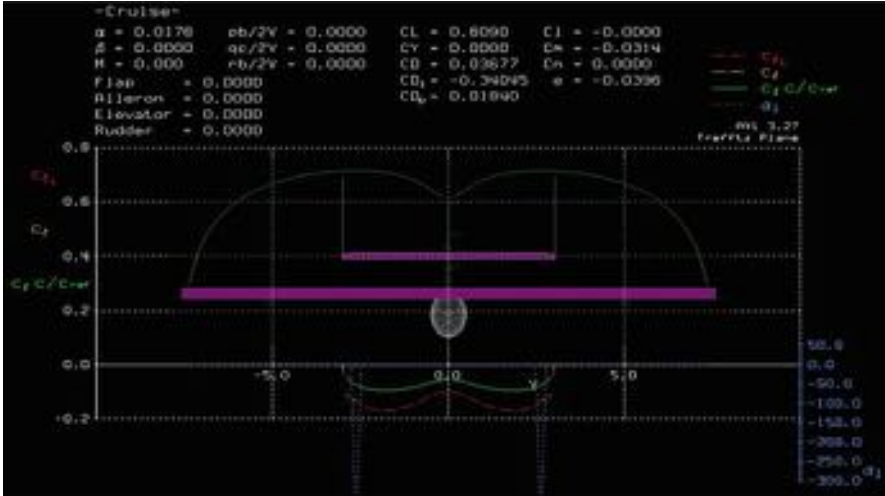

Fig. 8.21 Odyssey AVL model

instrumentation – including strain gauges, accelerometers, and thermocouples – tend to be bulky and heavy, limiting their application to a few sensors, usually near the wing root. Recent improvements in fiber optic strain sensing technology (FOSS) have enabled the use of embedded fiber Bragg gratings (FBGs), which can provide numerous distributed strain and temperature measurements from a variety of structural elements. A FBG is a photo-induced refractive plane that is etched onto a fiber-optic cable that reflects a low power signal when light pulses travel through it. As a FBG is stretched, undergoing strain, the spacing of the refractive plane changes as well. This change in the refractive plane spacing causes a change in the reflected signal's index of refractivity. The change in the index of refractivity is directly proportional to the strain felt by the fiber-optic line. By using a Bragg wavelength (λ_b) as a point of reference to track strain over time, the relationship for strain becomes

$$K\varepsilon = \frac{\lambda - \lambda_b}{\lambda_b}$$

where K is a proportionality constant based on the properties of the fiber-optic cable and λ is the wavelength being monitored by the FOSS system. Because of their accuracy, light weight, small size, and flexibility, these fiber-optic sensors are ideal for aircraft with strict weight and size limitations. Given this ability to provide a large number of sensor measurements, there is the potential to develop and implement methods of monitoring, which have a higher accuracy because of the increased sensor density. Thus, a higher accuracy of monitoring can be achieved by this large number of sensor measurements, which facilitates control and system reconfiguration. A strain-based method, known as the displacement transfer functions (DTF), has been developed by the NASA Dryden Flight Research

Center. The strain-based shape prediction algorithm, also known as the displacement transfer function, is derived from classical beam theory (Euler-Bernoulli) which relates the measured strain of the structure to the theoretical curvature, slope, deflection, and cross-sectional twist angle equations for uniform cantilever beams. The Euler-Bernoulli equation is the general differential equation that describes the relationship between load and deformation of a beam:

$$EI \frac{d^4 y(x)}{dx^4} = q(x)$$

where the variable x is the distance of the beam starting at the wing root and ending at the end of the beam, $y(x)$ is the displacement of a beam as a function of distance from the root, $q(x)$ is the loading function analogous to the lift generated by the wing, E the elastic modulus, and I is the second moment of area that is calculated with respect to the centroidal axis perpendicular to the applied loading. The moment-strain relationship of the classical beam differential equation is used to implement the shape prediction algorithm and states that the curvature, second derivative of displacement, of a beam is proportional to the applied bending moment:

$$\frac{d^2 y}{dx^2} = \frac{M(x)}{EI}$$

By relating the bending stresses to the definition of stress and strain in Hooke's law, it can be shown that the curvature of the beam is directly proportional to the strain felt by the beam during bending:

$$\sigma(x) = \frac{M(x)c}{I} \quad \& \sigma(x) = E\varepsilon \xrightarrow{\text{yields}} \frac{d^2 y(x)}{dx^2} = \frac{\varepsilon(x)}{c}$$

where c is the distance to the neutral axis of which the beam is bending.

By utilizing the high spatial resolution of the strain measurements, it is possible to numerically integrate the second-order differential by use of finite difference method, without accumulating a large amount of error. By integrating the curvature equation and applying boundary conditions, the slope equation of the n th strain location can be written in the general form:

$$\tan \theta_n = \frac{\Delta l}{2c} (\varepsilon_{n-1} + \varepsilon_n) + \tan \theta_{n-1} = \frac{\Delta l}{2c} \left[\varepsilon_0 + 2(\varepsilon_1 + \varepsilon_2 + \varepsilon_3 + \dots + \varepsilon_{n-1}) + \varepsilon_n \right]$$

$$\tan \theta_n = \frac{\Delta l}{2c} \left[\varepsilon_0 + 2 \sum_{j=1}^{n-1} \varepsilon_j + \varepsilon_n \right]$$

To obtain the displacement of the wing using the shape prediction algorithm, it is necessary to integrate the slope equation with the respect to the x -axis. Utilizing the high spatial resolution of the strain measurements, it is possible to numerically integrate the first-order differential by use of finite difference method, without

accumulating a large amount of error. The displacement of the beam at any given strain sensing station is approximated by

$$y_0 = 0 \quad \& \quad \tan \theta_0 = 0$$

$$y_1 = \frac{(\Delta l)^2}{6c} (2\varepsilon_0 + \varepsilon_1) + \Delta l \cdot \tan \theta_0 + y_0$$

$$y_2 = \frac{(\Delta l)^2}{6c} (2\varepsilon_1 + \varepsilon_2) + \Delta l \cdot \tan \theta_1 + y_1$$

After applying boundary conditions, the displacement equation of the n th strain location can be written in the general form:

$$y_n = \frac{(\Delta l)^2}{6c} \left[2\varepsilon_0 + 3(\varepsilon_1 + \varepsilon_2 + \varepsilon_3 + \dots + \varepsilon_{n-1}) + \varepsilon_n \right]$$

$$+ \Delta l (\tan \theta_1 + \tan \theta_2 + \tan \theta_3 + \dots + \tan \theta_{n-1})$$

$$y_n = \frac{(\Delta l)^2}{6c} \left[2\varepsilon_0 + 3 \sum_{i=1}^{n-1} \varepsilon_i + \varepsilon_n \right] + \Delta l \sum_{i=1}^{n-1} \tan \theta_i$$

This method coupled with the Dryden developed FOSS technology allows for real-time deformation shape prediction. The FOSS technology has shown great potential for applications on various other structures, including smaller-scale and fixed-wing UAVs, as well as space structures and is being used on the Odyssey UAV. Excessive deformations of these structures can potentially induce damage to the wing, which may lead to flight instabilities and even catastrophic in-flight breakups. For fixed wings, the FOSS system has the potential to allow for the prevention of aerodynamic flutter by monitoring resonance frequencies and by providing crucial status of the vehicle's overall structural integrity.

Currently, a computational model has been created and used to investigate and assess the viability of the deflection algorithm as a displacement-shape prediction tool for potential monitoring and control applications. The geometric and physical properties of the FEA model have been addressed, and shape deflection algorithms were developed by subjecting the model to three different loading cases. A number of sensitivity analyses have been investigated and include the placement of the fiber lines on the wing, the density of sensors along the lines, the measurement uncertainty, and the effects of loading on the wing.

8.4.2 Computational Model

The finite element model was created to represent an actual experimental swept plate that was designed, fabricated, and instrumented at NASA's Dryden Flight Research Center. Fiber-optic strain sensors were placed at the top and the bottom surfaces of

Fig. 8.22 Swept plate dimensions (inches)

Fig. 8.23 Swept plate sensor layout

the experimental swept plate, and strain data were collected from the plate when it was subjected to various loading conditions. The swept plate is made of 6061-T6 aluminum with a Young's modulus of $E = 10$ Msi. The swept plate is 12 in. wide and 0.19 in. thick and has a span of approximately 51 in. The plate is swept horizontally at a 45° angle from the fixed end (Fig. 8.22).

Three fibers are located at the top and the bottom surfaces, for a total of six fibers on the plate. Two fiber lines are placed 0.5 in. from the leading and the trailing edges, while the third fiber line is located in the middle of the plate (Fig. 8.23). There are a total of 102 fiber gratings along each fiber line, and strain measurements are available from each.

A combination of Femap and Nastran packages were used to create and analyze the computational models. The FEA models were created such that their physical properties and geometric constraints represent the actual experimental model.

Three loading cases have been considered. The uniform-load (UL) case consists of a total of 12 point loads, 6 along each the leading and trailing edges of the wing. The trailing-edge load (TE) case consists of six equally spaced point loads that are applied to the trailing edge of the wing. Finally, the single-point (SP) load case consists of a single point load located at the corner of the plate located at the tip of the trailing edge, opposite the root. The trailing-edge and single-point loading cases are investigated to assess the torsional load effects on the performance of the deflection prediction algorithm. In the case of the leading-edge loads, the 6 lb point loads are applied closest to the fixed end of the plate. In the case of the uniform load, all point loads are 2 lb each. In the case of the single-point load, the point load is 11 lb.

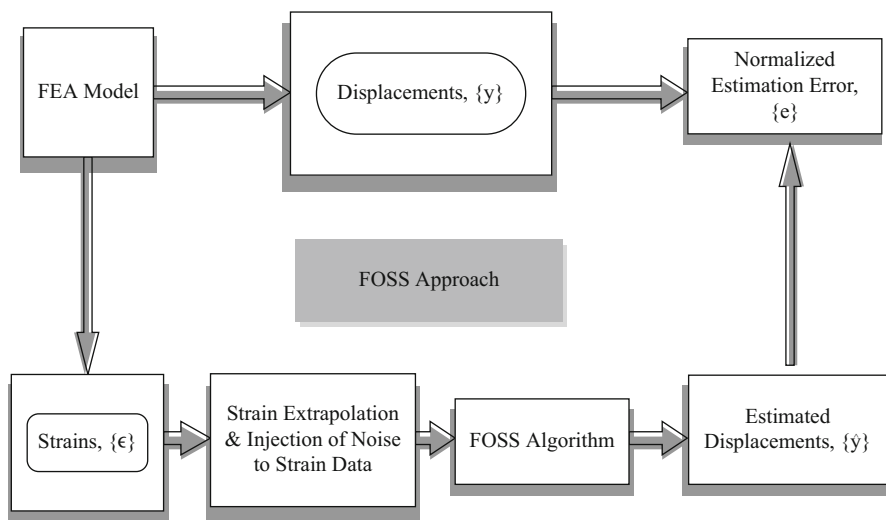

Fig. 8.24 FOSS approach sensitivity analysis

8.4.3 Sensitivity Analysis

A simulation was performed where three fiber lines were placed on both the top and bottom of the swept plate. The fibers were placed 0.5 in. parallel to the leading and trailing edges and one directly in the middle of the plate. Real-life situations were considered when assessing the effectiveness of the deflection prediction algorithms. Placement of the fibers on the wing and spacing of the sensing stations will drastically affect the accuracy of the predictions.

Strain and deflection data were extracted from the finite element model in order to compare the results of the algorithm. Because the algorithm requires the root deflection and strain information, the data was extrapolated to the root using curve fitting techniques and the known locations of the sensing stations. The strain data may be manipulated to add various levels of uncertainty as needed for the analysis. The deflections were estimated using the FOSS DFT transformations.

For each study, the displacements have been estimated, and the corresponding normalized estimation errors, e , were calculated. This process is shown in Fig. 8.24.

8.4.4 Location of Fiber Line and Effects of Loading

The top plate fibers were considered when assessing the effects of fiber location and torsion from loading. The results of the study on the fiber locations and loading conditions are shown in Fig. 8.25. Each case shows the error in deflection prediction for a particular fiber line under three loading conditions. The first loading condition

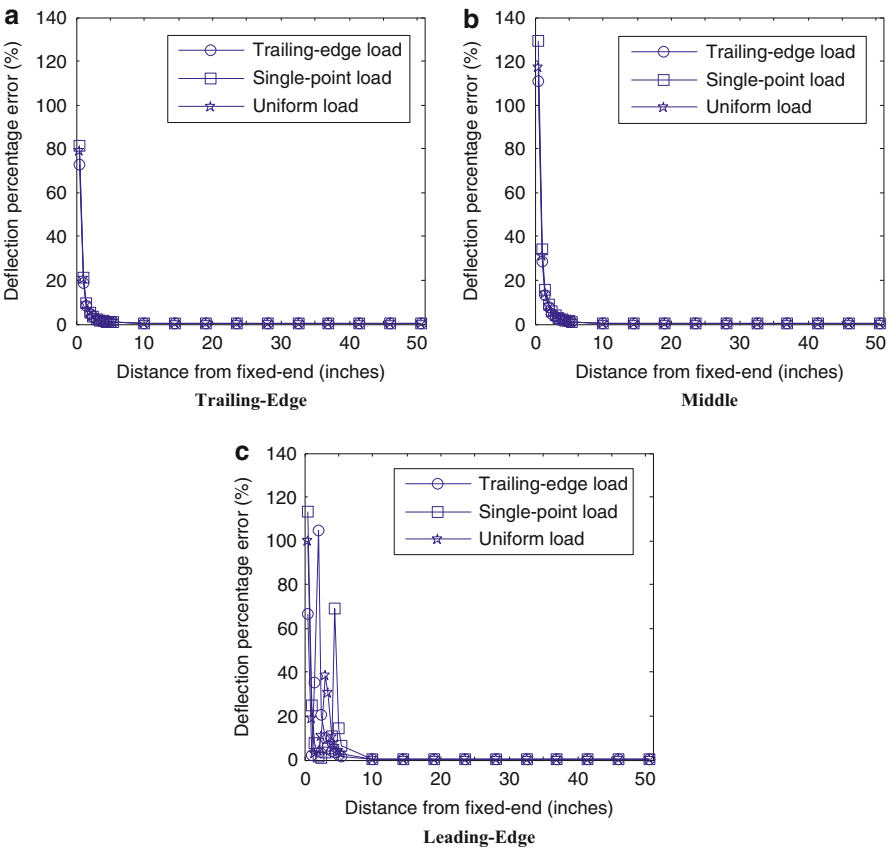

Fig. 8.25 Loading study-fiber line

is the trailing-edge load case, followed by the single-point load and uniform-load cases. Figure 8.25a shows the results for the trailing-edge fiber line, Fig. 8.25b shows the results for the middle fiber line, and Fig. 8.25c shows the results of the leading-edge fiber line.

The deflection prediction algorithm obtained promising results for both the trailing-edge and middle fiber lines. However, the results of the leading-edge fiber line showed high errors near the root of the wing for all three loading conditions. Such high prediction errors and erratic behavior can pose large problems for monitoring applications during flight. As expected, the higher percentage errors are located near the fixed end of the swept wing, where deflections are minimal, while the prediction percentage errors quickly improve toward the tip of the wing.

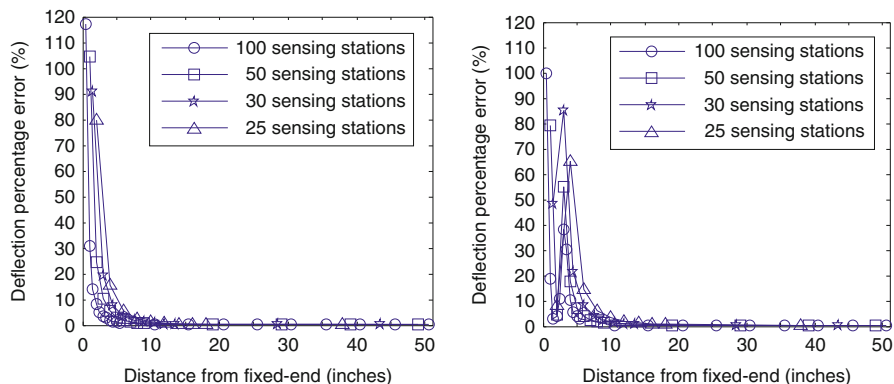

Fig. 8.26 Sensor spatial resolution comparison: uniform loading, middle fiber

8.4.5 Number of FBG Sensors

Fiber-optic technology using FBG provides the potential for providing high spatial resolution. In a real-life application, increasing the spatial resolution of the fiber-optic sensors provides increased accuracy in capturing strain values. However, increasing the spatial resolution raises computational considerations. The degree of resolution needs to be increased in order to obtain the desired accuracy while maintaining a reasonable computational demand. In order to assess the effects of spatial resolution, four cases were considered using a sensor spacing of 0.5, 1, 1.5, and 2 in. This resulted in a total number of sensing stations per fiber of roughly 100, 50, 30, and 25 sensing stations, respectively. Figure 8.26 shows the results of the uniform loading case on the middle fiber. As expected, increasing the spatial resolution greatly increases the accuracy of the algorithm. Additionally, the percentage errors increase at the free end as the spatial resolution decreases.

8.4.6 Sensor Integration and Loading

A Femap/Nastran FEA model was constructed and included the structural elements of the aircraft skin and internal structures, while the nonstructural items were excluded. All panels and the spar have been modeled using both 2-D orthotropic materials with laminate properties. For the wing-boom-tail assembly, all lift loads were applied by using point loads. The lift load was calculated by incorporating a maximum aerodynamic load of 3.0 g. The applied lift load was a distributed load that decreases toward the wing tips, classified as an elliptical load. The moments about the quarter chord of the main wing were also applied to the model by use

Fig. 8.27 Femap model with loading

Fig. 8.28 UAV wing strain direction

of nodal loads, and a distributed load was applied to the tail. The wing-boom-tail structure load was applied by specifying the aircraft accelerations in the FEA model. The wing was constrained at the interface between the bulkheads of the fuselage and the main spar of the wing.

For this design study, strain data have been extracted from the FEA model of the UAV wing from along the quarter chord and on either side of the quarter chord. These nodes represent the potential placement of the fiber-optic line on the top of the UAV wing (Fig. 8.27). The direction of the strain is along the span of the wing and can be seen in Fig. 8.28.

Unlike a simple aluminum plate, the UAV wing is not a homogenous structure. It is constructed using various materials and has complex changes in geometry. These abrupt changes in geometry or material properties can be observed from strain measurements. While the overall behavior of the strain from the root of the wing to the tip of the wing agrees with what would be expected in a cantilever beam-like structure, there are abrupt discontinuities in the strain at locations where the materials or geometry in the wing changes. This could be seen near 40 in. from the wing root. These areas are crucial to ensure the structural integrity of the wing.

Fig. 8.29 Comparison of deflections for top right and left wing fibers

8.4.7 Analysis and Results

The analysis was performed by extracting the strain data along the span of the wing. Each side of the wing, left and right, was treated as an individual cantilever beam for the purpose of the DTF. Deflection and slope at the root of each fiber were assumed to be zero. In order to obtain evenly spaced strain sensing stations, the locations, strains, and deflections from the FEA model of the UAV were extracted and interpolated at evenly spaced intervals using a polynomial curve fitting function in MATLAB before using in the deflection equations and performing error analysis. Lastly, the half-beam depth was assumed to be equal along the span of the wing.

Figure 8.29 shows the comparison of the calculated deflection along the quarter chord of the UAV wing using the FEA strain data and the DTF deflection equations. Thus, the displacement equations accurately predict the shape of the wing for both the right and left side of the wing.

Using the results from the FEM, the fiber-optic lines have been implemented onto the Odyssey UAV. Two lines of sensors have been routed along the span of the UAV, and a series of diagonals run in between the two lines. The 2 lines of optic fiber that run in the spanwise direction have approximately 360 strain readings per fiber line and will capture strain due to bending. As shown in Fig. 8.30, the diagonal lines are aligned in the 45° orientation and will be utilized to obtain strain due to torsion.

8.5 Flight Simulation

8.5.1 X-Plane Simulation Model

By connecting the Odyssey UAV flight control system hardware to the X-Plane flight simulator, real-time hardware-in-the-loop (HIL) simulations were conducted to verify the flight behavior of the design as well as the optimized theoretical gains.

The geometry of the UAV was simulated using the Plane Maker software and then uploaded into the X-Plane virtual environment (Fig. 8.31). The aerodynamic

Fig. 8.30 Fiber optics on odyssey UAV

Fig. 8.31 X-plane simulation model

forces and moments calculated from this blade element theory model is a good representation of the aircraft in real environmental conditions. Specifically, wind speed, gust speed, shear angles, and turbulence were obtained in X-Plane as shown in Fig. 8.32 to analyze the dynamic stability of the UAV design.

8.5.2 Autonomous Design

8.5.2.1 Introduction to Flight Control System

If time and resources are not a major concern, designing a custom UAV flight control system (FCS) is a viable option. This allows personalized selection of sensors,

Fig. 8.32 Blade element physics with environmental disturbance

actuators, and processors as well as complete control over the underlying software architecture. The disadvantage of designing a custom FCS is that its design and implementation will have to proceed in pace with the design and the manufacturing of the UAV. Last-minute changes to design, manufacturing, or mission objectives may compromise previous avionic layouts or sensor precision/accuracy requirements in the FCS. In addition, an enormous amount of time is required to code, debug, integrate, and test the finalized FCS first in a simulation environment and then in actual flight.

To save time and recourses, an option to custom designing the FCS is the integration of an “off-the-shelf” FCS/autopilot system such as Cloud Cap Technology’s Piccolo Autopilot or the ArduPilot Mega (APM) FCS into the UAV. The advantage of this choice is time and effort saved on design/layout/programming, but the disadvantage is the possibility of experiencing difficulties from software problems or hardware failures of a system that may have no transparency of the underlying hardware and software architectures.

The “off-the-shelf” APM FCS was selected over the Piccolo Autopilot for the Odyssey UAV since there is more transparency in the APM hardware and software architectures. Further, the APM is more suited for control since it allows the setting of PID (proportional-integral-derivative) controller gains for the servos based on empirically and analytically derived UAV models.

8.5.2.2 Aerodynamic State-Space Models

Various depending system model implementations may need to be implemented based on the mission requirements of the UAV. For high-speed high-maneuverability aircraft, a nonlinear system model may be necessary. However, for aircraft that may need to have considerably large changes in flight conditions, multiple linear models may be needed with the addition of an active gain scheduler if one controller is incapable of meeting the demands of all expected flight regimes. The plant model of an aircraft can be derived analytically based on the well-known equations of motion and linearized about an operating point. Alternatively, there are existing software packages, such as the AVL that will provide a linear plant model based on design data such as the mass distribution and geometry of the aircraft. The disadvantage of this approach is the unknown underlying assumptions in the creation of such a model.

To address the uncertainty in the automatically created plant model delivered by AVL, an alternative approach was used to extract the aircraft's aerodynamic stability and body-axis coefficients and build new state-space (SS) models under the following assumptions: (1) the longitudinal and lateral degrees of freedom (DOF) are uncoupled, and (2) the aircraft's motion will mostly consist of small deviations from its equilibrium flight condition. Equations below show the SS structure assumed and the terms calculated based on available sensor data and assuming the FCS board is placed right at the center of gravity (CG) of the aircraft.

$$\begin{bmatrix} \Delta \dot{u} \\ \Delta \dot{w} \\ \Delta \dot{q} \\ \Delta \dot{\theta} \end{bmatrix} = \begin{bmatrix} X_u & X_w & 0 & -g \\ Z_u & Z_w & u_0 & 0 \\ M_u & M_w & M_q & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta w \\ \Delta q \\ \Delta \theta \end{bmatrix} + \begin{bmatrix} X_{\delta_e} \\ Z_{\delta_e} \\ M_{\delta_e} \\ 0 \end{bmatrix} \Delta \delta_e$$

$$\begin{bmatrix} \Delta u \\ \Delta w \\ \Delta q \\ \Delta \phi \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta w \\ \Delta q \\ \Delta \phi \end{bmatrix}$$

$$\begin{bmatrix} \Delta \dot{v} \\ \Delta \dot{p} \\ \Delta \dot{r} \\ \Delta \dot{\phi} \end{bmatrix} = \begin{bmatrix} Y_v & 0 & (Y_r - u_0) & -g \\ L_v & L_p & L_r & 0 \\ N_v & N_p & N_r & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \Delta v \\ \Delta p \\ \Delta r \\ \Delta \phi \end{bmatrix} + \begin{bmatrix} 0 & Y_{\delta_r} \\ L_{\delta_a} & L_{\delta_r} \\ N_{\delta_a} & N_{\delta_r} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \Delta \delta_a \\ \Delta \delta_r \end{bmatrix}$$

$$\begin{bmatrix} \Delta v \\ \Delta p \\ \Delta r \\ \Delta \phi \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta w \\ \Delta q \\ \Delta \theta \end{bmatrix}$$

The uppercase letters denote aerodynamic derivatives/interactions between subscripted states or control surfaces. The states (u,v,w) represent orthogonal velocity components in a body-centered right-hand system with positive (x,y,z)

Fig. 8.33 Root locus for Δu with respect to δe

measured along the nose, right wing, and undercarriage of the aircraft, respectively. The angular states ($p, q, r, \theta, \phi, \psi$) denote angular rates of change in pitch, roll, yaw, pitch angle, bank angle, and yaw angle, respectively. The elevator, ailerons, and rudder are denoted by δe , δa , and δr , respectively.

Stability analysis should be performed to determine whether the aircraft has any uncontrollable, unobservable, or unstable modes once the model has been derived. For example, Fig. 8.33 shows the root locus for the longitudinal acceleration (Δu) with respect to elevator input (δe) for the Odyssey's half-scale prototype. Further analysis showed that the SS models are both controllable with only one unstable mode corresponding to the lateral spiral mode (not uncommon for most aircraft).

This chapter has shown the design process of a fixed-wing UAV using a case study. At the time of publication, this aircraft was designed, simulated, and constructed. The maiden flight of the Odyssey will be in about 4 months.

Acknowledgments The authors want to acknowledge and thank the technical support provided by the NASA Dryden Flight Research Center, all the faculty, and the students who have contributed in the past and present to the design and development of the Odyssey UAV at the Structures, Propulsion, And Control Engineering (SPACE) – a NASA sponsored University Research Center (URC) of Excellence at the California State University, Los Angeles (CSULA).

Abstract

This chapter discusses the payload design issues for small unmanned aerial vehicles (UAVs). Details of several payload design principles to overcome various small UAV constraints imposed by stringent weight, power, and volume are discussed. Throughout the chapter, the efficacy of these principles is demonstrated with the help of the payloads for a fixed wing UAV developed by the

Center for Unmanned Aircraft Systems Research at the U.S. Air Force Academy, using this example payload design, a UAV is to be used to autonomously search, detect, localize, and track ground targets. The system requirements for the example application are closely related to those for other small UAV applications.

9.1 Introduction

Clearly, a small UAV has limited payload volume and weight capacity. These limitations drive several additional constraints: electronic components must avoid electromagnetic interference (EMI) interactions, a risk increases by their close proximity; power is limited by the space and weight available for energy storage devices such as batteries; total payload operational time is limited by the available; power processor speed is limited by the weight and power available, and sensor capabilities such as video frame rate and image resolution are limited by available weight allocation.

Researchers and developers in academia as well as in industry have worked on designing UAV payloads. Pastor et al. designed a low-cost embedded hardware/software architecture for micro UAVs (Pastor et al. 2007), and Semke et al. suggested an approach to use remote sensing payload design for digital imaging on UAVs for educational development (Semke et al. 2007). Stuckel et al. proposed a payload design for a platform stabilization system to remotely deliver more stable imagery during flights (Stuckel et al. 2011). And Everaerts et al. provided various remote sensing payload designs for visual, infrared, laser, or atmospheric sensors (Everaerts et al. 2004). The focus of this chapter is to design payloads for small UAVs, which can autonomously perform specific intelligence, surveillance, and reconnaissance missions only with an onboard computer and the supporting subsystem payloads.

The constraints of volume and weight play critical roles in the following major trade-offs for a small UAV payload:

- Autonomy versus human operator
- Autonomy (onboard processing) versus available communication bandwidth
- Autonomy (onboard capability) versus flight time
- Minimalist design versus flexibility and adaptability
- Optimal design versus simplicity

Designing a small UAV payload involves trade-offs among the basic subsystems shown in Fig. 9.1. Decisions made for one subsystem will affect the design of another subsystem. While managing this balance, the overall small UAV system constraints of weight and volume must be maintained. For example, if an extensive image processing algorithm is executed on images at a rate of five images per second, the single board computer (SBC) needs to handle the computational load. The larger the computer needs are the more power and cooling are necessary to complete the task. Since the payload battery capacity cannot be increased due to the overall weight restriction, the mission time has to be reduced. If mission time is not negotiable, can another choice be made that still accomplishes the goal of

Fig. 9.1 Major payload subsystems

the mission? Can the image processing rate be reduced from five to one image per second, or can a less computational image processing algorithm be used? These are typical questions that must be answered before a design is chosen.

This chapter provides a method to design an integrated payload that maximizes performance in a small UAV package. The chapter is organized to:

- (a) Define the mission requirements of the payload (Sect. 9.2).
- (b) Create preliminary weight, power, and volume budgets for the payload (Sect. 9.3).
- (c) Start an iterative design of the payload subsystems, constantly interacting among all subsystem designs to ensure that performance is maximized within the system constraints (Sect. 9.4).
- (d) Address other areas that can affect the payload design (Sect. 9.5).

Throughout this chapter, examples are provided to help explain the related concepts. There is also an underlying emphasis to ensure EMI does not contribute to the loss of the UAV's global positioning system (GPS) signal. Most small UAVs rely on GPS signals for navigation, so reliable performance of the GPS system is necessary for the success of a small UAV mission.

9.2 Payload Mission Requirements

Before a detailed design can be developed, the requirements of the payload must be defined. Some questions that should be asked that affect a small UAV payload design are:

- What is the flight duration required for the mission?
- What is the specific task of the mission? For example, searching for specific targets, setting up surveillance posts, providing a communications relay, etc.
- What are the detailed mission subtasks? How large is the search area?
- How long will the payload systems need to be operated on the ground before the flight?
- What is the maximum distance from the ground station that the UAVs will be operating?
- How many UAVs will be in flight?
 - If multiple UAVs, how is collision avoidance incorporated? For a small UAV, altitude separation is typically used so that avoidance hardware isn't necessary.
- What are the target characteristics?
 - Required accuracy of localization
 - Moving or stationary targets
 - Number of targets
 - Target separation
 - Size, shape, and color of targets
- What are the allowed frequencies that can be used for communication between UAVs and the ground station?
- What are the situational awareness requirements of the ground station operator?
 - Imagery refresh rate
 - Image quality and size
 - UAV position, mission status, and health
- Will other devices be operated in the same area that can cause communication interference?
- What are the environmental requirements (vibration, shock, humidity, and temperature)?

9.3 Preliminary Payload Design Budgets

The preliminary payload design is governed by two limiting factors: payload weight and volume. Power, in the form of batteries, is the main contributor to the payload's weight. Any reduction in power requirements of the payload subsystems will result in either an overall weight reduction or an increase in the possible mission time. Thus, in the flow diagrams used in each of the subsystem design sections, a reference to WPV is used to represent weight, power, and volume. Note that cost is another important factor in developing a design. This is specific to each small UAV application and is not addressed in this chapter.

When developing a preliminary design budget, an investigation of likely components needs to be completed. These components can then be used to determine the preliminary allocations of weight and volume. Figure 9.2 is an example payload

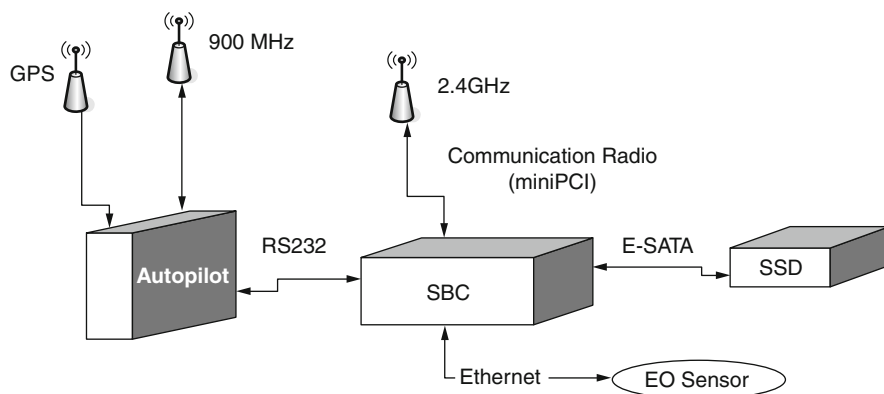

Fig. 9.2 An example of a payload hardware design: *SBC* (single board computer), *EO* (electro-optic) sensor, *SSD* (solid-state disk), and *E-SATA* (external serial advanced technology attachment)

hardware design including major components and I/O between the components. To start the payload sizing, a preliminary power budget is useful since battery weight is a major weight contributor.

9.3.1 The Power Budget

For a small UAV gasoline propulsion system, having an onboard generator is unlikely due to the weight constraint, so a battery is necessary to support the payload system. If the propulsion system is electric, the propulsion batteries are typically used just for propulsion to maximize flight time, again requiring the payload to have its own battery. Note that if the payload has small power requirements, the small UAV design may opt to use the propulsion batteries to support the payload with the understanding that the flight duration will be impacted. This section will focus on an example payload system with its own battery.

An estimated payload is used to compute an overall payload power requirement. Table 9.1 presents an example payload using an atom-based processor, a 2.4-GHz radio, and a security camera as the key payload components. Note that the camera in this example has electronic panning capability, so it addresses all requirements of an electro-optical (EO) sensor system. Since this table is developed early in the design, a 30 % management reserve is added to the power for use if needed as the design progresses. Based on this analysis, the SBC system (processor and disk) has a 14-W budget, the communications system has a 3-W budget, and the EO sensor system has a 3.6-W budget. Note that the current requirement for the wireless card assumes it is transmitting a little more than 50 % of the time and that the solid-state disk (SSD) has 50 % utilization. Based on the mission's requirements, these average currents can be adjusted. The available battery life is 0.9 h. If the combination of ground time and flight time usage is close to 0.9 h, a higher capacity battery should be employed.

Table 9.1 Example power budget

| Component | Voltage | Current | Watts |
|---|---------|-------------------|------------------------|
| Aurora/Corona SBC (http://www.diamondsystems.com/products/aurora/) | 5 | 2.0 | 10.0 |
| 32 GB SSD | 5 | 0.8 | 4.0 |
| Ubiquiti XR2 wireless card (http://www.ubnt.com/xr2) | 3.3 | 0.9 | 3.0 |
| Axis 212 PTZ camera (http://www.axis.com/products/cam_212/) | 5 | 0.7 | 3.6 |
| Misc. parts (servo switch, RC receiver, etc.) | 5 | 0.2 | 1.0 |
| Total watts | | | 21.6 |
| | | <i>Efficiency</i> | <i>Watts</i> |
| Adjusted for efficiency of DC-DC converter | | 0.9 | 24.0 |
| Adjusted for 30 % management reserve | | 0.7 | 34.3 |
| | | <i>Batt volt</i> | <i>Needed current</i> |
| Battery voltage and current for required power | | 14.8 | 2.3 |
| | | <i>Batt AH</i> | <i>Available hours</i> |
| Lithium polymer battery amp hours (AH) and available operational hours | | 2.1 | 0.9 |

Table 9.2 Example weight budget

| Component | Weight (g) | Percent weight |
|---|------------|----------------|
| Aurora/Corona SBC w/enclosure | 400 | 18.0 |
| 32 GB SSD, enclosure, and cable | 200 | 9.0 |
| Ubiquiti XR2 wireless card, cables, antenna | 100 | 4.5 |
| Axis 212 PTZ camera | 500 | 22.5 |
| Misc. parts | 100 | 4.5 |
| Power system (battery, DC-DC, wires) | 480 | 21.5 |
| Total weight | 1,780 | |
| Adjusted for 20 % management factor | 2,225 | 20.0 |
| Total weight estimate | 2,225 | 100 |
| UAV payload weight allowance | 2,270 | |
| Additional weight buffer | 45 | |

9.3.2 The Weight Budget

The maximum available payload weight, an important design constraint, is predetermined by the aircraft's lift and gross weight limits. Using the same components used for the power budget, Table 9.2 shows a preliminary weight budget. This example assumes that the small UAV allocation for maximum payload weight is 5 lb. In this case, the management reserve is 20 %. The resulting weight budgets are 27 % for the SBC system (includes the SSD), 4.5 % for the communications system, 22.5 % for the communications system, and 26 % for the power system which includes miscellaneous components.

Fig. 9.3 Kadet senior UAV

9.3.3 Volume Allocation

When considering the volume available for payload components, it is not sufficient to simply allocate volume for each component. Instead, components must be configured within the payload compartment(s) so that they are placed for proper payload assembly and do not cause any electronic interference to each other. Furthermore, components must be arranged so that the aircraft center of gravity is maintained for stable flight. For example, Fig. 9.3 shows a small UAV (Kadet Senior aircraft, <http://www.sigmfg.com/IndexText/SIGRC58.html>). To maintain the proper location of the center of gravity, the heaviest objects, the propulsion and payload batteries, were placed in the front of the fuselage, and the electro-optic camera was placed behind the landing gear.

9.4 Subsystems Design

The following sections are introduced with a flow chart that presents the design flow for each subsystem. The number in each flow element corresponds to the items in the accompanying lists that further explain the flow chart elements.

9.4.1 Communications Subsystem

The design flow of the communications subsystem is described in Fig. 9.4.

1. Define mission constraints.
 - (a) Allowed frequencies. Unless licensed radios are available, the UAV will be using the unlicensed ISM (industrial, scientific, and medical) bands. For UAVs, the 902–928-MHz, the 2,400–2,483.5-MHz, and the 5,725–5,850-MHz bands are commonly used. These bands can provide one to multiple 20-MHz channel bands, and compliant radios are readily available.

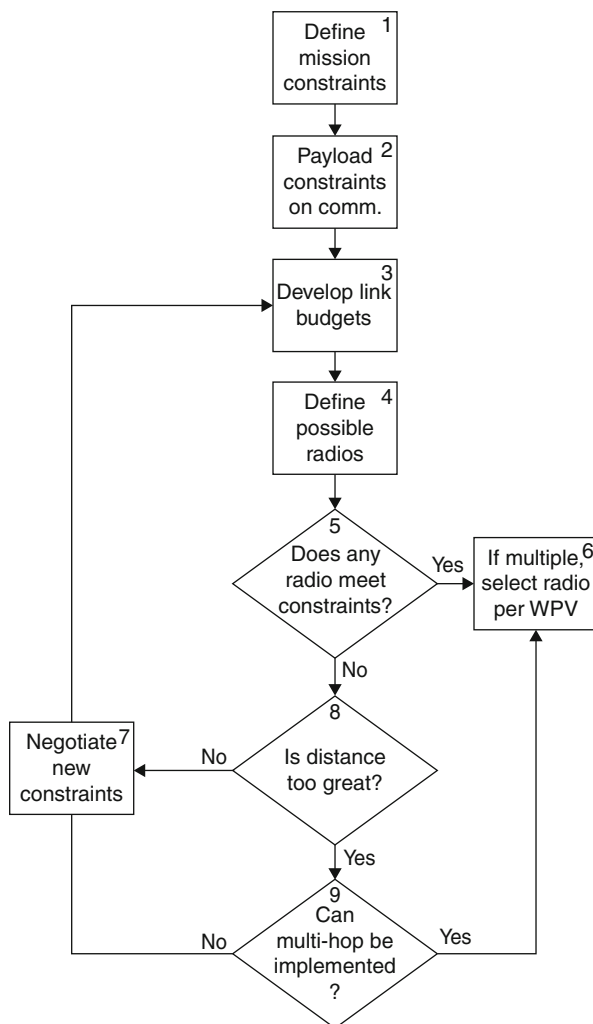

Fig. 9.4 Communications subsystem design flow

Transmission power is restricted per FCC regulations; radios and antenna gain need to be selected that comply with these regulations. Note that the 902–928-MHz band is frequently used for the autopilot wireless link.

- (b) Maximum distance. This distance is used to determine the link budget.
- (c) Number of UAVs in flight will determine if a multi-hop network is possible and the total bandwidth available at the ground station.
- (d) Other devices operating in the same area create noise and limit the communication system range if broadcasting over the same frequencies.

- (e) Situational awareness requirements of the ground station operator drive the bandwidth requirements of the system. A number of key questions to be asked are:
- (i) What command and control messages are necessary and what is the update rate of the messages?
 - (ii) What aircraft status messages need to be reported to the ground station? i.e., aircraft health, stage in mission, etc.
 - (iii) What size and compression factor of images are acceptable? Imagery is the largest consumer of the communication bandwidth. If a communication link is broken during a mission, imagery collected during the lost link may not be useful for the operator. If the imagery is sent using Transmission Control Protocol (TCP), the images have guaranteed delivery. During a lost link, these images are placed in a transmission queue and sent when the link is reestablished. Critical command and control messages need to wait until the queue is emptied of images. If only the current imagery is needed for situational awareness, imagery should be sent using User Datagram Protocol (UDP) which does not guarantee delivery. Thus, the imagery will not sit in a queue, and command and control messages are not delayed when the link is reestablished.
 - (iv) If multiple UAVs are used, how does the imagery need to be presented? To minimize the overall bandwidth, a thumbnail image can be displayed to the operator. The operator then has an option to select a thumbnail to start receiving larger imagery, reducing the overall system bandwidth.

Table 9.3 is an example calculation used to estimate the bandwidth requirements. In this UAS configuration, four UAVs converse with the ground station. Only one operator-selected UAV sends high-resolution imagery (320×240 pixels) to the ground station, and all four UAVs send thumbnail images. The “Number/s” column defines how many messages per UAV are allowed, and the “Total

Table 9.3 Estimated communication bandwidth requirements

| Information | Size (Kb) | Number/s | Total streams | Total Kb/s |
|------------------------------------|-----------|-----------------|---------------|--------------|
| Image 320×240 @ 10 % comp | 20 | 10 | 1.25 | 250 |
| Image 80×60 @ 30 % comp | 1 | 4 | 5 | 20 |
| Control messages | 0.1 | 5 | 5 | 2.5 |
| Health messages | 0.1 | 1 | 5 | 0.5 |
| Ground station messages | 0.1 | 2 | 5 | 1.0 |
| Other | 0.1 | 1 | 5 | 0.5 |
| Total | | | | 274.5 |
| Bandwidth efficiency | 25 % | | | |
| Bandwidth available (Kb/s) | Kb avail | <i>Kb avail</i> | | <i>Usage</i> |
| 6,000 | 1,500 | 187.5 | | 146 % |
| 12,000 | 3,000 | 375 | | 73 % |
| 24,000 | 6,000 | 750 | | 37 % |

streams” column is based on the number of UAVs in the system plus an increase of 25 % to assume 25 % of the messages are being relayed through another UAV (multi-hop). An assumed 25 % efficiency for the system accounts for message overhead and resends of lost messages. The total message bandwidth required is then compared to available data bandwidths for the 802.11-g protocol. The 6-Mb/s system does not have the capacity and a 12-Mb/s system is required. Since imagery is the largest bandwidth consumer, a reduction in frames per second could get the bandwidth requirement to a more manageable size:

2. Define payload constraints on the communication system. These are constraints generated by the other components of the payload. Some of the questions that must be answered are:
 - (a) If multiple UAVs are used, does one UAV need to communicate with another, or do all UAVs communicate directly with the ground station? If UAVs communicate with each other, is the link between UAVs direct or can the messages be routed through an access point at the ground station?
 - (b) What is the weight allocation for the communication system?
 - (c) What is the power allocation for the communication system?
 - (d) What are the input/output (I/O) interfaces available from the onboard computer?
3. Develop a communications link budget. A communications link budget is a method to estimate how well a communication channel will work for a specific system. It is a good tool for comparing multiple radios, antennas, and frequency bands. This section will not provide a detailed description but gives an example calculation.

The link budget is based on the Friis equation (1946): $P_R = P_T G_T G_R \left(\frac{\lambda}{4\pi d}\right)^2$. The power received by a radio, P_R , is equal to the power transmitted by a second radio, P_T , that is focused by the gains of the transmit and receive antennas, G_T and G_R , but is attenuated by the distance the signal has to travel. The last term, $\left(\frac{\lambda}{4\pi d}\right)^2$, is usually referred to as the *free space loss*: the λ represents the wavelength of the carrier wave, and d is the distance between the antennas.

The equation can be expanded to include additional losses and represented in decibels to simplify the calculations. $P_{R_{dB}} = P_{T_{dB}} + G_{T_{dB}} + G_{R_{dB}} - L_{FS_{dB}} - L_{Cbl_{dB}} - L_{Pol_{dB}} - L_{Pnt_{dB}}$, where transmit and receive gains are the maximum gains of the antennas, free space loss (L_{FS}) is defined above, cabling losses (L_{Cbl}) are due to the interconnections between the radio and the antenna, polarization loss (L_{Pol}) is due to misalignment of the electric fields, and pointing losses (L_{Pnt}) are due to misalignment of the physical antennas. The actual gain of an antenna varies as measured around the antenna. The typical antennas used on a UAV are dipoles and monopoles which have a gain pattern similar to a doughnut, with the antenna being the axle of the doughnut. These antennas are referred to as omnidirectional due to equal gain in all directions away from the antenna in a plane perpendicular to the antenna.

Fig. 9.5 Antenna pointing loss

The design of an antenna generates an alignment of its electric field, referred to as polarization. The most common type used in UAVs is linear polarization, where the electric field aligns with one plane. In the case of a dipole antenna, the field is aligned with the length of the antenna. Thus, for a UAV with a half-wave dipole antenna mounted vertically to the fuselage, the ground station antenna should also be mounted vertically. During flight, the antennas will not always be aligned due to the pitch or roll of the aircraft. This misalignment is referred to as polarization loss and is defined as $20 \log_{10}(\cos(\theta))$, where θ is the maximum misalignment angle. For missions where altitude is held constant, θ can be approximated by the maximum roll angle allowed by the autopilot.

Even if the antennas have no polarization loss, there will still be losses because the aircraft is at a different altitude from the ground station and when the aircraft is rolling away from the ground station. Figure 9.5 is an example of these two conditions. The blue outline is the gain pattern for a $\frac{1}{2}$ wavelength dipole antenna, the red line is the line of sight, and the black lines mark the point in the antenna gain pattern where the gain is $\frac{1}{2}$ of the maximum pattern gain. Antennas should be selected to ensure that the geometry of the UAV system stays within these $\frac{1}{2}$ power or 3 dB points. When maintained, the maximum pointing losses can be assumed to be 3 dB.

Let’s demonstrate the use of the link budget through an example. Two radio systems are being compared, a 2.4-GHz radio and a 900-MHz radio. A data bandwidth of 11 Mb/s needs to be maintained, resulting in transmit and receive powers presented in Table 9.4. Other system parameters are also defined in Table 9.4.

Table 9.4 Communications link budget problem definition

| Parameter | 2.4 GHz radio | 900 MHz radio |
|--|----------------------|----------------------|
| Required receive power for 11 Mb/s (dBm) | −92 | −90 |
| Transmit power for 11 Mb/s (dBm) | 28 | 28 |
| Maximum distance (mile) | 1 | 1 |
| Ground station antenna gain (dBi) | 4 | 4 |
| Aircraft antenna gain (dBi) | 2 | 0 |
| Maximum pointing error | Half power beamwidth | Half power beamwidth |
| Maximum bank angle (°) | 15 | 15 |
| Radio to antenna cable losses at each end (dB) | 0.5 | 0.5 |

Table 9.5 Communications link budget example solution

| Parameter | 2.4 GHz radio | | 900 MHz radio | |
|--|---------------|-----|---------------|-----|
| Power transmit for 11 Mb/s | 28.0 | dBm | 28.0 | dBm |
| Ground cabling loss | −0.5 | dB | −0.5 | dB |
| Ground station antenna gain | 4.0 | dBi | 4.0 | dBi |
| Ground pointing loss (half power pointing error) | −3.0 | dB | −3.0 | dB |
| Free space loss | −104.4 | dB | −95.8 | dB |
| Polarization loss | −0.3 | dB | −0.3 | dB |
| Aircraft pointing loss (half power pointing error) | −3.0 | dB | −3.0 | dB |
| Aircraft antenna gain | 2.0 | dBi | 0.0 | dBi |
| Aircraft cabling loss | −0.5 | dB | −0.5 | dB |
| Power received (total of above) | −77.7 | dBm | −71.1 | dBm |
| Required receive power for 11 Mb/s | −92.0 | dBm | −90.0 | dBm |
| Link margin | 14.3 | dB | 18.9 | dB |

Table 9.5 presents the solution of the link budget. The free space losses are calculated as

$$2.4 \text{ GHz radio} : 2.45 \text{ GHz} : 20 * \log_{10}((4\pi * 1,609)/0.122) = 104.4 \text{ dB}$$

$$900 \text{ MHz radio} : 915 \text{ MHz} : 20 * \log_{10}((4\pi * 1,609)/0.328) = 95.8 \text{ dB}$$

And the polarization loss is calculated as

$$\text{PolarizationLoss} : 20 * \log_{10}(\cos(15^\circ)) = 0.3 \text{ dB}$$

A good link margin should be above 10 dB. In this case, both radios exceed the link margin. Since both systems have sufficient link margin, other factors should

be considered such as in-band interferers. If the autopilot wireless link uses the 900-MHz band, there is potential interference for that radio. It would then be better to choose one of the 2.4-GHz channels.

4. Define possible radios. The link budget in Step 3 guides the choices of possible radio solutions. After possible radios are chosen, additional link budget comparisons can be made for final selections. Other considerations when choosing a radio are:
 - (a) What I/O interfaces are available from devices connected to the radio? Typical radio interfaces available are mini-PCI and PCI-Express. There are also radios available for connecting to the USB or Ethernet busses.
 - (b) What antenna connectors are available on the radios? A smaller connector, such as an SMA, is much lighter than the bulky N connector.
 - (c) Select antennas based on required coverage of the mission area. Directional antennas are not feasible on a small UAV because there isn't a sufficient weight budget to carry a pointing device. Also, the more directional an antenna is, the larger it is. Thus, small UAVs use omnidirectional antennas. On the other hand, the ground station can use a directional antenna if the UAV mission area is away from the ground station such that the UAVs will remain within the 3 dB beamwidth of the antenna.
5. Does any radio meet the communication system constraints?
6. Introduce WPV factors to make the final decision. Reduction in weight and power can either leave more allowance for other payload subsystems or increase flight time.
7. If a solution cannot be found, identify what can be supported and work with the customer to develop new constraints. Multiple design loops are typically required to develop a robust system.
8. Is the only constraint that wasn't met due to having an insufficient link margin at the required distance?
9. A multi-hop solution may be possible. In a multi-hop solution, messages from a distant UAV are relayed by another UAV. Note that this requires a doubling of bandwidth for any multi-hopped messages since they are sent first by the originating UAV and then again by the relaying UAV. Also, standard 802.11 a/b/g access points do not support multi-hop so an ad hoc network would need to be created.

9.4.2 Single Board Onboard Computer Subsystem

Note that references to the SBC refer to the entire computing system, including storage devices. Figure 9.6 shows the design flow.

1. Define mission constraints.
 - (a) Mission time. Define how long the SBC will be running, both prior to takeoff and during the mission.
 - (b) Environmental requirements affect the selection of the SBC system.

- (i) Will the interconnection of the SBC with other systems handle shock and vibration?
 - (ii) Will a hard disk be a viable solution or must a solid-state disk (SSD) be employed?
 - (iii) Do expected humidity and temperature conditions affect the SBC choice?
2. Define payload constraints on the SBC system.
 - (a) What are the computing requirements for processing images?
 - (b) What are the computing requirements for control algorithms?
 - (c) What are the computing requirements for processing sensor outputs?
 - (d) What I/O is needed to interface to autopilot, sensors, and communications systems?
 - (e) What operating system is necessary to support software requirements?
 - (f) What is the weight allocation for the SBC system?
 - (g) What is the power allocation for the SBC system?
3. Develop performance budgets. Table 9.6 is an example that assigns the SBC resources to different software tasks.
4. Look for possible SBC solutions that meet the performance budgets. The solution must also consider storage requirements.
5. Were any SBCs found that meet the requirements?
6. If there were, does the SBC create any GPS noise?
7. If multiple choices exist, select the best choice using WPV factors. Reduction in weight and power can either leave more allowance for other payload subsystems or increase flight time.
8. If no viable computing solution can be found, new constraints must be negotiated with the customer.
9. If an onboard SBC solution can't be found, is a ground solution viable?
10. Can a solution to the GPS EMI issue be found?
 - (a) In attempts to minimize weight, an SBC without an enclosure may be selected. Without the enclosure, the Faraday cage that contains the EMI is not present and noise may interfere with GPS.
 - (b) Directly connecting an SSD to the SBC via the serial advanced technology attachment (SATA) bus will generate severe GPS noise. SATA generates broadband noise to over 2 GHz. If requiring an external drive, either choose a parallel bus or incorporate SBC and SSD enclosures that support E-SATA and use the shielded E-SATA cable between them.
11. Areas to consider for a ground-based computing solution:
 - (a) A faster computer that doesn't need to meet weight requirements could be available for ground use. If performing image processing, high-resolution images from the aircraft may be required. Larger images require greater communication bandwidth, which increases with the number of UAVs in use. Can the communications system handle this bandwidth?
 - (b) With all processing on the ground, what happens to the success of the mission if messages are lost?

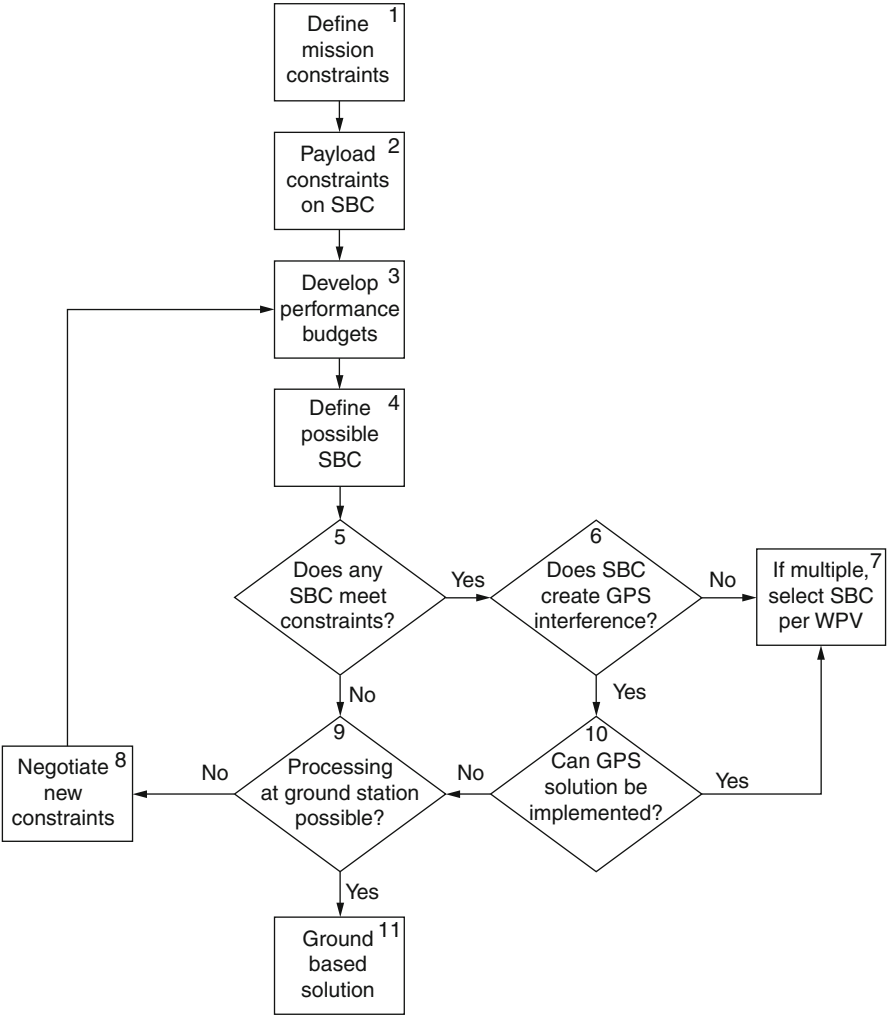

Fig. 9.6 SBC subsystem design flow

Table 9.6 Example of aircraft software budget table

| Priority | Component | CPU allocation (%) |
|----------|----------------------|--------------------|
| 1 | Image capture | 10 |
| 2 | Planning and control | 10 |
| 3 | Image processing | 45 |
| 4 | Data fusion | 15 |
| 5 | Housekeeping | 10 |
| Total | | 100 |

9.4.3 EO Sensor Subsystem

Though other sensors may be used, the electro-optical sensor is predominantly employed in small UAVs. This section presents design considerations for the EO sensor, but the methods can be readily applied to other types of sensors. The EO sensor subsystem includes the sensor hardware, image capture method, and any required gimbal mechanism for panning the sensor. Note that an inertial measurement unit (IMU) is not listed. For a small UAV, weight considerations limit the use of an IMU dedicated to the sensor. The aircraft attitude can be provided by the autopilot to the image processing system to geo-register the image. Figure 9.7 shows the design flow.

1. Define mission constraints.
 - (a) If multiple UAVs are used, is collision avoidance achieved through altitude separation? Would a camera with variable zoom level be needed so that a common ground footprint is maintained for all altitudes that will be used?
 - (b) Based on the target characteristics and ground coverage,
 - (i) What image processing techniques need to be employed?
 - (ii) Will sensor panning be required?
 - (iii) What image quality and size are needed?
 - (iv) How many images per second are required to process?
 - (c) Environmental requirements.
 - (i) Will aircraft vibration impact image quality and registration?
 - (ii) Will the sensor meet humidity requirements? Will it meet shock requirements?
2. Determine constraints from rest of payload. The EO sensor needs to comply with its allocation of weight, power, and volume, but it also drives the SBC computational requirements. The image processing algorithm selection needs to consider a reasonable SBC capability for a small UAV. Sensor fusion techniques may be employed to account for inaccuracies in the image processing results.
3. Develop a decision matrix for the EO sensor. Table 9.7 presents an example decision matrix with three possible candidates.
4. Define possible EO sensors. Two general types of EO sensors are typically employed: analog and digital. The analog sensor either complies to National Television System Committee (NTSC) or Phase Alternation Line (PAL) formats, with NTSC common in the U.S. and PAL common in Europe. An analog sensor requires an image capture board to convert the image stream to individual images in a common digital format such as Joint Photographic Experts Group (jpeg). Digital sensors provide an image that can be directly processed, usually in a raw format.

Each manufacturer of an EO sensor has specifications for their product, but the specifications don't provide sufficient information to determine if the color quality will meet the project's image quality requirements. After defining the best candidates, samples should be purchased so that image quality can be evaluated for the project's application.

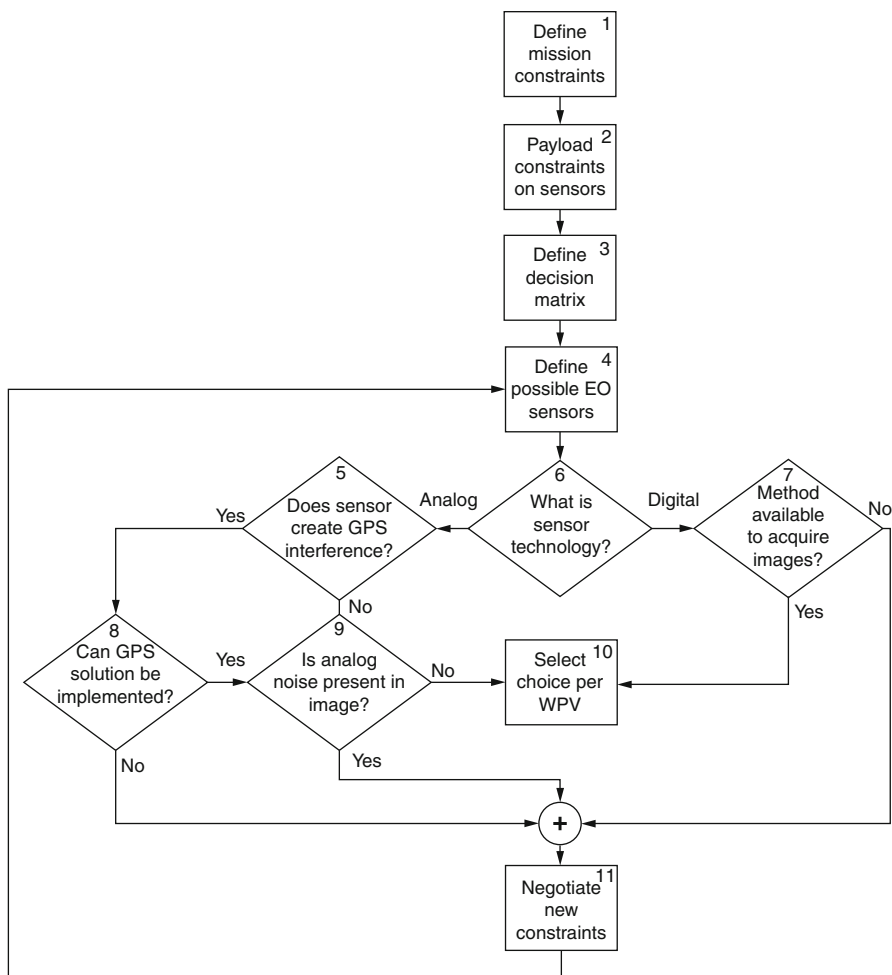

Fig. 9.7 EO sensor subsystem design flow

5. Will the analog sensor generate GPS noise? Though a digital EO sensor should also be checked, NTSC analog sensors use a clock speed that has a harmonic signal at the GPS frequencies. This noise is further increased during the image capture process. PAL analog EO sensors use a different frequency and do not generate the same noise.
6. Determine path between analog and digital.
7. Many digital EO sensors do not directly connect to a common SBC bus such as USB or Ethernet; thus, a field programmable gate array interface must be used. Test interface units are typically available from the manufacturer of the EO sensor though they tend to be bulky and don't have robust connections. Some complete sensors are available with either Ethernet or USB interfaces.

Table 9.7 Comparison of pan-tilt-zoom camera systems

| | AXIS-212 PTZ (http://www.axis.com/products/cam_212/) | WV-SC385 (http://panasonic.net/pss/security/products/hd/wv-sc385/index.html) | EVI-D100 (http://pro.sony.com/bbsec/ssr/cat-industrialcameras/cat-robotic/product-EVID100/) |
|------------------------------|--|--|--|
| Manufacturer | Axis communications | Panasonic | Sony |
| Image sensor type | 1/2" CMOS | 1/3" CMOS | 1/4" Super HAD CCD |
| Pixel resolution | 640 × 480 | 1,280 × 960 | 768 × 494 |
| Frame rate (fps) | 30 | 30 | 30 |
| Video signal output | HTTP/FTP (digital) MPEG-4 JPEG | HTTP/FTP (digital) H.264 JPEG | NTSC (analog) Y/C |
| Pan/tilt | ±70°/±52° (electronic) | 0–350°/–30 to 90° (mechanical) | ±100°/±25° (mechanical) |
| Zoom | 3× electronic zoom | 18× optic + 12× digital zoom (3.2–55.2° (H)/2.4–42.1° (V) AOV) | 10× optic + 40× digital zoom (6–65° AOV) |
| Weight (g) | 504 | 900 | 860 |
| Dimension (mm ³) | 89 × 94 × 77 | 115 × 115 × 155 | 113 × 130 × 122 |
| Power consumption (W) | 3.6 | 12.0 | 13.2 |

8. GPS EMI may be mitigated using a PAL versus NTSC sensor. If the UAV is large enough, separating the analog sensor and capture board from the GPS antenna may sufficiently mitigate the GPS interference.
9. Most analog sensors interlace its image which means that it creates all odd lines in an image and then the even lines of the image. This can create jagged edges since the UAV is moving while the odd lines are captured followed by the capture of the even lines. The performance of edge detection algorithms are impacted by the jagged edges.

Other considerations:

- If an analog sensor is used and images are transmitted to the ground station for processing, additional noise will be introduced from the analog wireless transmission.
- If a greater pan angle is required just for orbiting an object, mounting the sensor at an angle and then always orbiting in the direction that uses the desired tilt of the camera may eliminate the need for a more cumbersome gimbal system.

9.4.4 Power Subsystem

The power system includes batteries and DC-DC converters. Figure 9.8 shows the design flow.

1. Define mission constraints.
 - (a) Flight time will define the amount of battery capacity required for the mission. If the payload operates for a while on the ground before a UAV

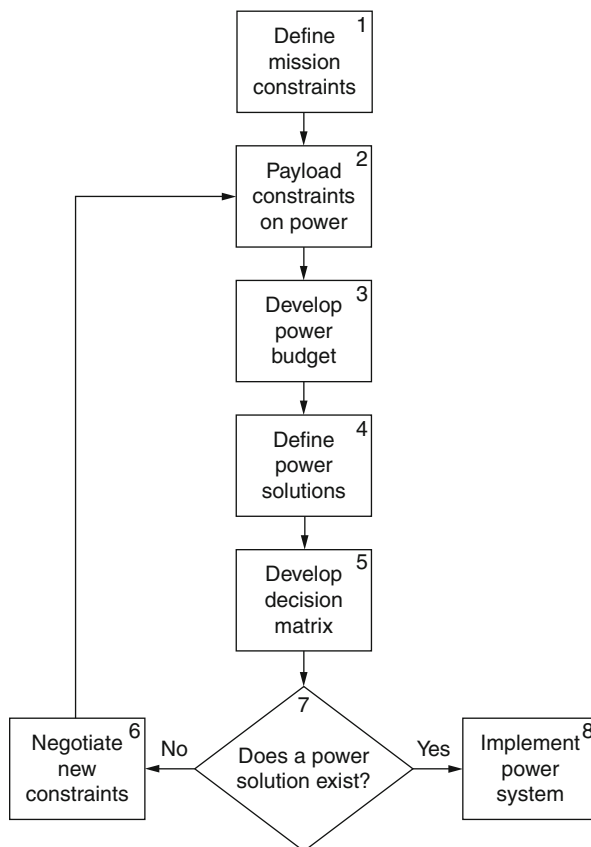

Fig. 9.8 Power subsystem design flow

takes off, additional capacity is needed. A battery backup switch may be employed which allows an external battery to be connected while on the ground and then removed before take-off. With a properly designed battery backup switch, the payload does not see a drop in voltage when the external battery is removed.

2. Payload constraints on the power system.
 - (a) What is the weight allocation for the power system?
 - (b) As subsystem designs evolve, are additional power requirements identified?
3. While completing the subsystem design, verify the power budget using the technique displayed in Table 9.1.
4. Nickel metal hydride (NiMH) and lithium polymer (li-po) batteries are the most common choices of battery technology in use for UAVs. Table 9.8 presents a comparison of the two types. Though a li-po is more expensive, it is a better choice for UAVs because of the higher power density for the same weight. Special care must be taken with li-po technology to ensure that no overcharging occurs and that the batteries are not discharged to less than 3 V per cell.

Table 9.8 Battery trade analysis

| Criteria | Nickel metal hydride | Lithium polymer |
|---------------------|-------------------------|-----------------|
| Cost | Half of lithium polymer | Expensive |
| Rechargeable | Yes | Yes |
| Volume (cu. in.)/AH | 13.6 | 6.6 |
| Weight (ounces)/AH | 18.1 | 6.9 |
| Charge rate (Amps) | 1 | 8 |

5. DC-DC conversion is done with a switching power supply. DC-DC ATX supplies that have been developed for use in automobiles are a good choice. They can use a wide input voltage range and output 3.3-, 5-, and 12-DC voltages that are commonly used by SBCs, sensors, and communication systems.
6. If a power solution is not feasible, a new design needs to be considered with new constraints.
7. If no viable power solution can be found, new constraints must be negotiated with the customer.
8. Decision box regarding existence of viable power solution.
9. Implement the selected power system, always recognizing opportunities to reduce weight and size wherever possible.

9.5 Other Payload Design Considerations

- Flight Time Restrictions: Most small UAV missions will be flown during good visibility and daylight hours so that the aircraft can always be observed in case of erratic behavior. Select sensors to optimize this time of day. Thermal sensors have difficulty identifying targets against warm backgrounds.
- Gas engines create greater vibration than electric motors. If a gas engine is required to increase the flight duration, place a vibration reduction mechanism at the engine instead of each of the payload subsystems.
- Autopilots and thermal cameras often fall under U.S. International Traffic in Arms Regulations (ITAR). Even though you may not be shipping these items to foreign countries, they also cannot be used by foreign nationals located at the facility. Also, if any software that directly communicates with the drivers of these products is also ITAR controlled, it must comply with the same restrictions.
- An autopilot with hardware in the loop (HIL) capability will greatly help in development of control algorithms. The SBC can be directly connected to the autopilot, and the control software can be executed in flight simulators.

Conclusion

In this chapter, payload design principles for small UAVs were discussed and proposed. An example based on a system design used by the USAF Academy Center for Unmanned Aircraft Systems Research described various issues and the corresponding solutions for a system with an autonomous ground target detection

and tracking intelligence, surveillance, and reconnaissance mission. In more detail, mission requirements (budget allocations for power, weight, and volume; and individual subsystem design) were explained with commercial hardware examples.

Abstract

This chapter describes a rationale for selecting a low-risk UAV (Unmanned Aerial Vehicle) configuration and a methodology for sizing and optimizing the shape of both fueled and electric-powered aircraft. Three examples are given of low-risk UAV configurations. These are shown to be essentially similar from the point of view of optimization and sizing. The sizing methodology for fueled aircraft is described in detail, and a similar one for electric-powered aircraft is

described to the extent that it differs from that for fueled aircraft. The chapter also gives typical values of technology-related parameters used in sizing calculations. It then shows an example of a small UAV designed using this methodology. The UAV design project showed that the methodology is useful in obtaining aircraft of minimum size for the performance and payload required.

10.1 Introduction

The two important questions which a small UAV designer must answer about the air vehicle itself are “What will this aircraft look like?” and “How big will it be?” This chapter describes a rationale for selecting a low-risk UAV configuration and a methodology for sizing and optimizing the shape of both fueled and electric-powered aircraft. It then shows an example of a small UAV designed using this methodology.

10.2 Configuration Selection

To answer the question “What will it look like?,” the savvy UAV designer might easily just ask “What do most other small UAVs look like?” Indeed, there is a very Darwinian process in the small UAV industry that tends to eliminate designs that are less useful, have less performance, or are more expensive and more difficult to use. Figure 10.1 illustrates three aircraft configurations commonly used in small UAVs. Note their similarities.

Although they do not look exactly alike, the three example UAV designs in Fig. 10.1 all employ a single main lifting wing placed high on the fuselage and a stabilizing tail aft. Since the days of the Wright brothers, this general configuration, as opposed to canard or tailless flying wing configurations, has proven most successful. For reasons why, see Brandt (2004).

The three configurations above differ in the details of their aft stabilizing surfaces or empennages. The left-hand one has an inverted T-tail arrangement with the vertical stabilizer and rudder mounted on top of a horizontal stabilizer and elevator. The middle one employs a V-tail which combines the horizontal stabilizing surfaces into a V-shape and combines the rudder and elevators into “ruddervators.” The right-hand design adds to the V a downward-projecting vertical surface. Historically, none of these tail arrangements has proven significantly better than the others, so the choice is left as a matter of preference for the designer.

The other main differences in the three configurations in Fig. 10.1 are the placement of the motor/propeller and the consequent shape of the rear fuselage. The two left-hand designs place their motor/propellers in the front, while the third places it at the aft end of the fuselage. The aft-facing motor/propeller then requires the extra downward-projecting vertical tail to protect it from hitting the ground on landing.

Fig. 10.1 Typical UAV designs

In general, aft-facing motor/propellers have more cooling difficulties and result in heavier designs. The decision to use such a configuration would probably result from a design requirement to keep the nose area of the UAV clear for sensors or other mission payloads. If such a requirement does not exist for a particular design, then a forward placement of the motor/propeller is preferred.

Neither of the main differences in the typical UAV designs just described has a large effect on the sizing and optimization which answers the second question “How big will it be?” Because aft placement of the motor/propeller usually results in a slightly heavier aircraft structure, it usually has a slight effect on the aircraft size. For initial UAV sizing and optimization, this slight effect can be ignored.

Sizing and optimization methodologies differ somewhat between fueled aircraft and those that use electric power. This chapter will describe methods for both types of aircraft.

10.3 Fueled Aircraft Sizing and Optimization

The main difference between fueled and battery-powered aircraft is in the way the aircraft weight changes during the mission. For fueled aircraft, fuel is burned during the mission, so the aircraft’s weight decreases as the mission unfolds. In general,

the weight of battery-powered aircraft does not change unless payload is dropped or otherwise released during the mission. Also, the amount of energy which can be extracted from a given mass of fuel is at present much higher than can be extracted from a similar mass of batteries. For these two reasons, fueled aircraft are often the least expensive way to achieve extremely long flights.

10.3.1 Sizing Equation

The central equation in this analysis is a simple statement that the sum of the weights of the various components of the aircraft must equal the aircraft total weight:

$$W_{TO} = W_{airframe} + W_{payload} + W_{engine} + W_{f_{mission}}$$

When divided by the wing area, the equation expresses the equality between the wing loading of the aircraft and the sum of the portions of that wing loading due to each of the components:

$$\frac{W_{TO}}{S} = \frac{W_{airframe}}{S} + \frac{W_{payload}}{S} + \frac{W_{engine}}{S} + \frac{W_{f_{mission}}}{S}$$

The total wing loading, the left side of the equality, is usually chosen in order to allow the aircraft to meet performance requirements specified by the customer. That analysis is called constraint analysis. The payload is specified by the customer, the airframe and engine wing loading portions are obtained from weight analysis, and the wing loading portion for mission fuel burn is obtained from the mission fuel fraction calculated in mission analysis. The strategy for using this equation to size and optimize the aircraft involves determining values for all but the payload wing loading portion term and then using the weight of the required payload to solve for the required wing reference planform area, S . The resulting equation is called the sizing equation:

$$S = \frac{W_{payload}}{\frac{W_{TO}}{S} - \frac{W_{airframe}}{S} - \frac{W_{engine}}{S} - \frac{W_{f_{mission}}}{S}} \quad (10.1)$$

10.3.2 Aerodynamic Analysis

All of the analysis that follows depends on having good models for the aerodynamics of the UAV being sized. Methods for predicting aerodynamics of small subsonic aircraft are abundant and have acceptable accuracy. See Brandt (2004) for a simple, accurate aerodynamic prediction method. In many cases, a model of the UAV configuration in question may be tested in a wind tunnel for even better accuracy.

10.3.3 Constraint Analysis

Constraint analysis is a method for defining a solution space such that all design points within that space allow the aircraft to satisfy all of the customer's performance requirements. The design points are defined by combinations of wing loading, W_{TO}/S and thrust-to-weight ratio, or thrust loading, T_{SL}/W_{TO} , where W_{TO} is maximum takeoff gross weight and T_{SL} is sea-level static maximum thrust, that is, the maximum thrust the aircraft propulsion system can produce at sea level when the aircraft is sitting still on the ground. The equation for constraint analysis is based on a modification of the equation for specific excess power. Power is the rate of doing work, so for an aircraft thrust power is the thrust produced by the aircraft's propulsion system, T , multiplied by the aircraft's velocity, V . Excess thrust is the difference between the aircraft's thrust and its drag, D . Drag is the resistance created by the air to the aircraft's motion through it. Excess power is the excess thrust multiplied by the aircraft's velocity and specific excess power is the excess power divided by the aircraft's weight. Specific excess power, P_s , is a measure of the aircraft's ability to increase its energy either by climbing or accelerating. All of these ideas are captured in the following equation for specific excess power:

$$P_s = \frac{(T - D)V}{W} = \frac{dh}{dt} + \frac{V}{g} \frac{dV}{dt}$$

where T is thrust, D is drag, W is weight, V is true airspeed, h is altitude, and g is the acceleration of gravity. Dividing by velocity yields

$$\frac{T}{W} - \frac{D}{W} = \frac{1}{V} \frac{dh}{dt} + \frac{1}{g} \frac{dV}{dt} \quad (10.2)$$

The master equation for constraint analysis is obtained by substituting the following relations into (10.2): $T = \alpha T_{SL}$, where α is the ratio of available thrust to maximum sea level static thrust. Available thrust is the maximum thrust an aircraft is able to produce at full throttle for a given flight condition.

$W = \beta W_{TO}$, where β is the specified weight fraction for that design requirement. This is usually specified as a value of 1 for takeoff and a value based on full payload and 50 % internal fuel for most mission performance constraints.

$q = \frac{1}{2} \rho V^2$ is a quantity called dynamic pressure. In the equation for q the symbol ρ represents the air density.

The drag on the aircraft for a given flight condition is represented by a drag coefficient C_D multiplied by dynamic pressure and the reference planform area of the wing, S . Planform area is the area of the shadow of the wing when the sun is directly overhead, including the shadow of the part of the wing that is inside the aircraft's fuselage. The expression for C_D in turn is a quadratic equation called the aircraft's drag polar. The drag polar has three constants and a variable called lift coefficient, C_L . Lift coefficient is related to the actual lift produced by the aircraft in the same way that drag coefficient is related to the aircraft's drag. The constants

in the drag polar are zero-lift drag coefficient C_{D_o} , the induced drag factor k_1 , and a camber effect term, k_2 .

When an aircraft is producing zero lift, $C_L = 0$ and $C_D = C_{D_o}$. When an aircraft produces lift, normally when it is flying, additional drag results from swirling tornado-like vortices which form at the wingtips. This additional drag-due-to-lift is modeled by the k_1 term in the drag polar. Wings with special shaping called camber have less drag for a given amount of lift, an effect modeled by the k_2 term in the drag polar. The value of k_2 is usually negative while k_1 is positive in a typical aircraft drag polar:

$$D = C_D q S = (C_{D_o} + k_1 C_L^2 + k_2 C_L) q S$$

$$C_L = \frac{L}{q S} = \frac{n W}{q S}$$

These substitutions produce the “master equation” for constraint analysis:

$$\begin{aligned} \frac{T_{SL}}{W_{TO}} = \frac{q}{\alpha} \left[\frac{C_{D_o}}{\left(\frac{W_{TO}}{S} \right)} + k_1 \left(\frac{n\beta}{q} \right)^2 \left(\frac{W_{TO}}{S} \right) + k_2 \left(\frac{n\beta}{q} \right) \right] \\ + \frac{\beta}{\alpha} \left[\frac{1}{V} \frac{dh}{dt} + \frac{1}{g} \frac{dV}{dt} \right] \end{aligned} \quad (10.3)$$

The master equation is written in a form that expresses the minimum T_{SL}/W_{TO} which can achieve a given performance requirement at a particular value of W_{TO}/S . A separate form of the master equation is written using values of velocity, load factor, acceleration, rate of climb, etc., for each design requirement specified by the customer. Lines representing these equations are plotted as boundaries on a thrust-to-weight ratio vs. wing loading diagram. Combinations of design thrust-to-weight ratio and wing loading which fall outside the boundary specified by each constraint result in an aircraft design which will not meet that design requirement. When all the constraint boundaries are plotted, they define a solution space which, for all combinations of thrust-to-weight ratio and wing loading within the space, allows the aircraft to meet all the design requirements. Figure 10.2 illustrates a typical constraint diagram. Ideal and actual design points are shown by the circle and plus sign on the plot.

The design point chosen on the constraint diagram specifies the value of W_{TO}/S to be used in the sizing equation. It also specifies the value of T_{SL}/W_{TO} which, with a little manipulation, produces the value of W_{engine}/S required to solve the sizing equation. This manipulation requires only a knowledge of the technology level of the engine, as expressed by the thrust-to-weight ratio of the engine itself, T_{SL}/W_{engine} . With this value in hand, W_{engine}/S is calculated as follows:

$$\frac{W_{engine}}{S} = \frac{\frac{T_{SL}}{W_{TO}} \frac{W_{TO}}{S}}{\frac{T_{SL}}{W_{engine}}}$$

Fig. 10.2 Typical constraint diagram

10.4 Mission Analysis

Mission analysis uses the aircraft's drag polar and the design point determined from constraint analysis, plus an appropriate model for engine thrust-specific fuel consumption, to predict the amount of fuel the aircraft will burn on its design mission(s). The master equation for mission analysis is essentially the time integral form of the constraint analysis master equation substituting actual thrust for thrust available and multiplying by thrust-specific fuel consumption, c , to yield fuel flow rate:

$$cT = -\dot{W}_f$$

The minus sign in front of fuel flow rate indicates that aircraft weight decreases as fuel is burned. The integral of fuel flow rate yields fuel burn which, divided by weight, is the fuel fraction:

$$\begin{aligned} \int_{t_0}^{t_1} \frac{cT}{W_{TO}} dt &= \int_{t_0}^{t_1} \frac{-\dot{W}_f}{W_{TO}} dt \\ &= \int_{t_0}^{t_1} c q \left[\frac{C_{D_o}}{(W_{TO}/S)} + k_1 \left(\frac{n\beta}{q} \right)^2 \left(\frac{W_{TO}}{S} \right) + k_2 \left(\frac{n\beta}{q} \right) \right] dt \\ &\quad + \int_{t_0}^{t_1} c\beta \left[\frac{1}{V} \frac{dh}{dt} + \frac{1}{g} \frac{dV}{dt} \right] dt \end{aligned}$$

which is easily integrated for the most common cases of constant velocity climbs and cruise, constant altitude accelerations, and for relatively short mission legs where it is acceptable to assume the aircraft's drag polar and weight fraction are approximately constant:

$$\begin{aligned} \frac{W_0 - W_1}{W_{TO}} &= \frac{\Delta W_f}{W_{TO}} = \\ &= c_q \left[\frac{C_{D_0}}{(W_{TO}/S)} + k_1 \left(\frac{n\beta}{q} \right)^2 \left(\frac{W_{TO}}{S} \right) + k_2 \left(\frac{n\beta}{q} \right) \right] (t_1 - t_0) \\ &\quad + c\beta \left[\frac{1}{V} (h_1 - h_0) + \frac{1}{g} (V - V_0) \right] \end{aligned} \quad (10.4)$$

Equation (10.4) is known as the master equation for mission analysis. Note that W_{TO}/S in (10.4) is, for this analysis, a constant, since it was chosen as a result of constraint analysis. The assumption of constant β is not acceptable for long cruise or loiter legs, and the assumption of constant drag polar is not acceptable for transonic accelerations, but these are easily accommodated in computer implementations of the method by breaking long legs into many similar short legs.

When the mission analysis master equation is applied to each leg of a typical design mission, the fuel fractions from all preceding legs of the mission are used to determine the weight fraction for each subsequent leg. When the fuel fractions for each leg are summed, the total fuel fraction for the mission is obtained:

$$\begin{aligned} \beta_{takeoff} &= 1 \quad (\text{since } W = W_{TO}) \\ \beta_{accel} &= \beta_{takeoff} - \frac{W_{f_{takeoff}}}{W_{TO}} \\ \beta_{c\ lim\ b} &= \beta_{accel} - \frac{W_{f_{accel}}}{W_{TO}} \\ \beta_{cruise} &= \beta_{c\ lim\ b} - \frac{W_{f_{climb}}}{W_{TO}} \\ \beta_{loiter} &= \beta_{cruise} - \frac{W_{f_{cruise}}}{W_{TO}} \\ \frac{W_{f_{mission}}}{W_{TO}} &= \frac{W_{f_{takeoff}}}{W_{TO}} + \frac{W_{f_{accel}}}{W_{TO}} + \frac{W_{f_{climb}}}{W_{TO}} + \frac{W_{f_{cruise}}}{W_{TO}} + \frac{W_{f_{loiter}}}{W_{TO}} \end{aligned}$$

$W_{f_{mission}}/W_{TO}$ is known as the design mission fuel fraction. It is multiplied by the design point wing loading to yield the value of $W_{f_{mission}}/S$ needed to solve the sizing equation:

$$\frac{W_{f_{mission}}}{S} = \frac{W_{f_{mission}}}{W_{TO}} \frac{W_{TO}}{S}$$

10.5 Weight Analysis

Once mission analysis has predicted the mission fuel burn and fuel fraction, weight-estimating methods are used to predict the structural weights per unit area of the airframe components. For a small UAV, it is often adequate to weigh a similar UAV airframe to obtain approximate weights per area for the various airframe components. Whether predicted or measured, the component weights per unit area are then scaled by the ratios of their component reference areas to the UAV reference planform area and summed to obtain the airframe wing loading portion needed to solve the sizing equation. Once a value of S is determined, it may be multiplied by the design point wing loading to obtain the sized takeoff gross weight:

$$W_{TO} = S \left(\frac{W_{TO}}{S} \right) \quad (10.5)$$

The results obtained in (10.1) and (10.5) are final, provided some other size or volume constraints, such as the dimensions of the payload, do not force redesign of the aircraft configuration. The entire aircraft is just scaled up or down as necessary to achieve the specified wing area.

It is more common, however, that the fuselage of a small UAV is sized by payload dimensions, so that when the aircraft is sized up or down, the fuselage size remains unchanged. In this common situation, after resizing, the entire analysis must be accomplished again. This is because resizing the wing and tail without resizing the fuselage changes the aircraft's drag polar. Since drag polar is one of the required inputs to constraint analysis, constraint analysis must be reaccomplished, yielding new values for wing loading and thrust loading. A change in the configuration also changes the value of the airframe wing loading portion, and a new solution to the sizing equation results. The process must be repeated iteratively until a converged solution is obtained. Convergence may require human intervention, since the numerical scheme is not necessarily stable. In addition, the savvy UAV designer will explore variations of the configuration to find the optimum design, that is, that design which can meet all the customer's requirements for the lowest cost.

10.6 Electric Aircraft Sizing and Optimization

The use of electric power in small UAVs has increased significantly as cost and weight of batteries have decreased. The advantages of batteries over chemical fuels for UAV storage, transportation, and deployment are obvious. As battery performance continues to improve, a larger proportion of UAVs will likely use electric power.

10.6.1 Sizing Equation

The sizing methodology for electric-powered aircraft is based on a similar analysis for solar-powered aircraft described in Brandt and Gilliam (1994). As in the method for fueled aircraft, the central equation in this analysis is a simple statement that the sum of the weights of the various components of the aircraft must equal the aircraft total weight.

When divided by the wing area, the equation expresses the equality between the wing loading of the aircraft and the sum of the portions of that wing loading due to each of the components:

$$\frac{W_{Takeoff}}{S} = \frac{W_{Airframe}}{S} + \frac{W_{Battery}}{S} + \frac{W_{Motor \& Prop}}{S} + \frac{W_{Payload}}{S}$$

The strategy in using this equation to size and optimize an electric aircraft is identical to that used to obtain Eq.(10.1) for fueled aircraft and the resulting equation is similar:

$$S = \frac{W_{payload}}{\frac{W_{TO}}{S} - \frac{W_{aircraft}}{S} - \frac{W_{battery}}{S} - \frac{W_{motor}}{S}} \quad (10.6)$$

As for fueled aircraft, total wing loading is usually chosen in order to allow the aircraft to meet performance requirements specified by the customer, commonly represented on a constraint diagram such as Fig. 10.3. The details of constraint analysis for electric aircraft are identical to those for fueled aircraft, except that the thrust lapse, α , for electric aircraft behaves somewhat differently. From a constraint diagram the designer selects values for wing loading and thrust or power loading which will allow the aircraft to meet the customer's needs. In the case of Fig. 10.2, the selected values are $W_{TO}/S = 1.1$ and $T/W_{TO} = 0.21$.

The thrust values graphed in the constraint diagram are specified as those at static sea level conditions. Wind tunnel tests of the motor and propeller may be used to correct the thrust required for each of the constraints to sea level static values for plotting.

10.6.2 Airframe Wing Loading Portion

As with fueled aircraft, determining a value for the airframe wing loading portion involves determining representative values for similar aircraft and estimating what is achievable with current and future structures and materials technology. Since weights of aircraft components typically vary with their areas, this airframe wing loading portion, once calculated for a given aircraft configuration, will not vary significantly as the aircraft is sized up or down. A nominal value for airframe wing loading portion for a conventional configuration small UAV constructed of carbon fiber and epoxy composite skin over a Styrofoam core is 0.2 lb/ft².

Fig. 10.3 Example small UAV constraint diagram

10.6.3 Battery Wing Loading Portion

The weight of the battery depends on the level of battery technology, represented by its energy density, e , the efficiency of the motor and propeller, η_{motor} and η_{prop} , and the total thrust energy which the motor and propeller must provide to overcome the aircraft’s drag and to increase the aircraft’s mechanical energy by climbing or accelerating. The total thrust energy required will therefore depend on the details of the design mission profile. Figure 10.4 illustrates the mission profile for a small backpack UAV.

For this mission, the only change in energy occurs immediately after launch, when the aircraft climbs 500 ft. above its launch altitude. Throughout the mission, the aircraft will fly at an approximately constant speed, and since its weight will not change, neither will its drag. As a result, the total thrust energy required for the mission is given by

$$E = W_{TO}\Delta h + DVt \tag{10.7}$$

where Δh is the change in altitude during the initial climb, D is the drag throughout the mission, V is the velocity, and t is the total mission duration. The required weight of the battery is the total energy which must be provided by the battery divided by the battery’s energy density. This energy provided by the battery must be enough so that after losses in the motor and propeller, modeled by efficiency factors for these devices, there is useable thrust energy equal to that required by (10.7).

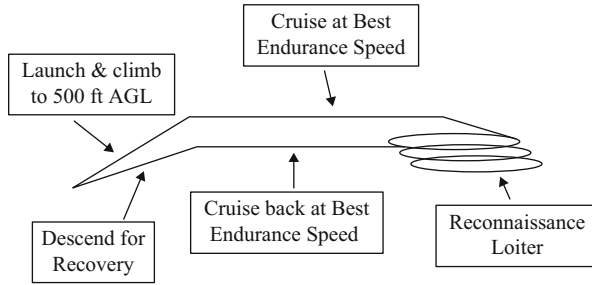

Fig. 10.4 Backpack UAV general mission profile

If, as is the case in the mission profile of Fig. 10.3, the energy to climb is small compared to the total energy required for the mission, then the weight of the battery required is approximated by

$$W_{\text{Battery}} = \frac{DVt}{e\eta_{\text{Motor}}\eta_{\text{prop}}} \quad (10.8)$$

Dividing (10.8) by the aircraft weight, W_{TO} , which is equal to the required lift, L , yields

$$\frac{W_{\text{Battery}}}{W_{TO}} = \frac{Vt}{\frac{L}{D} e\eta_{\text{Motor}}\eta_{\text{prop}}} \quad (10.9)$$

Note that the ratio L/D in (10.9) is a common means of describing the aerodynamic efficiency of an aircraft and is a function of the aircraft configuration and flight conditions. For the simple mission profile being considered, L/D will be essentially constant throughout the mission. Multiplying (10.9) by the total wing loading chosen from constraint analysis yields

$$\frac{W_{\text{Battery}}}{S} = \frac{W_{\text{Battery}}}{W_{\text{Takeoff}}} * \frac{W_{\text{Takeoff}}}{S} = \frac{W_{\text{Takeoff}}}{S} \frac{Vt}{\frac{L}{D} e\eta_{\text{Motor}}\eta_{\text{prop}}} \quad (10.10)$$

10.6.4 Motor and Prop Wing Loading Portion

Finally, the motor and propeller wing loading portion is estimated using the thrust loading and wing loading obtained from constraint analysis and an estimate of available motor and propeller technology expressed as a motor and prop thrust-to-weight ratio:

$$\frac{W_{\text{Motor}}}{S} = \frac{T}{W_{\text{Takeoff}}} * \frac{W_{\text{Motor}}}{T} * \frac{W_{\text{Takeoff}}}{S} \quad (10.11)$$

The motor and prop thrust-to-weight ratio, along with values for η_{motor} and η_{prop} , may be obtained by testing several typical motor/prop combinations in a low-speed wind tunnel. Figure 10.5 illustrates the results of a typical test. It plots the variation of motor and propeller efficiency for the best motor/propeller combination tested, as a function of free-stream velocity.

Fig. 10.5 Variation of efficiency with forward velocity for typical small UAV electric motor and propeller

10.6.5 Solving the Sizing Equation

With all terms evaluated, Eq. (10.6) is solved for planform area. As with fueled aircraft, this result is then used in Eq. (10.5) to solve for sized takeoff gross weight. The results are final provided payload volume or some other size constraint does not force a change to the configuration. In the common case where the fuselage must remain a constant size while the wing is sized up or down, the resulting new configuration will require an updated drag polar and weight model. This in turn will require a complete new iteration through the sizing method. Frequently, several iterations are required to reach a final solution. This numerical scheme may be unstable, so human intervention may be required to enforce convergence. In general, adjusting the wing area to an average between that modeled in the previous iteration and that recommended by the new solution to the sizing equation will lead to faster convergence.

In the extreme case, the analysis may not converge. This typically happens when specified mission duration is too long. When this occurs, radical changes to the configuration or radical new technologies like increased battery energy density may be required to meet the requirements.

10.6.6 Optimization

The configuration modeling, aerodynamic analysis, constraint analysis, and sizing cycle just described can be repeated for a variety of aircraft configurations. If configuration parameters such as wing sweep, aspect ratio, airfoil thickness, and camber are varied systematically, an optimization carpet plot such as Fig. 10.6 can be obtained. From such a plot, an optimum wing planform or other configuration characteristic can be selected, which minimizes the aircraft size while still meeting all customer requirements.

Fig. 10.6 Typical wing optimization carpet plot

10.6.7 Example: The Red Falcon

Results of a recent UAV design effort at the United States Air Force Academy (USFA) will illustrate how the method may be applied to a typical UAV design problem. The example design problem required a UAV small enough to fit in a backpack and when deployed able to carry a small spy camera, as depicted in Fig. 10.7. This camera, with its built-in downlink transmitter and its power supply weighed approximately 100 g or slightly more than 3 ounces. The design team selected rechargeable lithium-ion batteries, with an energy density of 68 W-h/lb, as their power source. The team measured motor and propeller efficiencies during wind tunnel testing. They also performed wind tunnel tests of several candidate aircraft configurations including pusher, canard, and flying wing variations but in the end settled on a conventional tractor propeller, tail aft configuration with an unswept wing with an aspect ratio (AR) of 4. Figures 10.8 and 10.9 illustrate the wing sweep and aspect ratio optimization plots for this configuration. In the end, an aspect ratio of 4 was selected for ease of packaging in the backpack and because the decrease in size for higher aspect ratios was minimal.

The above design decisions led to an aircraft configuration which sized to a wing area of slightly over 1 ft² and a maximum design flying weight of slightly over 1 lb. The aircraft, named the “Red Falcon,” is shown in Fig. 10.10. This aircraft flew a number of flight test missions to verify performance predictions and flying qualities. Although it never went into production, it provided a sizing example for a number of subsequent UAV developments. It served to verify the validity of the methodology described in this chapter and the practicality of using a small UAV for this design mission.

Fig. 10.9 Wing aspect ratio optimization plot

Fig. 10.10 The Red Falcon

10.7 Conclusion

This chapter has presented a rationale for the UAV designer to choose an aircraft configuration and a methodology for sizing it. By iteratively changing such aircraft configuration parameters as wing aspect ratio and camber, the designer can determine the smallest/cheapest UAV that can meet the design mission. This process is one way to optimize UAV designs for maximum performance and minimum size/cost.

Abstract

This chapter presents a guideline to systematically design and construct an ultralight micro aerial quadrotor vehicle, capable of autonomous flight. The guideline details the steps to design a stable quadrotor with not more than 50 g takeoff weight while having a flight duration of 8 min. Optimization was done to all mechanical parts of the vehicle with the constraints of its weight and

its performance. The guideline first covers the structural analysis of the micro quadrotor air frame, followed by its design in a 3D virtual simulator. Then, design of avionic system such as processor and sensors will be discussed, followed by controller implementation with the aid of software simulation. Components of the micro quadrotor are then fabricated and implemented based on the optimum results obtained from various simulations. Finally, the feasibility of the constructed aircraft is tested and confirmed with real flight missions.

11.1 Introduction

With more requirements imposed on unmanned aerial vehicle (UAV) for military tasks of surveillance, reconnaissance, and detecting in obstacle-rich areas, clandestine military bases, radiant areas, and other dangerous regions, the desire and interest in research of micro aerial vehicle (MAV), or even nano aerial vehicle (NAV), are aroused (Wang et al. 2011). These requirements involve higher intelligence for simultaneous localization and mapping (SLAM), path planning, and obstacle avoidance, along with battery technology to maintain long endurance flight and communication with the ground control station (Achtelik et al. 2009; Eresen et al. 2012; Meier et al. 2011; Phang et al. 2010). In the recent few decades, the development of integrated circuits and micro-electromechanical systems (MEMS) triggered the emergence of smaller and lighter electronics and mechanical systems. It provides the possibility to shrink the size and weight of the UAV to a new milestone.

In 1997, the Defense Advanced Research Projects Agency (DARPA) sets an official definition for MAV, which requires maximum dimension of the aircraft in any direction to be no greater than 15 cm and that the gross takeoff weight should not exceed 100 g, with up to 20 g devoted to payload. Based on these requirements, many UAV research groups initiated their MAV study with different design approaches, including fixed-wing, rotary-wing, flapping-wing, and other unconventional platforms (Al-Qadi et al. 2006; Michelson 2010; Petricca et al. 2011). One good example would be the Black Widow, an 80 g fixed-wing MAV developed by AeroVironment, which has a 15 cm wingspan and is claimed to be fully autonomous (Grasmeyer and Keennon 2011). It is, however, difficult for the fixed-wing platform to show its capability in indoor environments or cluttered outdoor environments such as forest and urban environment full of building and other obstacles, due to its limitation of hovering and vertically taking off and landing (VTOL) ability. Flapping-wing is a promising platform with its VTOL and hovering capabilities like that of an insect or a bird. In 2007, a 3 cm size flapping-wing MAV was developed by Harvard University, biologically mimicking the dipteran insects (Wood 2007). Unfortunately, there is no mature development of autonomous flapping-wing platforms due to the sophisticated flapping mechanism and wing structure aerodynamic analysis. Ducted-fan platform is also a possible approach for miniature aerial vehicle. A 150 g ducted-fan platform was developed by University of Bologna. This platform requires extra fins to control its attitudes, resulting in a large takeoff weight (Naldi et al. 2010).

Recently, due to its extreme stability and mechanical simplicity, quadrotor platforms have aroused the research interests of many researchers. There are, however, not many quadrotor MAV platforms lower than 50 g capable of autonomous flight. A research group from Stanford University has developed a micro quadrotor “Mesicopter”, with an impressive weight of 3 g. It is, however, unable to take off due to its rotor efficiency problem (Kroo and Kuns 2001). Mellinger and his collaborators from GRASP lab have been working on the formation flight of quadrotor MAVs weighing 60 g each and have achieved impressive results (Mellinger et al. 2010, 2012). From the perspective of the platform approach, rotary-wing platforms, especially in the form of quadrotor, have the advantages in maneuverability and mechanical feasibility.

In this chapter, a guideline to design a micro aerial quadrotor vehicle, or in short quadrotor MAV, with the following specifications will be presented:

1. Target weight not higher than 50 g
2. Largest dimension smaller than 15 cm in any direction
3. Flight duration of 8 min

Systematic design procedures with scopes of the design blueprint in virtual 3D environment, functionalities analysis in simulations, hardware selection and avionic system design, electrical circuit and software debugging, mathematical modeling and parameters identification, model simulation and verification, as well as aircraft orientation control with real flight test will be discussed in detail. In regard to this work, great effort was made to investigate the feasibility of overall structure and to evaluate the platform from the aspects of weight, size, and power consumption with both experiments and simulations before manufacturing, which guarantees a flyable and stable platform.

Main contents of this chapter are divided into five sections. Section 11.2 is the virtual design of the overall platform, with respect to mechanical structure and natural frequency analysis. Section 11.3 describes the hardware selection and avionic design procedures. Section 11.4 is the nonlinear mathematics model derivation concerning the aspects of kinematics, rigid body dynamics, and motor dynamics, followed by parameters identification methods and controller design. In Sect. 11.5, real flight test data is used to verify the mathematical model and control laws.

11.2 Virtual Design Environment

Before constructing the quadrotor platform, the design was done in virtual design environments. Differing from the usual UAV in larger scale, the natural modes of the structure or platform play an important role in determining the stability of the quadrotor MAV. As the aircraft gets smaller and lighter, the effect of its vibration due to natural modes is disastrous. Therefore in this section, two design processes in developing small-scale quadrotor MAV are proposed to systematically determine the optimum shape for the platform, in terms of lightweight and natural mode avoidance.

The first process is to perform finite element analysis (FEA) on various platform shapes. FEA is a numerical approach in solving structural problems by discretizing

the problem where the domain to be analyzed is divided into a number of discrete elements. Using this approach, it offers great flexibility to model complex geometries which would be near impossible if analytical approach is taken. By undergoing FEA, the natural modes and frequencies of the platform can be estimated numerically. With this, a best possible candidate can be chosen from among the designs.

Upon obtaining an optimum structural shape of the platform according to the FEA results, the platform of the quadrotor MAV can then be designed with a 3D simulation software, where each individual part of the aircraft could be assembled in the software for an overall design. An advantage of utilizing simulation software is that it could estimate various important parameters of the designed aircraft, such as the weight, density, and the moment of inertia, in a way that the design could be customized freely in order to meet their requirements before they are fabricated to real physical objects.

11.2.1 MSC Patran and Nastran

MSC Nastran, one of the most widely used FEA commercial software, is utilized in simulating the vibration properties of the quadrotor MAV. It is a useful tool which simulates static and dynamic cases for a wide variety of complicated structural problems. In addition to Nastran, a modeler software called Patran is employed for finite element modeling. Patran provides geometry modeling, meshing, boundary condition, and material properties set up for Nastran. It is also used for postprocessing purpose. Provided in Nastran, Lanczos (1950) method is utilized for eigenvalue and eigenvector extraction purpose.

To investigate and design the quadrotor platform, single arm and full quadrotor models are constructed in Patran with the properties of carbon fiber composite material assigned to the software. The model is then fetched to Nastran to investigate its structural resonance. In corresponding specifically to the design of micro aerial quadrotor, the study is concentrated on natural mode analysis to determine the natural frequencies and mode shapes of the model. The natural mode analysis predicts the resonance for the structure and the type of resonance. On the other hand, the displacement response of the model can be determined using frequency response analysis when external steady-state oscillatory excitation (simulating rotor rotation) is applied.

11.2.1.1 Single Quadrotor Arm

A quadrotor consists of four extended arms attached to a body which holds the onboard electronics. The aim of carrying out the single quadrotor arm analysis is to provide a useful summary on the performance of different quadrotor arm shapes, and then among the few possible candidates under the constrained of weight and size, a best solution in terms of shape, length, and dimension can be obtained. In this analysis, the quadrotor arm is approximated as a cantilever beam which has a fixed end and a free end.

Fig. 11.1 Cross sections of five common beams

Five different types of cantilever beams are designed and analyzed. The cross sections for each of the beams are shown in Fig. 11.1. A few different parameters on the dimension of the beams will be varied, and the corresponding natural mode (1–4) will be compared. Note that the composite material for all beams to be simulated has the properties of carbon fiber code name carbon/epoxy T300/976. All simulations are done in Nastran by employing the discrete element with six degrees of freedom (DOF) per node, and all nodes at one of the tips are assumed to be fixed by setting all six DOF to zero.

The first variable to be investigated is the length of the beam. It is well known that slender bodies are more easily exposed to vibration, or in other words, shorter beams are stiffer. To verify the relationship between the length of the beam and its natural modes, the rectangular beam (first cross section in Fig. 11.1) with different length is analyzed in the simulation. In Table 11.1, a summary of the Nastran natural mode analysis results obtained for this study is given. Based on the results, it is evident that natural frequencies for the first four modes increase as the structure becomes shorter. In general, beams of other shape show similar behavior, and thus the results are trivial and not to be included here. Despite the results favoring shorter beams, there are other restrictions on the minimum length of the quadrotor arms. One important factor would be the aerodynamic interferences between the rotors, which generally limits the minimum length of the quadrotor arms to be at least twice the rotor radius.

Table 11.1 Natural frequencies of thin plate with varying length

| Length (mm) | Natural frequency (Hz) | | | |
|-------------|------------------------|----------|----------|----------|
| | Mode 1 | Mode 2 | Mode 3 | Mode 4 |
| 50 | 614.6 | 3, 656.7 | 3, 803.4 | 10, 518 |
| 60 | 426.85 | 2, 546.1 | 2, 642.6 | 7, 313.4 |
| 70 | 313.62 | 1, 873.6 | 1, 942.1 | 5, 377.1 |
| 80 | 240.3 | 1, 437.1 | 1, 491.3 | 4, 137.1 |
| 90 | 189.73 | 1, 135.4 | 1, 175.3 | 3, 255.4 |
| 100 | 153.68 | 920.14 | 952.05 | 2, 637.5 |

Table 11.2 Natural frequencies of beam with different cross sections and thickness

| Type of cross section | 1 mm thickness | | 0.5 mm thickness | |
|-----------------------|----------------|-------------|------------------|-------------|
| | Weight (g) | Mode 1 (Hz) | Weight (g) | Mode 1 (Hz) |
| Rectangular | 0.5328 | 426.85 | 0.2664 | 213.45 |
| Rectangular hollow | 1.776 | 3,032.4 | 0.9768 | 3,270.7 |
| Circular hollow | 1.3949 | 2,647.9 | 0.767 | 2,851.6 |
| T shape | 0.9768 | 1,902.8 | 0.5106 | 1,845.3 |
| N shape | 1.4208 | 2,717.5 | 0.7548 | 2,810.4 |

The second variable to be investigated is the thickness of the material. As two common thickness of carbon fiber sheet or beam available commercially are of 0.5 and 1 mm thick, the natural mode of all five general shapes of beams are analyzed and compared in 0.5 and 1 mm thickness. For fair comparison, the model for each cross section was constructed with length $l = 60$ mm, width $w = 6$ mm, and height $h = 6$ mm (see Fig. 11.1 for illustration). Table 11.2 shows the comparison between beam with thickness $t = 1$ mm and $t = 0.5$ mm, together with their calculated weight. One can notice that in general, the beam having a closed cross-sectional shape, i.e., the rectangular hollow and circular hollow beams, has a much higher natural frequency compared to other shapes. Also, the thickness of the material has little effect on them, while the weight could be half as light.

The last variable to be investigated is the width and height of these closed cross-sectional beams. It can be seen from Table 11.3 that the height variation of the rectangular hollow beam affects the first mode frequency more severely than the second mode frequency. On the other hand, the width variation of the beam affects the second mode frequency much more than the first mode frequency. In conclusion, utilizing a square beam with equal height and width will give similar frequencies for the first and second modes. This is further proven in Table 11.4 where the circular hollow beams were analyzed.

In general, although the rectangular solid and T-shape configurations show better weight budget, their natural frequencies are comparatively much lower than that of rectangular hollow and circular hollow shapes, which are in the closed cross section forms. In the following section, a full quadrotor configuration with rectangular hollow beam of 3 mm height and 3 mm width will be investigated.

Table 11.3 Natural frequencies of the rectangular hollow beam with different width and height (0.5 mm thickness)

| Height (mm) | Width (mm) | Natural frequency (Hz) | | | |
|-------------|------------|------------------------|---------|---------|--------|
| | | Mode 1 | Mode 2 | Mode 3 | Mode 4 |
| 3 | 5 | 1,625.9 | 2,515.8 | 9,673.4 | 14,904 |
| 3 | 6 | 1,651.8 | 2,979.7 | 9,718.5 | 17,415 |
| 3 | 7 | 1,670.3 | 3,430.8 | 9,708.0 | 19,762 |
| 3 | 8 | 1,683.5 | 3,871.3 | 9,656.9 | 21,954 |
| 3 | 9 | 1,693.0 | 4,302.7 | 9,576.0 | 23,571 |
| 3 | 10 | 1,699.4 | 4,725.6 | 9,472.4 | 22,983 |
| 4 | 6 | 2,218.0 | 3,105.6 | 12,845 | 17,908 |
| 5 | 6 | 2,756.0 | 3,199.4 | 15,699 | 18,185 |
| 6 | 6 | 3,270.7 | 3,270.7 | 18,312 | 18,312 |

Table 11.4 Natural frequencies of the circular hollow beam with different radius (0.5 mm thickness)

| Radius (mm) | Natural frequency (Hz) | | | |
|-------------|------------------------|---------|--------|--------|
| | Mode 1 | Mode 2 | Mode 3 | Mode 4 |
| 2.0 | 1,839.3 | 1,839.3 | 11,070 | 11,070 |
| 2.5 | 2,347.5 | 2,347.5 | 13,875 | 13,875 |
| 3.0 | 2,851.6 | 2,851.6 | 16,495 | 16,495 |
| 3.5 | 3,349.6 | 3,349.6 | 18,911 | 18,911 |
| 4.0 | 3,840.1 | 3,840.1 | 21,117 | 21,117 |
| 4.5 | 4,322 | 4,322 | 23,116 | 23,116 |
| 5.0 | 4,794.3 | 4,794.3 | 24,918 | 24,918 |
| 5.5 | 5,256.1 | 5,256.1 | 26,538 | 26,538 |

11.2.1.2 Full Quadrotor Configuration

Due to structure stability shown by closed shape beams, the full configuration is then tested using rectangular hollow beam and circular hollow beam to form the arms attached to each corner of the main frame. The main frame is designed to be 28.28×28.28 mm with thickness 2 mm. Meanwhile, 60 mm long beam is employed as the quadrotor arm. Again, unidirectional carbon/epoxy T300/976 is used. In Patran, the main frame is modeled as 2-D shell element while the quadrotor arm using 1-D beam.

For this analysis, the main frame is assumed to be rigid and thus fixed in all three translation DOF. For a quadrotor model with 3 mm width, 3 mm height, and 1 mm thickness rectangular hollow beam, the resulted natural frequency for the first and second modes are 971.92 and 5,843.3 Hz. On the other hand, the natural frequency for quadrotor model using circular hollow beam with outer diameter of 3 mm and thickness of 1 mm is at 940.35 Hz for the first mode and 5,070.7 Hz for second mode.

Subsequently, dynamic analysis is performed to investigate the response of the quadrotor to oscillatory excitation produced by the propeller blades. In this simulation, a 0.25 N oscillatory force is applied to the tip of each quadrotor arms. The analysis is performed over frequency range of 0–4,000 Hz. Results obtained from the Nastran are displayed in Fig. 11.2a, b. From the response spectrum, the frequency at peak for both quadrotor models matches the first natural mode

Fig. 11.2 Displacement at tip of the arm with rectangular (a) and circular (b) hollow beam

simulated earlier. Based on the simulation result, both models are suitable for miniature quadrotor design as they have the highest stiffness to weight ratio among the tested shapes. In conclusion, using a beam with a closed cross-sectional shape as the quadrotor arm can guarantee extreme stability for the whole quadrotor model.

11.2.2 SolidWorks

An overall design blueprint of this quadrotor platform is essential to provide a broad overview of the quadrotor functionalities, size, weight, and appearance design. A 3D mechanical design software named SolidWorks, developed for efficient and quicker design of mechanical products and components, facilitates the design tasks for the platform. This 3D software is chosen as the design and analyzing software over other mechanical design tools due to a few advantages, such as increase design efficiency, ease of fabricating, and easy access to simulated geometric data.

Table 11.5 Weight budget for quadrotor MAV

| Components | Amount | Estimate weight (g) | Current weight (g) |
|---------------------|--------|---------------------|--------------------|
| Battery | 1 | 10 | 9.8 |
| Motor and propeller | 4 | 3.5 | 3.59 |
| Quadrotor arm | 4 | 1 | 0.93 |
| Quadrotor frame | 1 | 4 | 2.13 |
| Onboard system | 1 | 10 | 7.32 |
| Miscellaneous | | 2 | 1.7 |
| Total | | 44 | 39.03 |

Fig. 11.3 Quadrotor arm and frame design in SolidWorks

Based on the natural mode analysis in Nastran (see previous section), a cross-shaped frame structure is designed with four rectangular hollow carbon fiber beams fixed into a holder locating the avionic system along with the battery. The design takes the following considerations:

1. The CG should be located on the z -axis at the geometrical center of the cross shape.
2. Mechanical parts should be carefully designed with the weight and moment of inertia symmetrically distributed along the x - and y -axis.
3. Materials with low density and high intensity are to be used as the frame and protection to satisfy weight limit.

In order to accurately approximate the weight and dimension of the overall design, components are to be drawn on scale, with the correct weight and density assigned to it in SolidWorks. As weight is the main constraint to the design of the MAV, the design parts are minimized. Table 11.5 details the total parts in the design of the quadrotor MAV, with specific weight budget assigned to each of them. On the right of the table listed the real weight of the components or designed parts, which will be detailed here and also in the next sections.

- The structure design can be separated into two different parts:
1. *Quadrotor arms*: A protection scheme is developed as a shell to encapsulate the motor into a tight chamber to fix its position. Carbon fiber beam can be mounted and screwed to the side, as shown in Fig. 11.3a.

Fig. 11.4 Mechanical structure layout and size of the quadrotor

2. *Main body*: The main frame structure has four slots for the quadrotor arms and contains two layers, where the avionic system is placed on the top and the battery is located in the lower level, as shown in Fig. 11.3b. It is fabricated with acrylonitrile butadiene styrene (ABS).

The mechanical structure layout of the proposed quadrotor MAV is shown in Fig. 11.4a with all the parts assembled together as shown in Fig. 11.4b. Distance of two diagonal rotors is 142.54 mm, with a total height of 22.50 mm. Details of weight breakdown are reflected in Table 11.5. In this table, the estimated weight is approximated based on the design guideline shown in this chapter, while the current weight on the right of the table is the measured weight of the quadrotor MAV prototype, code name KayLion, made by National University of Singapore, following the guideline.

11.3 Hardware Design

Hardware system and the avionics are the core of any unmanned aircraft design. The hardware system includes the motors and propellers, avionics such as onboard processor (CPU), sensors like inertial measurement unit (IMU), and power supply. Suitable choices of the hardware and components will be proposed based on the requirement on their performance under the constraint on weight and size.

11.3.1 Motor and Propeller

Motor and propeller sets are the main actuators of the quadrotor MAV. As each quadrotor consists of four sets of motor and propeller, they need to be chosen carefully as their characteristics must satisfy the design requirements. A few

important design requirements of the quadrotor MAV are directly related to the characteristic of the motor and propeller. They are the operation voltage and current consumption of the motors, the weight of the motors, and the maximum thrust it can produce with different propellers.

Based on the requirements stated above, a 8,000kV single cell brushed direct current (DC) motor is utilized. Combined with two sets of propeller, each has a clockwise and an anticlockwise propellers; the total weight of a single motor and propeller is approximately 4 g. Test bench experiment has proved that the combination could produce a maximum thrust of 16 g each, which combined to be approximately 1.5 times larger than the proposed MAV at 40 g.

11.3.2 Electronics

The avionic system consists of electronic components for the electrical system of the quadrotor MAV. Different from the conventional design of the avionic system for larger UAV, where each component can be chosen from the commercially off-the-shelf (COTS) product, with firm packaging and plug-and-play connection ready, the choices of electronic components for the quadrotor MAV need to be made down to integrated chip (IC) level. A printed circuit board (PCB) incorporated all onboard electronics will then be designed.

11.3.2.1 Control CPU

The processor is the core of the avionic system. In the compact MAV design, the main tasks of the processor are (1) collecting data from IMU sensor from serial port, (2) receiving command from the receiver in the form of pulse position modulation (PPM) signal, (3) decoding and analyzing data, (4) realizing flight control laws, (5) sending control signals in the form of pulse width modulation (PWM) signal to the electronic speed controllers (ESC), and (6) sending logging data to the logger via serial port.

For the selection of the microprocessor for the abovementioned tasks, ATmega328P, a high-performance Atmel 8-bit AVR RISC-based microcontroller, is adopted because of the following features: (1) availability of various ports, such as UART, SPI, and PWM ports; (2) low power consumption; and (3) ease of coding.

It is proved that the ATmega328P microprocessor is good enough to run the software for the tasks mentioned above within 5 ms. As a result, the control loop running in the software is user configurable up to 200 Hz, depending on the update frequency of the IMU sensor.

11.3.2.2 Inertial Measurement Unit

An IMU is an essential sensor to any autonomous aircraft. It provides important motion measurements of the body it attached to, such as accelerations, angular rates, and magnetic values. It is noted that for most of the aircraft orientation control, 3-axis Euler angle measurements must be provided. However, it is not necessary that all IMU provides the angular measurements as they can be estimated by using an extended Kalman filter (EKF) (Jang and Liccario 2007) or complimentary

filtering (Yun et al. 2007). These filters are, however, computationally intensive; thus, they might be a burden for the onboard AVR microprocessor. Here, a solution is to find a powerful IMU with in-built EKF algorithm in a small and light package.

The VN-100 SMD from VectorNAV is chosen in the design. It is a lightweight (3 g) and miniature ($24 \times 22 \times 3$ mm) high-performance IMU and Attitude Heading Reference System (AHRS). In this tiny package, it includes 3-axis accelerometer, 3-axis gyroscope, and a 3-axis magnetic sensor. An extra advantage of VN-100 is the in-built 32-bit microprocessor to compute and output a real-time and drift-free 3D orientation solution with EKF algorithm. The IMU output rate is user-configurable from 40 to 200 Hz, depending on the output methods.

11.3.2.3 Motor Speed Controller

ESC is essential for each brushed motor used in the MAV design. The main contribution of ESC is to convert the commonly used PWM signal to analog signal to be fed to the motor. The current of the analog signal will be further boosted to drive the motor. For the ESC design, a single 8-pin processor ATtiny13A is utilized for speed controlling. The processor is responsible for decoding PWM signals fed from the control CPU (ATmega328P) and outputting a stable analog voltage. The current output of the analog port is, however, too low to drive the motor. Thus a single MOSFET chip is also included to feed the current from the aircraft's power supply (battery) directly to the motor. Four ESCs and MOSFETs are needed for the quadrotor MAV design.

11.3.2.4 Radio-Frequency Receiver

Conventionally, a radio-frequency (RF) receiver is used to receive and decode RF signals sent from a transmitter controlled by a ground pilot in radio-controlled (RC) flights. In general, a receiver is not needed in a fully autonomous flight control system as no remote pilot is needed. Most of the UAV designs, however, retain the receiver component for fail-safe purposes, where a ground pilot has higher authority to remotely control the UAV during emergencies such as controller failures. In the quadrotor MAV design, the receiver has a different function. Besides receiving the control signals from the remote pilot, the receiver is utilized to receive control signals or measurement values from the ground control station in autonomous mode. It is particularly useful when the MAV system is navigating in indoor environment with the aid of VICON motion technology, where the VICON system measures the position and velocity of the MAV, then sends the control signals or the measurement values to the aircraft's onboard CPU via the transmitter to receiver link. This communication system could be realized with a PCTx cable, a product by Endurance R/C. The PCTx cable connects the ground station (desktop or laptop) to the transmitter, making use of the transmitter to send RF signals to the onboard receiver. Upon receiving signals from the ground, the receiver will then output the signals in the form of PPM signal to the onboard CPU for processing. In order to fulfill the mentioned requirement, a good candidate would be Rx31d from DelTang. It is chosen to be integrated in the avionic system due to its ultra tiny package of 10×10 mm with 0.21 g. It is able to provide up to seven channels of PPM signals.

11.3.2.5 Data Logger

In most UAV designs, important flight data such as state variables of the UAV model will be recorded for post-flight observation and investigation. In the design of the MAV, a logger is required to be small, light, and simple enough to work. An open source data logger, called OpenLog from SparkFun, is utilized in the design. OpenLog is presented in a tiny package with 1.70 g. It will start logging any serial data up to 115,200 baud rate to the micro SD card upon powered up. Optionally, as SparkFun provides OpenLog firmware and design files, it can be redesigned to the main PCB of the MAV.

11.3.3 Power Supply

The main consideration in designing the power supply is to meet the overall system and flight duration requirements. The choice of power supply is important as it constitutes most (approx. 30 %) of the overall weight of the MAV, and the power needed to lift the MAV will be increased due to its own weight. As all onboard components can be powered up with 3.3 V, a single cell Lithium-Polymer (Li-Po) battery with current capacity of 360 mAh is utilized to power the avionics and to drive the motors. A 3.3 V regulator is included to provide a clean voltage to the components, as single cell Li-Po battery's output varied from 4.2 V during full charged down to lower than 3.4 V when it is used up. The battery is as light as 10 g and is able to provide enough energy for an 8-min flight duration.

11.3.4 Avionics Design

In this subsection, the design process of the PCB for the avionic system of the quadrotor MAV will be described in detail. Among the five components to be included to the avionic system, the IMU, flight control CPU, and four ESCs will be incorporated into the design, while the receiver and the logger will be attached to the designed PCB. A general guideline to design avionics PCB for quadrotor MAV with Altium Designer is as follows:

1. *Schematic design* – A schematic diagram of the design must be drawn in Altium Designer with all the components needed, including four status indication LEDs. A 3.3 V voltage regulator is also included.
2. *Layout assignment* – The layout of the components of the PCB is important so as to reduce the electromagnetic interference between the components. To satisfy the dimension and weight constraints, a maximum of 4×4 cm PCB layout is imposed. The IMU must be placed in the middle of the design to be as closed to the CG as possible with the correct orientation. Then, components such as flight control CPU and motor speed controllers are placed at the opposite side of the board. Lastly, the four LEDs are located in a way that they are clearly visible to the user during flight.
3. *Routing* – The final step of designing PCB is the routing to connect each component according to the connection assigned in the schematic phase. The routing could be easily done (see Fig. 11.5) in a 2-layer-PCB setup.

Fig. 11.5 PCB layout

Once the design is done, it can be sent to PCB manufacturer to fabricate. With PCB thickness of 1 mm, the fabricated product is approximately 7 g including all components, within the dimension of $40 \times 40 \times 1$ mm.

11.4 Dynamic Modeling and Control

In this section, a nonlinear mathematic model of the quadrotor MAV is derived. The methods of parameters identification will also be discussed, which include direct measurement, test bench experiments, as well as evaluation in virtual environment. This mathematic model is further verified with the real flight test data obtained by the VICON motion capture system. PID control law is first implemented in the virtual model in Simulink, then further fine-tuned on the real platform based on the flight tests.

11.4.1 Nonlinear Mathematics Model

The mathematical models of quadrotor aircraft are quite well developed in the literature (Bouabdallah et al. 2004; Erginer and Altug 2007; Guerrero-Castellanos et al. 2011; Kim et al. 2007; Phang et al. 2012; Pounds et al. 2006). The overall structure view of this quadrotor platform is pictured in Fig. 11.6, where δ_{ail} , δ_{ele} , δ_{thr} , and δ_{rud} represent the normalized input signals from aileron, elevator, throttle, and rudder channels, respectively. δ_1 , δ_2 , δ_3 , and δ_4 are the normalized input values to each motors. Ω_1 , Ω_2 , Ω_3 , and Ω_4 are motors' individual rotational speeds. Linear velocity u , v , w and angular velocity p , q , r can be obtained by 6 degree-of-freedom (DOF) rigid body dynamics, and position in ground frame x , y , z and Euler angles ϕ , θ , ψ can be calculated through kinematics equation.

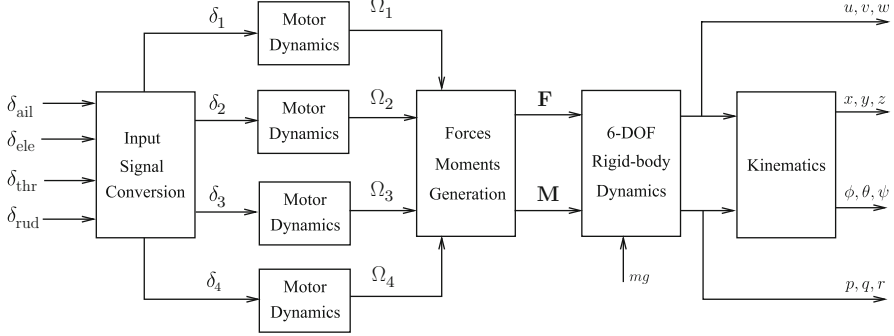

Fig. 11.6 Overall structure of the quadrotor

Two coordinate frames, north-east-down (NED) frame $[x_i \ y_i \ z_i]$ and the body frame $[x_b \ y_b \ z_b]$, will be considered (Wang et al. 2012). The NED frame is stationary with respect to a static observer on the ground, and the body frame is the coordinate frame with the origin located at the CG and orientation moving together with the aircraft fuselage. The origin of the body frame is located at the CG of the platform with x -axis parallel with rotor 2 and rotor 3 along with y -axis parallel with rotor 1 and rotor 2. Euler angles $\Theta = [\phi \ \theta \ \psi]^T$ are the angles rotating about x -, y -, and z -axis, describing the roll, pitch, and yaw motions. T_1 , T_2 , T_3 , and T_4 are the lift force created by rotor 1, 2, 3, and 4. Rotors 1 and 3 rotate clockwise, while rotors 2 and 4 rotate counterclockwise.

11.4.1.1 Kinematics and 6 Degree-of-Freedom Rigid Body Dynamics

At any time instant, the aircraft can be pictured as having a translational and rotational motion with respect to the stationary NED (or ground) frame. The following kinematics equations represent the navigation equations applicable to transformation between the two frames:

$$\dot{\mathbf{P}}_n = \mathbf{R}_{n/b} \mathbf{V}_b, \quad (11.1)$$

$$\dot{\Theta} = \mathbf{S}^{-1} \Omega, \quad (11.2)$$

where $\mathbf{R}_{n/b}$ represents the transformation matrix and \mathbf{S}^{-1} represents a lumped transformation matrix. They are given by:

$$\mathbf{R}_{n/b} = \begin{bmatrix} c_\theta c_\psi & s_\phi s_\theta c_\psi - c_\phi s_\psi & c_\phi s_\theta c_\psi + s_\phi s_\psi \\ c_\theta s_\psi & s_\phi s_\theta s_\psi + c_\phi c_\psi & c_\phi s_\theta s_\psi - s_\phi c_\psi \\ -s_\theta & s_\phi c_\theta & c_\phi c_\theta \end{bmatrix}, \quad \mathbf{S}^{-1} = \begin{bmatrix} 1 & s_\phi t_\theta & c_\phi t_\theta \\ 0 & c_\phi & -s_\phi \\ 0 & s_\phi/c_\theta & c_\phi/c_\theta \end{bmatrix}, \quad (11.3)$$

with $s_* = \sin(*)$, $c_* = \cos(*)$, $t_* = \tan(*)$.

Based on Newton-Euler formalism describing the translational and rotational dynamics of a rigid body, the dynamic equations can be written into the following input-output form:

$$m\dot{\mathbf{V}}_{\mathbf{b}} + \Omega \times (m\mathbf{V}_{\mathbf{b}}) = \mathbf{F}, \quad (11.4)$$

$$\mathbf{J}\dot{\Omega} + \Omega \times (\mathbf{J}\Omega) = \mathbf{M}, \quad (11.5)$$

where \mathbf{F} and \mathbf{M} are the force and moment vectors, m is the mass of aircraft, and \mathbf{J} is the tensor of inertia matrix.

11.4.1.2 Forces and Moments Generation

Based on the working principle of the quadrotor (Cai et al. 2011), the forces and torques are mainly generated by the four rotors (Goel et al. 2009). The following equation represents the component part of the overall force and moment vector:

$$\Lambda = \begin{bmatrix} \mathbf{F} \\ \mathbf{M} \end{bmatrix} = \begin{bmatrix} \mathbf{F}_g + \mathbf{F}_m \\ \mathbf{M}_m + \mathbf{M}_{gy} + \mathbf{M}_{rt} \end{bmatrix}, \quad (11.6)$$

where subscripts g , m , gy , and rt correspond to forces and moments generated by gravity, rotors, gyroscopic effect, and reactional torque, respectively.

As the platform is four-way symmetric, the CG is located on the z -axis, thereby the gravitational force only contributes to the force vector. Considering the coordinate frames, the gravity only exists on the z -axis in NED frame and needs to be transformed to the body frame by the transformation matrix:

$$\mathbf{F}_g = \mathbf{R}_{\mathbf{n}/\mathbf{b}}^{-1} \begin{bmatrix} 0 \\ 0 \\ mg \end{bmatrix} = \begin{bmatrix} -mg s_{\theta} \\ mg c_{\theta} s_{\phi} \\ mg c_{\theta} c_{\phi} \end{bmatrix}. \quad (11.7)$$

It is the motor and propeller pairs which produce the main movements to generate the forces and moments. As in Pounds et al. (2004), let T_i and Q_i be the thrust and torque created by i -th rotors ($i = 1, 2, 3, 4$); they can be expressed as below:

$$T_i = C_T \rho A (\Omega_i R)^2, \quad (11.8)$$

$$Q_i = C_Q \rho A (\Omega_i R)^2 R, \quad (11.9)$$

where C_T and C_Q are the propeller aerodynamic coefficient, ρ is the air density, A is the area of the propeller swept by the rotating rotor, and R is the radius of the rotor A . Assuming that the distortion of the propellers during high frequency rotation can be ignored, Eqs. (11.8) and (11.9) can be simplified as:

$$T_i = k_T \Omega_i^2, \quad (11.10)$$

$$Q_i = k_Q \Omega_i^2, \quad (11.11)$$

where these two coefficients k_T and k_Q can be obtained by a series of experiments. Thereby, the sum of these four thrusts will result in a total thrust in negative z -axis in the body frame, as below:

$$\mathbf{F}_m = \begin{bmatrix} 0 \\ 0 \\ -(T_1 + T_2 + T_3 + T_4) \end{bmatrix}. \quad (11.12)$$

The moments are generated when the four thrusts have different magnitudes, results in pitch, roll, and yaw movements, as shown below:

$$\mathbf{M}_m = \begin{bmatrix} \frac{\sqrt{2}}{2}l(T_2 + T_3 - T_1 - T_4) \\ \frac{\sqrt{2}}{2}l(T_1 + T_2 - T_3 - T_4) \\ Q_1 - Q_2 + Q_3 - Q_4 \end{bmatrix}, \quad (11.13)$$

where l is the distance from the center of the motor to the platform CG.

Gyroscopic effect is caused by the combinations of rotations of four propellers and can be modeled as

$$M_{gy} = \sum_{i=1}^4 J_r \left(\Omega \times \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \right) (-1)^i \Omega_i \quad (11.14)$$

$$= \begin{bmatrix} -J_r q(\Omega_1 - \Omega_2 + \Omega_3 - \Omega_4) \\ J_r p(\Omega_1 - \Omega_2 + \Omega_3 - \Omega_4) \\ 0 \end{bmatrix} \quad (11.15)$$

where J_r is the moment inertia of the rotor, including the propeller and motor shaft. The gyroscopic effects produced by the propellers are only related to the moments of the aircraft.

The first-order derivative of rotational movement can cause the inertia counter torque, and this torque only affects the movement in yaw direction, which is

$$\mathbf{M}_{rt} = \begin{bmatrix} 0 \\ 0 \\ -J_r(\dot{\Omega}_1 - \dot{\Omega}_2 + \dot{\Omega}_3 - \dot{\Omega}_4) \end{bmatrix}. \quad (11.16)$$

11.4.1.3 Motor Dynamics

Each brushed motor is controlled by a single cell brushed ESC, and the steady-state value of rotor angular speed to brushed ESC input can be approximated as a linear

process near the equilibrium (hovering) value. The transient property of this brushed motor can be approximated as a first-order process, as shown below:

$$\dot{\Omega}_i = \frac{1}{T_m} [K_m(\delta_i - \delta_i^*) - \Omega_i], \quad (11.17)$$

where δ_i is the normalized input to the i -th motor, T_m and K_m are the time constant and process gain of the first-order model, and δ_i^* is the offset to the normalized input values. Note that the offset values of each motor are determined in the hovering condition.

11.4.2 Parameters Identification

Several parameters need to be identified to obtain the complete model. Here, several methods of identifying each parameters will be presented. They are all to be done by direct measurement, experiments, or computer simulation.

11.4.2.1 Direct Measurement

Parameters that can be directly measured by a weighing balance and ruler are mass of each components and the length of quadrotor arms, as follows:

$$m = 0.032 \text{ kg}, \quad (11.18)$$

$$L = 0.058 \text{ m}. \quad (11.19)$$

Gravitational acceleration, depends on the location, can be easily calculated given the latitude of the location. In Singapore in particular,

$$g \approx 9.781 \text{ m/s}^2. \quad (11.20)$$

11.4.2.2 Computer Simulation

Several parameters can be estimated numerically with computer software. As mentioned in the previous section, mechanical parts of the quadrotor MAV are first designed in SolidWorks, with exact density and scale to the real physical parts. A few parameters, such as the tensor moment of inertia of the quadrotor MAV and the rotating moment of inertia of the propeller, are calculated with the mass property function of SolidWorks:

$$J = \begin{bmatrix} 3.0738 & 0 & 0 \\ 0 & 3.0849 & 0 \\ 0 & 0 & 5.9680 \end{bmatrix} \times 10^{-5} \text{ kg m}^2, \quad (11.21)$$

$$J_r = 5.897 \times 10^{-8} \text{ kg m}^2. \quad (11.22)$$

Note that J is diagonal as the designed quadrotor structure is highly symmetric.

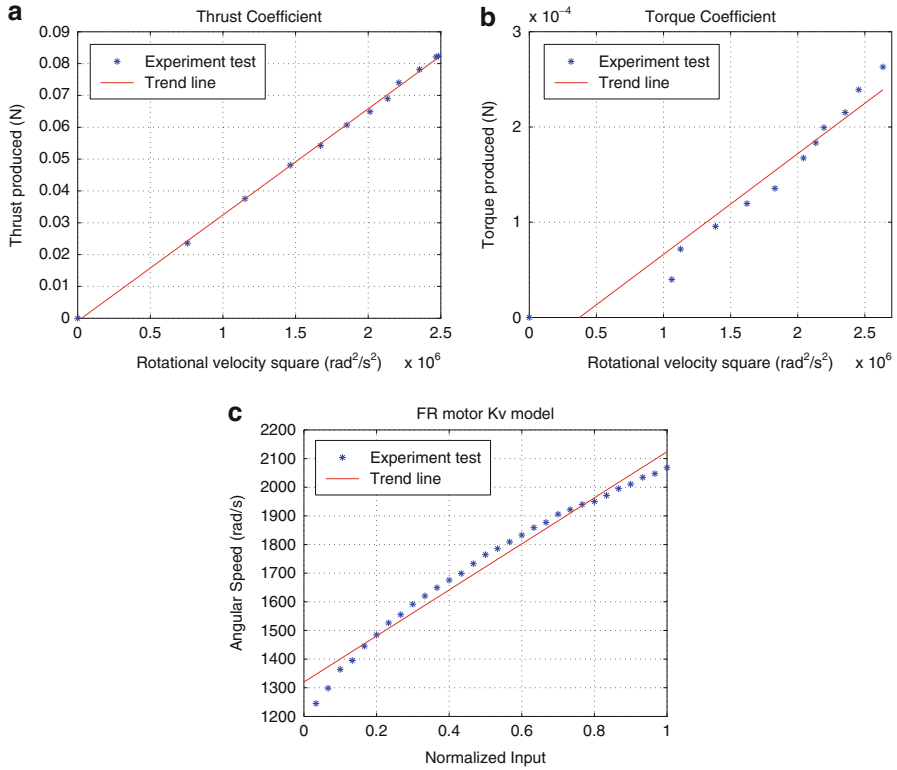

Fig. 11.7 Measurement of thrust coefficient, torque coefficient, and motor's steady-state gain

11.4.2.3 Test Bench Experiment

The thrust and torque coefficient of the rotor can be measured by lever-balance setup. An infrared transceiver is used to measure the time interval between two adjacent cutting of the propeller, where the real-time angular velocities can be calculated. Thrust and torque produced by the rotor can be measured from the weighing scale. The results are plotted in Fig. 11.7a, b. Thrust and torque coefficients k_T and k_Q can then be obtained as the gradient of the approximate line:

$$k_T = 3.334 \times 10^{-8} \text{ N}/(\text{rad}^2/\text{s}^2), \quad (11.23)$$

$$k_Q = 1.058 \times 10^{-10} \text{ Nm}/(\text{rad}^2/\text{s}^2). \quad (11.24)$$

The next experiment is conducted to estimate the brushed motor dynamics. Several different values of constant input are fed to the motor, and the resultant angular speeds of the motors are recorded with the similar setup as the experiment above. The results are plotted in Fig. 11.7c. Here the motor steady-state velocity is

assumed to be proportional to the input value at equilibrium (during hover). Thus, the steady-state gain, K_m , can be extracted as

$$K_m = 803.9. \quad (11.25)$$

Also, as presented in Eq. 11.17, the motor dynamics can be approximated as a first-order process:

$$\frac{\Omega_i(s)}{R_i(s)} = \frac{K_m}{T_m s + 1}, \quad (11.26)$$

where average time constant T_m is estimated from the transient response of a step input to the motor. The value obtained is

$$T_m = 0.0821 \text{ s}. \quad (11.27)$$

11.4.3 Controller Design

Upon obtaining the mathematical model of the aircraft, a simple yet reliable PID controller is designed and simulated with the aid of Simulink in MATLAB.

Generally, the dynamics of a quadrotor without orientation stabilizer is too fast even for a skilled human pilot. The fast dynamics is contributed by the roll and pitch movements, while the yaw movement exhibits much slower dynamics.

In the initial stage of the PID gains tuning, the controller is first designed in simulation by utilizing the Ziegler-Nichols method. Simulated result in Fig. 11.8 has shown a stable quadrotor system, with all the Euler angles, and angular rate signals are attenuated to zero within 5 s. This set of PID gains is further fine-tuned with real flight tests. Finally, a set of PID gains for each axis in which the aircraft is able to stabilize horizontally on this setup was obtained, as shown in Table 11.6.

11.5 Flight Test Results

The PID controller designed with software simulator shown above is implemented to the manufactured quadrotor MAV code-named KayLion (Fig. 11.9). Flight tests are then carried out to test the endurance of the vehicle and to verify the mathematical model derived in the previous section.

In particular, chirp-like oscillating inputs are sent to the MAV system, while its Euler angles and angular rates responses are recorded in the onboard logger. The recorded responses are then compared to the simulated responses by using

Fig. 11.8 Simulation results with PID gains

Table 11.6 PID gains implemented to the quadrotor MAV

| Channel | K_p | K_i | K_d |
|---------|-------|-------|-------|
| Pitch | 1.60 | 2.45 | 0.51 |
| Roll | 1.60 | 2.45 | 0.51 |
| Yaw | 4.00 | 0.75 | 0.10 |

the exact inputs to the simulator. Figure 11.10a shows the perturbation signal on elevator channel to the MAV, while Fig. 11.10b shows the responses of the system in pitch direction plotted together with the simulated results. Besides some random low-amplitude oscillations caused by the disturbances from the air movement, the responses match fairly well. Beside the pitch direction, the roll direction is assumed to be similar to the pitch, as the quadrotor MAV is of four-way symmetry.

In the other flight test, a chirp-like signal was injected to the throttle channel of the quadrotor MAV, resulting in agitated heave movement. In this experiment, a VICON Motion Tracking System is used to measure and compute the position of the quadrotor with reference to the start-up origin. Both the input signals and position measurement are logged and plotted in Fig. 11.11a, b. In the latter figure, it can be seen that the derived mathematical model on heave movement matches well with

Fig. 11.9 A full working prototype quadrotor MAV, KayLion, designed and built by the National University of Singapore (NUS)

the experimental data to a certain perturbation frequency, which is approximately 1 Hz. The quadrotor MAV was unable to respond to the perturbation signal above this frequency, as it was observed with naked eyes during the flight tests.

11.6 Conclusions

This chapter summarizes the steps to design and implement a micro scale quadrotor MAV, with a target take-off weight of less than 50 g. It has covered the full design areas, including the structural design, platform design, avionics design, and controller design, in which all areas are supported and verified by simulation or experimental results.

Structural analysis was first done in MSC Patran and Nastran to obtain suitable candidates for the platform design, where the shape of the beam with the highest stiffness against weight ratio was selected. The platform including the arms was then designed in SolidWorks to ensure proper placement of components. Next, the avionic system design was discussed, first with the selection of suitable electronics and constraints to the trade-off between weight and performance, followed by a detailed guideline to integrate these components to a single PCB. Once the platform was fabricated, a nonlinear mathematical model of the quadrotor MAV was derived. PID controller was implemented to the quadrotor, and flight tests were done to fine-tune the controller.

The flight test results have verified the design of the quadrotor MAV, from structural development to the avionic system implementation, and it has further proven the accuracy of the derived mathematical model. With the availability of the mathematical model for this quadrotor MAV, it serves as a good platform to test and verify control law design and implementation.

the structures. Although there has been a fair amount of research work of free-flying satellites with graspers, the more recent trend has been to outfit UAVs with graspers to assist various manipulation tasks. While this recent work has yielded impressive results, it is hampered by a lack of appropriate test beds for aerial mobile manipulation, similar to the state of ground-based mobile manipulation a decade ago. Typical helicopters or quadrotors cannot instantaneously resist or apply an arbitrary force in the plane perpendicular to the rotor axis, which makes them inadequate for complex mobile manipulation tasks. Based on the concept of force closure (a term from the dexterous manipulation community), this chapter introduces a new type of dexterous, 6-DOF UAV which provides the unique capability of being able to resist any applied wrench, or generalized force/torque, providing more precise control during low-altitude flight.

12.1 Introduction

A multicopter is a UAV (unmanned aerial vehicle) that is lifted and manipulated by a number of rotors. Rotors of contemporary multicopters are mostly installed on the frame such that all their thrust vectors are parallel and vertical. Control of vehicle motion is achieved by alternating the pitch or roll rotation rates.

Numerous multicopter systems have been developed as custom research platforms, custom teaching platforms, toys, and commercially available systems. There even exist a number of open-source projects. Most of these multicopters have a number of fixed-pitch propellers with parallel and vertical thrust vectors.

Depending on how these N thrust actuators are physically arranged, various combinations of thrust magnitudes result in net force/torque vectors that span a subset of the 6-D Cartesian space of generalized forces. Coriolis forces induced by the spinning rotors can even be used to augment the net force vector on the multirotor body. Mathematically, a matrix can be constructed that provides a mapping from N -D actuator space to 6-D Cartesian force space, but this matrix can have rank no greater than four when the thrusters are all parallel. In fact, the standard quadrotor configuration results in rank of exactly four as the four thrusters provide linear force along Z axis, and torques around X and Y , while Coriolis effects provide torque around the Z axis. (This is what makes tri-rotors infeasible, and conventional single-rotor helicopters also have four actuators: main rotor, tail rotor, and two actuators on the swash plate.) Instantaneous exertion of linear forces along X and Y is impossible with these configurations; they can only lift, pitch, roll, and yaw. They cannot move laterally without first rolling or pitching an angle, so these systems are nonholonomic.

The multicopter system is dynamically unstable but allows for high maneuverability. Some attempts have been made to change this system like quadrotors, to increase controllability, stability, or maneuverability, but they still only have four motors. This instability lends itself to surveillance where quick movement is key and inability to maintain a stable pose is not an issue, but not much else can be done with these platforms.

Several hexrotor platforms have been developed including a miniature version from Airbotix and robust six- and eight-rotor versions from Aerobot and Dragonfly. The U.S. Air Force announced a solicitation for hexrotor platforms for military procurement. All these known hexrotor configurations employ parallel thrust vectors (identical to the quadrotors) which result in rank-4 actuator-to-Cartesian mappings incapable of exerting arbitrary forces in 6-D space. These six-rotor helicopters have been created simply for the increased lift of six rotors, redundancy, and smoother operation.

Manipulation is making a comeback in robotics. Through most of the 1990s and early 2000s, mobile robots dominated research and application, such as the DARPA grand challenge and autonomous helicopters. Now in kind of the mid-2000s and later up to now, there has been research in manipulation again. Manipulation is about agility, dexterity, and immobilizing a part when grasping.

In harkens back in manufacturing, there is an emerging field of mobile manipulation, combining the growth of mobile robots with robots people can manipulate (Holmberg and Khatib 2000). The field of mobile manipulation combines two broad classes of robots, locomotors and manipulators, yet the potential impact is greater than the sum of the parts. Aerial mobile manipulation is an emerging field within mobile manipulation for which the locomotor is a UAV (Stramigioli et al. 2012). The popular quadrotor has become the main UAV of choice in robotics research, due to its ease of control and low cost. The added mobility and access that quadrotors provide brings a new dimension to the study of mobile manipulation and new challenges as well.

One of the greatest challenges that UAVs, in general, introduce, and quadrotors in particular, is the inability to instantaneously exert forces in the plane. Quadrotors are nonholonomic; in order for them to move forward or sideways, they first have to pitch the entire body of the quadrotor to direct the thrust vector in the desired direction. What this means for aerial mobile manipulation is that the quadrotor cannot resist an arbitrary generalized force/torque. In the parlance of the dexterous manipulation community, it lacks “force closure.” In fact, in one of the first attempts to use a UAV to interact physically with its environment, Albers et al. (2010) had to add an auxiliary actuator to maintain contact, so Newton’s third law of equal and opposite reaction would not immediately push the UAV away.

12.1.1 Force Closure

Force closure and *form closure* (Mason and Salisbury 1985) are concepts from dexterous manipulation that long predate the field of robotics. Reuleaux (1963) and his contemporaries analyzed mobility under constraint in the late 1800s. Since those early days, force closure and form closure have received significant attention, yet definitions have not always been consistent within the robotics literature. Historically, force closure has been the more mature research area with a well-defined theory and set of definitions revolving around screw theory. Form closure, on the other hand, historically, has been more imprecise. Rimon and Burdick

Fig. 12.1 A ski resort being assembled in Canada (Reprinted with permission from Judy Shellabarger Gosnell)

published a seminal work in robotics that rigorously defined first- and second-order force and form closure and showed their equivalence.

Force closure, as defined by Rimon and Burdick (1996), is the ability of a mechanism to directly resist any arbitrary wrench (combination of force and torque) applied to it. A “force closure grasp” in the dexterous grasping literature (Nguyen 1988; Bicchi 1995; Pham et al. 2006) is a grasp of an object that can resist an arbitrary wrench applied to the object. This class of grasps is important to the dexterous manipulation community but is often ignored by the mobile manipulation community because of the large mass of the mobile base and other issues have greater priority.

12.1.2 Aerial Mobile Manipulation

Aerial mobile manipulation is a newly emerging field even though it has existed for decades. Figure 12.1 shows a ski resort being assembled in Canada. There is a group of workers doing the adjustment as this big helicopter is doing the heavy lifting.

However, the helicopter can’t actually do the assembly. Due to Newton’s third law of equal and opposite reaction, as soon as the manipulated part comes into contact with the environment, it would balance away. This is because the helicopter

cannot exert forces instantaneously in the plane. It can only exert forces up and down, in addition to some pitch and yaw. Through most of the 1990s and early 2000s, mobile robots dominated research and application. And one of those things was quadrotors, helicopters with four blades. So people have started to apply helicopters and quadrotors to mobile manipulation.

Aaron Dollar has studied unstable dynamics of the vehicle and coupled object-aircraft motion while grasping objects during flight (Dollar et al. 2011). They also demonstrate grasping and retrieval of variety of objects while hovering, using Yale Aerial Manipulator. Paul Oh equipped the quadrotor with a gripper and studied about contact forces and external disturbances acted on the gripper and the entire manipulation system (Korpela and Oh 2011). Bernard et al. (2010) and the GRASP lab at the University of Pennsylvania (Mellinger et al. 2010) both have worked on using multiple collaborative UAVs in order to perform transportation tasks. They did research on the interactions between UAVs, physical couplings in the joint transportation of the payload, and stabilizing the payload along three-dimensional trajectories.

The helicopter or quadrotor approach is limited though, only the top of objects can be grasped by the underhung grasper and oddly balanced objects must be lifted by multiple UAVs. The UAV teams rigidly clamp to the manipulated object, but, due to their design, they can only apply limited forces and torques. These piloted helicopters and quadrotors manipulate objects by hanging them from a line and/or employ fewer than six vehicles, severely limiting the range of wrenches that can be applied to the object. In generalized force space, they are effectively degenerate.

The floating nature of aerial platforms and the highly compliant nature of their positioning bring the issue of force closure to the fore. With fixed-base manipulators, determining the degree of force closure of a manipulation system is simplified to determining the degree of force closure of the gripper or end effector. In mobile manipulation, the manipulator base is not fixed to the ground, so determining the set of wrenches that can be resisted is not strictly limited to the capabilities of the end effector. But due to the large differences in mass of the mobile base and end effector, it is generally safe to assume the degree of force closure is limited by the end effector and not by the ability of the mobile base to remain motionless. Therefore, for aerial mobile manipulation, the concept of force closure of the entire manipulation system needs to be considered.

Conventional aerial platforms are not able to resist an arbitrary wrench, so an end effector carried by such a vehicle will not be able to exhibit force closure. Force closure for arbitrary rigid objects in 3-D space requires six controllable degrees of freedom in force/torque space to truly accomplish. Current quadrotors lack both the number of degrees of freedom and independence of the degrees of freedom due to the fact that the force vectors are all parallel.

Furthermore, it is not sufficient to simply attach a 6-DOF manipulator to the bottom of a quadrotor or other degenerate aerial platform, as this does not guarantee force closure. While a 6-DOF manipulator can exert arbitrary wrenches when grounded, if the base upon which it is mounted cannot resist an arbitrary wrench, the combination remains degenerate.

Finally, with the multi-quadrotor approach, force closure has not been obtained; lateral forces must be compensated for by torques, not direct opposition. A single UAV can have more manipulation abilities, chiefly force closure; all forces put on the grasped object can be opposed directly. Also a single UAV has numerous advantages over a system that requires multiple UAVs including simplicity, communications, cost, and available poses.

12.1.3 3-D Translational Flight

Besides force closure, an interesting side effect of a UAV with control over six degrees of freedom is the ability to accomplish 3-D translational flight (hover at any orientations and translate in any directions). It would be much easier for a 6-degrees of freedom UAV to achieve unusual body attitudes as Mellinger et al. did (2010). In their work, they developed elaborate dynamic control methodologies to achieve unusual body attitudes during aggressive flight maneuvers to allow their quadrotor UAVs to pass through narrow windows and other hazards. Using high precision external sensing of the pose of the vehicle and an accurate dynamic model, their quadrotor is capable of passing through the diagonal of a rectangular orifice, presumably to enter a damaged building through a narrow window in response to a disaster. The window presents an orifice of which the horizontal width is not sufficient to allow passage of the UAV, but the diagonal distance is. Since a quadrotor cannot hover at an arbitrary orientation (the result of a mapping from actuator space to Cartesian generalized force space with rank less than six, indicative of incomplete force closure), an aggressive dynamic maneuver is required to achieve entry.

Therefore, as a way to gain full controllability over the 6-DOF robot pose and track an arbitrary trajectory over time (e.g., it can hover on one spot with an angled pose), some UAV platforms with tilting propellers have been designed. M. Ryll proposed a quadrotor design with tilting propellers (Ryll et al. 2012). In their work, to solve the problem of limited mobility of standard quadrotor, rather than four fixed rotors, four variable-pitch rotors are used to provide an additional set of control inputs. Because of standard quadrotor's inherent underactuation for 6 degrees of freedom parameterizing the quadrotor position/orientation in space, Ryll claims that they can gain full controllability over the quadrotor position/orientation by means of these four additional actuated degrees of freedom.

Developed about the same time as this Dexterous Hexrotor design, a similar nonplanar design was introduced by the University of Manchester (Langkamp et al. 2011). Using six fixed-pitch/variable-speed or variable-pitch/fix-speed rotors, the "Tumbleweed" is designed to achieve full flight envelope (their saying of 3-D translational flight).

A prototype is proposed with fixed-pitch/variable-speed rotors, and all rotors are pitched at 45° . But as they claimed, it cannot achieve full flight envelope because of limited forces it can generate in frame plane. So they abandoned this design and shifted to a variable-pitch/fix-speed rotor design. And by the use of high-thrust/weight electric variable-pitch units and a low airframe mass fraction,

the Tumbleweed can achieve full flight envelope if the robot can be lifted by only one pair of rotors.

In these two works, the actuation concept of tilting propellers during flight actually makes it possible to access all 6 degrees of freedom of the robot. But for *aerial manipulation* tasks, the aerial platform needs to exert forces as fast as possible to resist any arbitrary wrench. Tilting propellers during flight using servos may not be fast enough for our purposes. So each rotor on Dexterous Hexrotor is pitched at an optimized angle based on specific task.

This chapter proposes a new approach in aerial vehicles as Dexterous Hexrotor UAV that can instantaneously resist arbitrary forces – in other words, it provides force closure. To perform precise and effective mobile manipulation, this is a property that any locomotor must have, be it ground based, water based, or air based. To achieve this, the thrusters of Dexterous Hexrotor are canted so that the combined thrust vectors span the space of Cartesian forces and torques. This adds little cost or complexity to a conventional hexrotor.

With decomposed forces and torques, a thrust mapping from actuator space to force/torque for Dexterous Hexrotor is derived.

Since each rotor is rotated a cant angle around its radius, a metric for the optimization of Dexterous UAV performance for manipulation-based tasks based on the condition number of the conversion matrix in the thrust mapping is developed.

With an attitude controller created to stabilize the Dexterous Hexrotor for human-controlled flight, a flight-capable prototype with translational force control has been built and tested.

12.2 Dexterous Hexrotor Theory

The basic idea behind hexrotor is 6 actuators will be provided. So the input is 6 degrees of freedom. If it needs to control 6 degrees of freedom, it has to have a minimum of 6 actuators. Or else the matrix is going to be deficient. If only 4 actuators are provided as a quadrotor, it cannot possibly have independent control over 6 degrees of freedom.

There are many hexrotors in the commercial world today. They all have six parallel thrust propellers spaced evenly around the circumference of a circle. All its thrusters are vertical, just like typical quadrotors as in Fig. 12.2. Therefore, they still result in rank-deficient matrices; in other words, there are no components from parallel thrusts that act in the plane perpendicular to the rotor axis. In this kind of configuration, these hexrotors work like quadrotors.

Because all these thrusters are parallel and vertical, they can only provide linear force along Z axis, and torques around X, Y axes. Torque around Z is achieved indirectly through Coriolis forces resulting from differential angular velocities of the counterrotating propellers.

As shown in Fig. 12.3, if all the rotors spin at a particular same speed, the robot hovers. If the speed of these rotors varies, the robot can roll, pitch, and yaw.

Fig. 12.2 Typical quadrotor

This configuration only has controllability over 4 degrees of freedom parameterizing the robot position and orientation in space. But it still can move arbitrarily in 6 degrees of freedom space, because translational acceleration in the plane perpendicular to the rotor axis can be achieved by maintaining a nonzero pitch or roll angle. So with these four degrees of freedom, quadrotors can do hover, roll, pitch, and yaw. If the robot wants to move in the plane perpendicular to the rotor axis, it has to maintain a nonzero pitch or roll angle to get the translational acceleration.

To achieve 6 degrees of freedom, 6 actuators are provided as a typical hexrotor design. Then these parallel thrusters are made nonparallel to explore full entirely 6-D space of forces and torques.

As Fig. 12.4 shows, Dexterous Hexrotor has six independently controlled rotors arranged in pairs on three planes. Each rotor is rotated a cant angle around its radius. Therefore in-plane components result while still maintaining a symmetric basis of vectors, and forces and torques around each axis can be produced. Since Dexterous Hexrotor can span the force/torque space, by detaching and combining forces and torques produced by each rotor, forces and torques acting on the UAV around each axis can be accomplished, and controllability over full 6 degrees of freedom can be achieved. By varying the speed and choosing the direction of the rotation of the rotors, Dexterous Hexrotor can get not only forces along Z axis and torques around X, Y, Z axes but also forces along X, Y axes.

As shown in Fig. 12.5, with the force along Z axis and torques around X, Y, Z axes, Dexterous Hexrotor can hover, roll, pitch, and yaw just like typical quadrotor does. But instead of pitching or rolling an angle like typical quadrotors, Dexterous Hexrotor can get translational acceleration by simply varying speed of these rotors. It can truly control its 6 degrees of freedom mobility.

Fig. 12.3 How quadrotor moves: (a) hover, (b) roll, (c) pitch, and (d) yaw

12.2.1 Dexterous Hexrotor Structure

There are many ways to use six motors to create six independent degrees of freedom, but to create a design that was easy to fabricate, a disk design was used. To get linear independence for all six degrees of freedom, the thrust vectors could not be on the same axis nor pointed along one axis. This fact leads to an arrangement which these six rotors are put in pairs of three planes and each thruster is rotated a cant angle ϕ around its radius. These rotors are laid out along the edge of the disk canted tangentially to the edge of the disk alternating clockwise, counterclockwise, clockwise, and so on.

Position of six motors and their rotation are defined in Fig. 12.6. X configuration of multicopter configuration is chosen, so X axis aligns with Motor3 and Motor6.

To keep the direction of each rotor's torque same with its force's in-plane components, Motor1, Motor3, and Motor5 are rotating clockwise, while Motor2, Motor4, and Motor6 are rotating counterclockwise. And to minimize the effects

Fig. 12.4 Dexterous Hexrotor: note the rotors are nonparallel

of the torques from the motors themselves, pusher and puller propellers are used; Motor1, Motor3, and Motor5 use one type, while Motor2, Motor4, and Motor6 use the other.

12.2.2 Force Decomposition

Each rotor produces a force and a torque. The force is a thrust pointed out along the rotor axis. The torque is generated by the drag of the propellers and acts on the body of the robot. The direction of the torque will be in the opposite direction of the motion of the propeller. This torque serves as yawing torque in typical quadrotors. But for Dexterous Hexrotor, it will contribute to torque around all three axes.

The lift and drag produced by the propellers is proportional to the square of angular velocity. And the square of angular velocity is proportional to the pulse width modulation command sent to the motors. Therefore, force and torque produced by each motor can be expressed as Eq. (12.1):

$$\begin{aligned} F_{\text{motor}} &= K_1 * \text{PWM}_{\text{motor}} \\ \tau_{\text{motor}} &= K_2 * \text{PWM}_{\text{motor}} \end{aligned} \quad (12.1)$$

where F_{motor} and τ_{motor} are force and torque produced by the motors. K_1 and K_2 are motor-dependent parameters and can be determined experimentally. $\text{PWM}_{\text{motor}}$ is the pulse width modulation command sent to the motor.

Fig. 12.5 How Dexterous Hexrotor moves: (a) hover, (b) roll, (c) pitch, (d) yaw, (e) translational acceleration along X axis, and (f) translational acceleration along Y axis

Fig. 12.6 Motor definition of Dexterous Hexrotor, where n is the motor Number and θ represents angular displacements of the motors

To compute the net force/torque acting on the UAV from all thrusters, first each motor's thrust and torque is decomposed into X, Y, and Z components on the body frame. The components of Cartesian generalized forces from Motor1 can be put into a matrix as in Eqs. (12.2) and (12.3):

$$\begin{bmatrix} F_{1fx} \\ F_{1fy} \\ F_{1fz} \\ F_{1\tau x} \\ F_{1\tau y} \\ F_{1\tau z} \end{bmatrix} = \begin{bmatrix} -K_1 * PWM_1 * \cos(\theta_1) * \sin(\phi) \\ K_1 * PWM_1 * \sin(\theta_1) * \sin(\phi) \\ K_1 * PWM_1 * \cos(\phi) \\ d * K_1 * PWM_1 * \cos(\theta_1) * \cos(\phi) \\ -d * K_1 * PWM_1 * \sin(\theta_1) * \cos(\phi) \\ d * K_1 * PWM_1 * \sin(\phi) \end{bmatrix} \quad (12.2)$$

$$\begin{bmatrix} T_{1x1} \\ T_{1y1} \\ T_{1z1} \end{bmatrix} = \begin{bmatrix} -K_2 * PWM_1 * \cos(\theta_1) \sin(\phi) \\ K_2 * PWM_1 * \sin(\theta_1) \sin(\phi) \\ K_2 * PWM_1 * \cos(\phi) \end{bmatrix} \quad (12.3)$$

where K_1 and K_2 are the constants between force and torque produced by Motor1 and PWM1 (the pulse width modulation command sent to Motor1), ϕ is the cant angle from vertical, θ represents the rotor's position, and d is the distance from rotor 1 to the central axis (the radius of Dexterous Hexrotor). $[F_{1fx} \ F_{1fy} \ F_{1fz} \ F_{1\tau x} \ F_{1\tau y} \ F_{1\tau z}]^T$ are forces and torques decomposed from F_1 (the force produced by Motor1) and $[\tau_{1\tau x} \ \tau_{1\tau y} \ \tau_{1\tau z}]^T$ are torques decomposed from τ_1 (the torque produced by Motor1).

Then the total force/torque $[F_{1x} \ F_{1y} \ F_{1z} \ \tau_{1x} \ \tau_{1y} \ \tau_{1z}]^T$ acting on Dexterous Hexrotor from Motor1 can be derived as

$$\begin{aligned}
\begin{bmatrix} F_{1x} \\ F_{1y} \\ F_{1z} \\ \tau_{1x} \\ \tau_{1y} \\ \tau_{1z} \end{bmatrix} &= \begin{bmatrix} F_{1fx} \\ F_{1fy} \\ F_{1fz} \\ F_{1\tau x} + \tau_{1\tau x} \\ F_{1\tau y} + \tau_{1\tau y} \\ F_{1\tau z} + \tau_{1\tau z} \end{bmatrix} \\
&= \begin{bmatrix} -K_1 * PWM_1 * \cos(\theta_1) * \sin(\phi) \\ K_1 * PWM_1 + \sin(\theta_1) * \sin(\phi) \\ K_1 * PWM_1 * \cos(\phi) \\ PWM_1 * \cos(\theta_1) * (d * K_1 * \cos(\phi) - K_2 * \sin(\phi)) \\ PWM_1 * \cos(\theta_1) * (-d * K_1 * \cos(\phi) + K_2 * \sin(\phi)) \\ PWM_1 * (-d * K_1 * \sin(\phi) + K_2 * \sin(\phi)) \end{bmatrix} \\
&= PWM_1 * \begin{bmatrix} -K_1 C \theta_1 S \phi \\ K_1 C \theta_1 S \phi \\ K_1 C \phi \\ C \theta_1 (d K_1 C \phi - K_2 S \phi) \\ C \theta_1 (-d K_1 C \phi + K_2 S \phi) \\ d K_1 S \phi + K_2 C \phi \end{bmatrix} \tag{12.4}
\end{aligned}$$

Once one rotor is decomposed, forces and torques produced by other motors can be decomposed in the same way.

12.2.3 Mapping from Actuator Space to Force/Torque Space

After decomposition of force/torque produced by each motor, now the net force/torque of Dexterous Hexrotor can be computed as Eq. (12.5):

$$\begin{bmatrix} F_x \\ F_y \\ F_z \\ \tau_x \\ \tau_y \\ \tau_z \end{bmatrix} = \begin{bmatrix} F_{1x} \\ F_{1y} \\ F_{1z} \\ \tau_{1x} \\ \tau_{1y} \\ \tau_{1z} \end{bmatrix} + \begin{bmatrix} F_{1x} \\ F_{1y} \\ F_{2z} \\ \tau_{2x} \\ \tau_{2y} \\ \tau_{2z} \end{bmatrix} + \begin{bmatrix} F_{3x} \\ F_{3y} \\ F_{3z} \\ \tau_{3x} \\ \tau_{3y} \\ \tau_{3z} \end{bmatrix} + \begin{bmatrix} F_{4x} \\ F_{4y} \\ F_{4z} \\ \tau_{4x} \\ \tau_{4y} \\ \tau_{4z} \end{bmatrix} + \begin{bmatrix} F_{5x} \\ F_{5y} \\ F_{5z} \\ \tau_{5x} \\ \tau_{5y} \\ \tau_{5z} \end{bmatrix} + \begin{bmatrix} F_{6x} \\ F_{6y} \\ F_{6z} \\ \tau_{6x} \\ \tau_{6y} \\ \tau_{6z} \end{bmatrix} \tag{12.5}$$

where $[F_x \ F_y \ F_z \ \tau_x \ \tau_y \ \tau_z]^T$ is the net force/torque acting on the body of Dexterous Hexrotor.

From force decompositions, the right part of equation equals this 6×6 conversion matrix multiplied by $[PWM_1 \ PWM_2 \ PWM_3 \ PWM_4 \ PWM_5 \ PWM_6]^T$.

$$\begin{bmatrix} -K_1 C \theta_1 S \phi & K_1 C \theta_2 S \phi & K_1 C \theta_3 S \phi & K_1 C \theta_4 S \phi & K_1 C \theta_5 S \phi & K_1 C \theta_6 S \phi \\ K_1 S \theta_1 S \phi & -K_1 S \theta_2 S \phi & K_1 S \theta_3 S \phi & -K_1 S \theta_4 S \phi & K_1 S \theta_5 S \phi & -K_1 S \theta_6 S \phi \\ K_1 C \phi & K_1 C \phi & K_1 C \phi & K_1 C \phi & K_1 C \phi & K_1 C \phi \\ C \theta_1 (dK_1 C \phi - K_2 S \phi) & C \theta_2 (dK_1 C \phi - K_2 S \phi) & C \theta_3 (dK_1 C \phi + K_2 S \phi) & C \theta_4 (dK_1 C \phi - K_2 S \phi) & C \theta_5 (dK_1 C \phi - K_2 S \phi) & C \theta_6 (dK_1 C \phi + K_2 S \phi) \\ S \theta_1 (-dK_1 C \phi + K_2 S \phi) & S \theta_2 (dK_1 C \phi - K_2 S \phi) & S \theta_3 (-dK_1 C \phi + K_2 S \phi) & S \theta_4 (-dK_1 C \phi + K_2 S \phi) & S \theta_5 (-dK_1 C \phi + K_2 S \phi) & S \theta_6 (-dK_1 C \phi + K_2 S \phi) \\ dK_1 S \phi + K_2 C \phi & -dK_1 S \phi - K_2 C \phi & dK_1 S \phi + K_2 C \phi & -dK_1 S \phi - K_2 C \phi & dK_1 S \phi + K_2 C \phi & -dK_1 S \phi - K_2 C \phi \end{bmatrix}$$

Express this matrix as M_φ . This equation can be concluded as

$$\begin{bmatrix} F_x \\ F_y \\ F_z \\ \tau_x \\ \tau_y \\ \tau_z \end{bmatrix} = M_\varphi \cdot \begin{bmatrix} PWM_1 \\ PWM_2 \\ PWM_3 \\ PWM_4 \\ PWM_5 \\ PWM_6 \end{bmatrix} \quad (12.6)$$

In Dexterous Hexrotor, $[F_x \ F_y \ F_z \ \tau_x \ \tau_y \ \tau_z]^T$ is the desired force/torque vector. Values of this vector will decide the robot's orientation and position. $[PWM_1 \ PWM_2 \ PWM_3 \ PWM_4 \ PWM_5 \ PWM_6]^T$ are six independent controlled inputs for the robot. Based on this equation, a relationship between inputs (PWM commands) and outputs (force/torque) of Dexterous Hexrotor can be established, and a mapping from UAV's actuator space to Cartesian force/torque space can be built. Therefore, to control Dexterous Hexrotor and get desired force/torque vector, the inversed conversion matrix is multiplied by the desired force/torque vector, then PWM commands are calculated and sent to the motors. The force/torque control equation can be derived as

$$\begin{bmatrix} PWM_1 \\ PWM_2 \\ PWM_3 \\ PWM_4 \\ PWM_5 \\ PWM_6 \end{bmatrix} = [M_\varphi]^{-1} \cdot \begin{bmatrix} F_x \\ F_y \\ F_z \\ \tau_x \\ \tau_y \\ \tau_z \end{bmatrix} \quad (12.7)$$

The conversion matrix is the mapping from actuator space to force/torque space. With K_1 and K_2 determined for motors, if the cant angle is zero, the conversion matrix is M_{0° :

$$M_{0^\circ} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 5.7 & 5.7 & 5.7 & 5.7 & 5.7 & 5.7 \\ 1.33 & 1.3 & 0 & -1.33 & -1.33 & 0 \\ -0.769 & 0.769 & 1.54 & 0.769 & -0.769 & -1.54 \\ 0.13 & -0.13 & 0.13 & -0.13 & 0.13 & -0.13 \end{bmatrix}$$

which would conform to a typical hexrotor design. M_{0° only has a rank of 4. It has no ability to instantaneously control forces in X and Y axes through this matrix.

If the thrusters are canted at an angle, for example, at 20° , the thrust mapping becomes M_{20° :

$$M_{20^\circ} = \begin{bmatrix} -1.69 & 1.69 & 0 & -1.69 & 1.69 & 0 \\ 0.975 & 0.975 & -1.95 & 0.975 & 0.975 & -1.95 \\ 5.36 & 5.36 & 5.36 & 5.36 & 5.36 & 5.36 \\ 1.21 & 1.21 & 0 & -1.21 & -1.21 & 0 \\ -0.701 & 0.701 & 1.4 & 0.701 & -0.701 & -1.4 \\ 0.649 & -0.649 & 0.649 & -0.649 & 0.649 & -0.649 \end{bmatrix}$$

which would conform to a nonparallel design. This matrix provides a mapping from 6-D actuator space to 6-D force/torque space and has a rank of 6, indicating 6 independent controlled degrees of freedom in Cartesian force/torque space.

12.2.4 Dexterous Hexrotor Performance Optimization

The cant angle decides how much force it can get in $[F_z \ \tau_x \ \tau_y]^T$ or $[F_x \ F_y \ \tau_z]^T$. If $\varphi = 0^\circ$, the matrix becomes

$$M_{0^\circ} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 5.7 & 5.7 & 5.7 & 5.7 & 5.7 & 5.7 \\ 1.33 & 1.3 & 0 & -1.33 & -1.33 & 0 \\ -0.769 & 0.769 & 1.54 & 0.769 & -0.769 & -1.54 \\ 0.13 & -0.13 & 0.13 & -0.13 & 0.13 & -0.13 \end{bmatrix}$$

Clearly the matrix becomes degenerate as there are no forces in X or Y from rotor force/torque decomposition; this would conform to a fairly typical quadrotor design. There's no mapping from actuator space to forces in X and Y. It's rank deficient. The opposite happens when φ is 90° :

$$M_{90^\circ} = \begin{bmatrix} -4.94 & 4.94 & 0 & -4.94 & 4.94 & 0 \\ 2.85 & 2.85 & -5.7 & 2.85 & 2.85 & -5.7 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ -0.11 & -0.11 & 0 & 0.11 & 0.11 & 0 \\ 0.065 & -0.065 & -0.13 & -0.065 & 0.065 & 0.13 \\ 1.54 & -1.54 & 1.54 & -1.54 & 1.54 & -1.54 \end{bmatrix}$$

Force can be applied in X and Y but no lift and the matrix becomes deficient again. With these examples in mind, it is obvious that the closer to $\varphi = 0^\circ$, the more

Table 12.1 Parameters of Dexterous Hexrotor engineering prototype

| | |
|---------------------|--------|
| K1 | 5.7 |
| K2 | 1.3 |
| Diameter | 0.27 m |
| Mass of UAV | 2 kg |
| Mass of manipulator | 0.5 kg |
| Desired payload | 0.3 kg |

Fig. 12.7 Maximum forces Dexterous Hexrotor can achieve at different cant angles

Dexterous Hexrotor can lift, but the closer to $\varphi = 90^\circ$, the more lifting force can be obtained while tilted, or the more Dexterous Hexrotor can tilt.

A cant angle has to be chosen somewhere between 0° and 90° when a prototype of Dexterous Hexrotor is being built. So a metric for optimization of Dexterous Hexrotor UAV’s performance has been developed.

The performance of Dexterous Hexrotor at different cant angles is affected by several variables, including the thrust of the motors, the diameter of the UAV, and the load it needs to carry. For manipulation tasks, the engineering requirement for Dexterous Hexrotor is the desired payload.

So for Dexterous Hexrotor engineering prototype, the thrust of the motors and the diameter of the UAV are given based on the motors and frame. Given the system’s own mass and desired payload, the load it needs to carry is also set. The only thing undecided is the cant angle.

With parameters in Table 12.1, maximum forces and torques Dexterous Hexrotor that can achieve near hover condition at different cant angles can be plotted in Fig. 12.7.

Clearly at $\varphi = 0^\circ$, there are no forces in X or Y and not much torques around Z. The opposite happens when $\varphi = 35^\circ$, where all forces in Z are used to provide

lift, but more force can be applied in X and Y. This means Dexterous Hexrotor engineering prototype can operate from 0° to 35° . So a cant angle between 0° and 35° should be chosen.

To optimize the cant angle for the performance of Dexterous Hexrotor, Yoshikawa's concept of "manipulability" was adapted here. As defined by Yoshikawa, "manipulability measure" is a quantitative measure of manipulating ability of robot arms in positioning and orienting the end effectors, by looking at the isotropism of manipulator's motion in linear dimensions X, Y, Z and angles roll, pitch, and yaw (Yoshikawa 1985). So for Dexterous Hexrotor the combination of forces and torques is considered as a similar measure of mobility. The isotropism of the forces and torques is going to be checked, not just how strong is it. To visualize how isotropic are the forces and torques, these force/torque ellipsoids are plotted in Fig. 12.8.

The radius of these ellipsoids represents the magnitude of maximum force/torque Dexterous Hexrotor can achieve around X, Y, Z axes at near hover condition. When the cant angle is 0° , it gets no ability to control F_x , F_y , but a lot of ability to control F_z . It also has ability to control τ_x τ_y τ_z , but not too much control over yaw because Coriolis effect is weak. Then the motors are canted a little bit; it gets a little bit control over F_x , F_y , but still very strong control in F_z . And likewise it gets a little more control over yaw. At 20° , the force ellipsoid becomes almost equal, and the torque ellipsoid also gets more round. At 30° , both force ellipsoid and torque ellipsoid start to squash down again. Therefore, from 0° to 30° and beyond, the force/torque ellipsoid can get very isotropic at some point, which is good in this mobility measure.

The condition number of the conversion matrix is also a way to check the isotropism of the forces and torques. Condition number is a mathematic term from linear algebra, which is the ratio of maximum eigenvalue to the minimum eigenvalue of the matrix. It can be seen as the rate at which one side of the equation will change with respect to the other side. If the condition number is large, even a small error in one side may cause a large error in the other side.

As shown in Fig. 12.9, at 0° , when it has no control over F_x and F_y , the condition number would be infinite, because two of the eigenvalues are 0. Then it can get smaller and smaller when increasing the cant angle. It is hard getting to 1 since force and torque are measured under different scales. Eventually, it gets higher again and it will be infinite at 90° , because one of the eigenvalues is 0.

These two metrics can be combined on a same plot as shown in Fig. 12.10. The condition number of the conversion matrix with force/torque ellipsoids at different cant angles is plotted, giving a measure of the isotropism of Dexterous Hexrotor UAV.

Therefore, dependent on the motors, particular load of the manipulator, and diameter of the UAV frame, the cant angle is optimized at 20° for this Dexterous Hexrotor engineering prototype. If the load or any other parameters are changed, a different cant angle would probably result after the optimization. And for tasks other than manipulation, its performance can be optimized with other parameters as well as the cant angle.

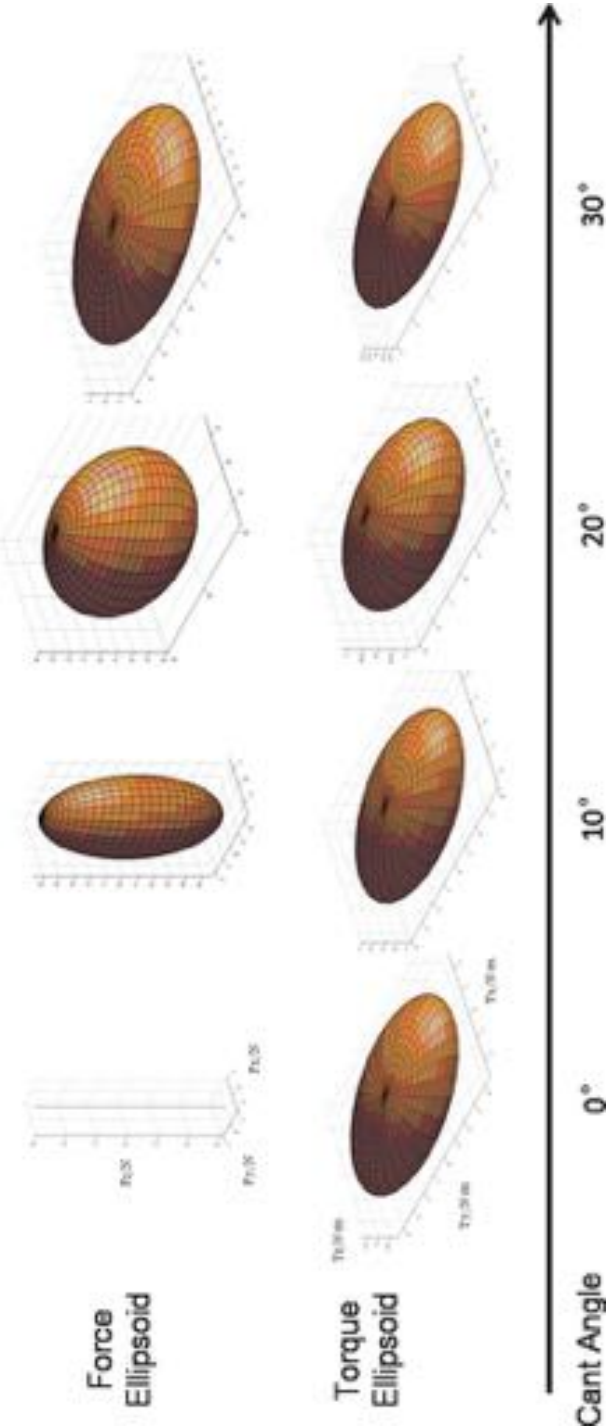

Fig. 12.8 Force/torque ellipsoids at different cant angles

Fig. 12.9 Condition number of the conversion matrix

12.3 Dexterous Hexrotor Control

12.3.1 Dexterous Hexrotor Control System

For human-controlled flight, the pilot controls Dexterous Hexrotor's orientation and position by manipulating the forces and torques acting on the platform. For Dexterous Hexrotor, there are six independent controlled forces and torques acting on itself. Therefore, control systems to help the pilot control Dexterous Hexrotor's orientation and position are developed.

Forces and torques acted on the Dexterous Hexrotor are generated by the thrust of each rotor. And the thrust is proportional to the PWM value put into the motor. Based on the force/torque control equation, to generate desired force/torque, PWM values which are calculated from desired force/torque vector $[F_x \ F_y \ F_z \ \tau_x \ \tau_y \ \tau_z]^T$ through thrust mapping need to be sent to each motor.

Multicopters are inherently unstable in the air. Therefore, an attitude controller is needed to stabilize the UAV during flight. A common control system used in quadrotors is as shown in Fig. 12.11.

This system is constructed by radio receiver, attitude controller, IMU (inertial measurement unit), thrust mapping, and motors. With the help of attitude controller stabilizing the UAV, the pilot only needs to control its attitude to change the orientation and position (e.g., pitching for moving forward).

The difference between controlling Dexterous Hexrotor and quadrotor is the thrust mapping. Thrust mapping of quadrotor only maps $[F_z \ \tau_x \ \tau_y \ \tau_z]^T$ to motors. Dexterous Hexrotor's thrust mapping needs to map all force/torque around three axes to motors. So the control system should be as it is shown in Fig. 12.12.

Fig. 12.10 Condition number with force/torque ellipsoids

Fig. 12.11 Quadrotor control system

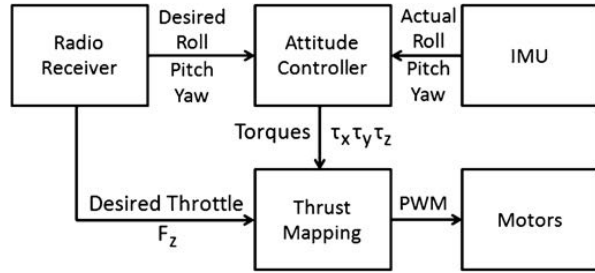

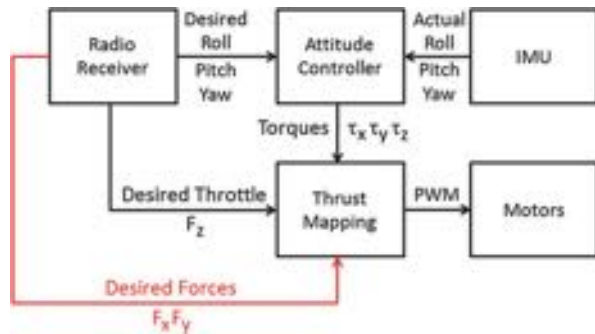

Fig. 12.12 Dexterous Hexrotor control system

Thrust mapping in this system maps $[F_x \ F_y \ F_z \ \tau_x \ \tau_y \ \tau_z]^T$ to $[PWM_1 \ PWM_2 \ PWM_3 \ PWM_4 \ PWM_5 \ PWM_6]^T$. It is a mapping from 6-D actuator space to 6-D force/torque space.

Control system of Dexterous Hexrotor has two more channels controlling F_x and F_y than quadrotor. These forces are in the plane perpendicular to the rotor's axis. They can provide horizontal acceleration. These forces can be used to exert forces immediately in the plane, and they also give the pilot another option of moving Dexterous Hexrotor. When the pilot wants to move the quadrotor, it needs to pitch or roll an angle in order to get the translational acceleration. Dexterous Hexrotor can simply generate the translational acceleration by F_x or F_y .

The difference between control system of Dexterous Hexrotor and typical quadrotor is as shown in Table 12.2.

12.3.2 Hexrotor Attitude Controller

The attitude controller is designed to stabilize Dexterous Hexrotor for human-controlled flight. It helps Dexterous Hexrotor maintaining desired attitude during flight by controlling Dexterous Hexrotor roll, pitch, and yaw. This is also a commonly used control structure in quadrotor community.

For stability and also fast response, three double-loop PID controllers for roll, pitch, and yaw have been developed, and they share same structure as it is shown in Fig. 12.13.

Table 12.2 Difference between control system of Dexterous Hexrotor and typical quadrotor

| | Quadrotor | Dexterous Hexrotor |
|--------------------------------------|---|--|
| Pilot controlled variables | Roll, pitch, yaw, Fz | Roll, pitch, yaw, Fx, Fy, Fz |
| Number of pilot controlled variables | 4 | 6 |
| Inputs to thrust mapping | $F_z \ \tau_x \ \tau_y \ \tau_z$ | $F_x \ F_y \ F_z \ \tau_x \ \tau_y \ \tau_z$ |
| Number of inputs to thrust mapping | 4 | 6 |
| Outputs of thrust mapping | PWM ₁ PWM ₂ PWM ₃ PWM ₄ | PWM ₁ PWM ₂ PWM ₃ PWM ₄ PWM ₅ PWM ₆ |

Fig. 12.13 Double-loop PID controller

The outer loop is using a PI controller for controlling the angle. It takes desired angle as input, actual IMU angle as feedback, and outputs desired angular rate to the inner loop.

The inner loop is using a PD controller for controlling angular rate. It takes angular rate as input, actual IMU angular rate as feedback, and outputs torques to adjust the attitude of Dexterous Hexrotor. The PI and PD combination is chosen for a good reason. A single traditional PID controller would work, but slow. An outer loop controlling angle and an inner loop controlling rate would be much better for its fast response. P item is necessary in both loops for fast response. A D term in the inner loop is for improving response time. An I term in the outer loop is for helping Dexterous Hexrotor dealing with persistent external forces, like wind or incorrect center of gravity.

12.4 Dexterous Hexrotor Prototype

A prototype that uses off-the-shelf components, preferably those commonly used by modern research quadrotors, has been built to improve cost, compatibility, and simplicity. The prototype of Dexterous Hexrotor design can be seen in Fig. 12.14.

The motors are mounted on in-house designed and fabricated ABS plastic adapters that cant 20° tangentially to the edge. These plastic adapters are then mounted on the end of each arm as shown in Fig. 12.15.

Fig. 12.14 Dexterous Hexrotor prototype built on a commercial frame

Fig. 12.15 Motor mounted on a 20° ABS plastic adapter

Standard 11.1 V lithium polymer battery packs are used to power the 30 A ESCs (electronic speed controllers). Each ESC drives a 1,130 kV brushless DC motor with a three-phase signal converted from the PWM command. The motors are installed with 9" \times 4.7" pusher or puller propellers.

A 2.4 GHz radio transmitter and receiver set are used for human-controlled flight. Four main joysticks are used for roll, pitch, yaw, and throttle. Two side knobs are used to set F_x and F_y values.

The controller is the RecoNode platform developed in collaborative mechatronics lab. A universal PCB board is used for routing signals between onboard electronics, the RecoNode Platform, IMU, radio receiver, and ESCs as shown in Fig. 12.16.

A Sparkfun 9-DOF sensor stick is used as IMU. It includes an ADXL345 accelerometer, an HMC5883L magnetometer, and an ITG-3200 gyro. It communicates with CPU by I2C interface.

Fig. 12.16 Onboard electronics of Dexterous Hexrotor

Fig. 12.17 RecoNode stack with Virtex4 FX20 CPU and two single-width wedges

The RecoNode is a multiprocessor architecture based on the Virtex 4 FPGA with multiple, hardcore PowerPCs. Capable of up to 1,600 MIPS from four PowerPCs plus hundreds of additional MIPS of special-purpose coprocessing from the FPGA fabric itself, this computational node is very high in performance compared to conventional wireless sensor nodes – roughly 100 times greater computational throughput. The RecoNodes are dual-processor models running at 400 MIPS with a power budget of 0.9 mW/MIPS.

The RecoNode used in Dexterous Hexrotor has two base boards and two same wedges. In Fig. 12.17, from bottom to top: DU105 power board, providing 1.2, 2.5, 3.3, and 5 V for the system; DU100 CPU board, carrying a Virtex4 FX20 CPU running at 100 MHz; DU121 servo wedge, transferring the PWM commands from CPU to ESCs and input signals from radio receiver and IMU to CPU.

12.5 Experiments and Results

12.5.1 6-DOF Force/Torque Test

Force closure in 3-D space requires six controllable degrees of freedom in force/torque space to truly accomplish. To prove Dexterous Hexrotor can apply force/torque in all six degrees of freedom or only one degree of freedom without affecting the others, the Dexterous Hexrotor is bolted on an ATI 6-DOF force sensor and tried to produce forces and torques in all three dimensions. The test setup and ATI force sensor software are as shown in Fig. 12.18.

During the test, unit forces and torques in the force/torque vector $[F_x F_y F_z \tau_x \tau_y \tau_z]^T$ were commanded sequentially for around 5 s each at near hover condition. For 5 s with a five-second off after, each of the script requests a force in X, then Y, and then Z axis. Then it requests a torque about X, then Y, and then Z axis. The result of the test is as shown in Fig. 12.19 and tabulated in Table 12.1.

In this plot, the first 5 s, all motors are off. It is apparent from F_z that at roughly 5 s, Dexterous Hexrotor “takes off” and then the sequence begins. Data was recorded by an ATI 6-DOF force sensor at 10 kSamp/s. Time is in milliseconds.

In Table 12.3, T1 is from 5 to 10 s, which shows half throttle. T2 is from 10 to 15 s, when Dexterous Hexrotor is generating a force in x axis. T3 is from 15 to 20 s, when Dexterous Hexrotor is generating a force in y axis. T4 is from 20 to 25 s, when Dexterous Hexrotor raises its throttle. T5 is from 25 to 30 s, when Dexterous Hexrotor is generating a torque around x axis. T6 is from 30 to 35 s, when Dexterous Hexrotor is generating a torque around y axis. T7 is from 35 to 40 s, when Dexterous Hexrotor is generating a torque around z axis. This data was produced by taking the time average of the central 3 s of each period.

In Table 12.4, error of each force is compared to the magnitude of required force vector. For example, during T1, required force vector in Z axis has a magnitude of 11.56 N. F_x and F_y should be zero during T1, but they are not. So values of F_x and F_y are compared to the magnitude of the force vector and get percentage error of $0.08/11.56 = 0.69\%$ and $0.04/11.56 = 0.34\%$. It's same in T4, T5, T6, and T7, but different in T2 and T3. During T2 and T3, required force vector points along a direction between Z axis and X or Y axis. Since errors are no more than 1 %, it proves it can actually control force in each axis accurately with no coupling to the other axes.

In Table 12.5, error of each torque compared to its peak value is checked. For example, τ_x during T1 should be 0, as it is given a force/torque command of $[0 \ 0 \ F_z \ 0 \ 0 \ 0]^T$, producing only a force vector in Z axis. So comparing the value of τ_x during this period to its peak value happened in T5, its error is $0.01/1.13 = 0.8\%$. Values of torques are much smaller than the magnitude of force vector, so their percentage error looks much larger. But still an error of torques at most 6.6 % can be observed, proving that it can actually control torque in each axis with no coupling to the other axes.

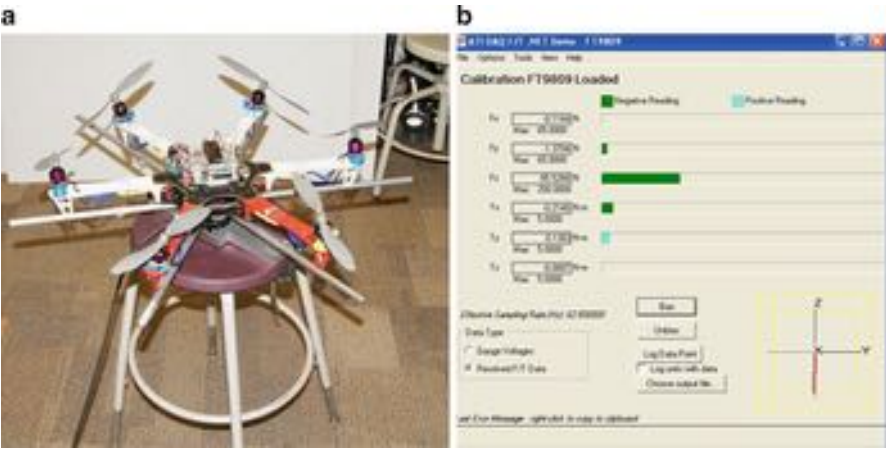

Fig. 12.18 Force/torque test setup: (a) Dexterous Hexrotor bolted on an ATI 6-DOF force sensor. (b) ATI 6-DOF force sensor software

With the ability of controlling force/torque in each axis with no coupling to the other axes, it shows full controllability over six degree of freedoms of Dexterous Hexrotor and linear independence between them.

12.5.2 Exert Forces Test

To test the response time of the Dexterous Hexrotor corresponding to external forces, a staged peg-in-hole task is presented with Dexterous Hexrotor and a normal quadrotor. A frame diagram in Fig. 12.20 shows the experiment’s setup. The peg was held rigidly by the UAV. With the peg trapped halfway in a hole which is attached to the 6-DOF ATI force sensor, the UAV starts to take off and increases its throttle until it can carry its own weight. Then it exerts a horizontal force perpendicular to the axis of the peg.

The result is shown in Fig. 12.21. Changes in force sensor measurements of F_y are direct measurements of the force which Dexterous Hexrotor and quadrotor applied on the hole. A positive pulse and a negative pulse are detected around 500 and 1,500 ms. At the meantime, the attitude of Dexterous Hexrotor was recorded and plotted in the same figure.

When Dexterous Hexrotor is exerting a force in Y axis, its attitude, especially pitch angle, does not change more than 1° . This proves Dexterous Hexrotor is exerting a force in Y axis without pitching.

When the quadrotor is trying to apply the same force, it pitches about -20° and 20° . This is because quadrotor can only generate a horizontal force by tilting an angle and Dexterous Hexrotor can do it by simply changing the rotational velocity of the rotors without tilting.

Fig. 12.22 Dexterous Hexrotor and quadrotor measurements of F_y

Therefore, as shown in Fig. 12.22, when it needs to exert an external force, it is obvious that the lag varying speeds of propellers of Dexterous Hexrotor will be much smaller than that caused by tilting an angle of a quadrotor. This is Dexterous Hexrotor’s advantage to typical quadrotors.

Table 12.6 Difference between Dexterous Hexrotor and typical quadrotor

| | Quadrotor | Dexterous Hexrotor |
|------------------------------------|--------------|--------------------|
| Number of actuators | 4 | 6 |
| Cant angle of each actuator | 0° | 0°–90° |
| DOFs in force/torque space | 4 | 6 |
| Controllable DOFs | 4 | 6 |
| Ability to achieve force closure | No | Yes |
| Mobility in 3-D space | Nonholonomic | Holonomic |
| Response of exert horizontal force | Slow | Fast |

12.6 Conclusion

This chapter introduces a truly holonomic aerial rotorcraft that provides force closure for controlled interaction with external structures. The difference between Dexterous Hexrotor and quadrotor is listed in Table 12.5. The key contribution of this chapter is to derive the mapping from actuator space to force/torque space based on decomposed net force/torque and develop a metric for the optimization of Dexterous UAV's performance for manipulation-based tasks. A flight-capable prototype with translational force control has been built and tested (Table 12.6).

It should be noted that Dexterous Hexrotor can “instantaneously resist arbitrary forces” is not strictly true as the Dexterous Hexrotor can only change the torque of its motors instantaneously. The required change in the thrust magnitude is not dependent on torque, for a propeller, but on speed. Therefore, the independent thrust magnitudes and the resulting net force/torque experience a lag due to the inertia of the thrusters. The lag due to the rotor inertia is much smaller than that due to pitching the entire vehicle, as for a conventional quadrotor, and is smaller than the pitching of the variable cant angle. To achieve force closure, we cant all thrusters of Dexterous Hexrotor at an angle and make all thrust vectors nonparallel and vertical. This would definitely influence the power efficiency of the UAV. When typical quadrotor hovers, all its power is used to combat gravity. But for Dexterous Hexrotor, some of its power will be used to cancel out each rotor's thrust. This is the main drawback of nonparallel design.

Section III

UAV Fundamentals

Isaac I. Kaminer

Kimon P. Valavanis and George J. Vachtsevanos

The first two sections of the handbook have introduced the reader to UAVs in general and in particular to their design principles, paving the way for this third section, UAV Fundamentals, which details those fundamentals that constitute the foundational elements of UAV design technologies. This section covers kinematics and dynamics for fixed-wing, rotorcraft, quadrotors and flapping-wing MAVs, as well as *principles* of UAV guidance, navigation, and control.

► [Kinematics and Dynamics of Fixed-Wing UAVs](#) by Dobrokhodov provides a thorough review of the fundamentals required for accurate mathematical modeling of flight of a fixed-wing UAV, including kinematics and dynamics of motion and transformation of forces and moments acting on the airplane. The main objective is to familiarize the reader with the “kinematics–dynamics–actions” triad as it applies to a generic fixed-wing UAV. Emphasis is given to the understanding of reference frames and their dynamics as this is essential for the design of the UAV guidance, navigation, and control systems.

► [Dynamic Model for a Miniature Aerobatic Helicopter](#) by Gavrillets presents a nonlinear dynamic model of a miniature aerobatic helicopter following a component buildup to derive the model using simplified analytical expressions for the component forces and moments. Key parameters are estimated based on flight-test experiments. The derived model is used to design control logic for aerobatic maneuvers performed entirely under computer control.

► **Quadrotor Kinematics and Dynamics** by Powers, Mellinger, and Kumar presents an overview of the rigid body dynamics of a quadrotor, starting from describing the Newton–Euler equations that govern the quadrotor motion. This is followed by the derivation of a linear controller based on a linearized model of the dynamics and a nonlinear controller derived from the original dynamic model. Experimental results that illustrate the dynamics and control of small quadrotors are also presented.

► **Dynamics and Control of Flapping Wing MAVs** by Doman, Oppenheimer, and Sigthorsson focuses on presenting methods suitable for hover-capable flapping-wing vehicles. This is a challenging problem as flapping-wing motion is characterized by seven wing motion parameters like wing stroke amplitude, symmetric and asymmetric frequency, bias, upstroke and downstroke angle-of-attack limits, and wing stroke plane inclination. A method is presented that enables the designer to estimate how the seven wing motion parameters change in response to changes in the control mechanism position, followed by a method for estimating the combined effect of fuselage motion and flapping-wing motion. Control design considerations and simulation methods are also discussed.

► **Principles of Guidance, Navigation, and Control of UAVs** by Elkaim, Pradipta Lie, and Gebre-Egziabher presents two easily reconfigurable system architectures for guidance, navigation, and control of small UAVs. The presented system architectures integrate a low-cost inertial measurement unit, a GPS receiver, and a triad of magnetometers to generate a navigation solution which, in turn, is used in the guidance and control algorithms. The full system architecture – the hardware, software, and algorithms – is included for completeness. Hardware in the loop simulation and flight-test results documenting the performance of these two systems is given.

With this background, the reader, novice or expert, is now well prepared to study “specifics” and those constituent technologies, such as sensors and sensing strategies, propulsion, control, and communications, to name a few, which will enable him/her to gain a thorough understanding of the subject or explore key areas of interest.

Abstract

This chapter provides a review of basic knowledge required for accurate mathematical modeling of flight of a fixed-wing UAV. These include the kinematics and dynamics of motion, and the transformation of forces and moments acting on the airplane. The detailed discussion of the “kinematics–dynamics–actions” triad in application to a generic fixed-wing UAV is the main objective of this chapter. Therefore, the presentation starts with an introduction to the coordinate frames,

V. Dobrokhodov

CA, USA
e-mail: vldobr@nps.edu

their transformations, and differential rotations. Kinematics of the coordinate frames is what connects states of a fixed-wing UAV and transforms forces and moments acting in different coordinate frames. Understanding of reference frames and their dynamics is essential for the guidance, navigation, and control systems design. Next, the chapter provides a detailed derivation of the equations of motion using the Newtonian approach. Assuming that a fixed-wing UAV can be represented as a rigid body moving in an inertial space allows for the derivation of the linear and angular momentum equations. Starting in an inertial frame, it is shown how the final form of translational and rotational equations of motion becomes written in a body-fixed coordinate frame. The development of both the kinematic and dynamic equations is carried out first in a general vector form; then, using simplifying assumptions applicable to a generic fixed-wing symmetric UAV, the vector equations are expanded into a scalar form to better represent the resulting simplification and the physical meaning of the remaining components. Finally, the chapter presents the principles of defining the external forces and moments acting on a generic fixed-wing airplane. Since the forces and moments found on an airplane act in a number of coordinate frames including inertial, body-fixed, and wind frames, the chapter utilizes the concepts and tools built in the kinematics section to transform the forces and moments into the body-fixed frame. Such transformations complete the presentation of the “kinematics–dynamics–actions” triad.

14.1 Introduction

The chapter objective is to provide an overview of the necessary theoretical material to enable a reliable mathematical modeling of the free and controlled motion of a generic fixed-wing UAV. Although the subject is not new and is well presented in existing literature, the rapid advancements of the last decade in research and development of fixed-wing UAV technologies open new applications that require understanding and a careful application of the existing assumptions. New materials, novel structural designs, new aerodynamic configurations, and advanced onboard instrumentation including miniature sensors, actuators, and tremendous onboard processing power enable much wider operational envelop of fixed-wing UAVs and significantly higher utility of their payloads. Depending on the UAV configuration and its intended operational use, the standard 12 equations of motion might not suffice for the task at hand and require deeper consideration of the UAV components interaction.

This chapter starts with some preliminaries required to describe kinematics of a rigid body motion in three-dimensional (3D) space. Thus, the kinematics of 3D rotation is introduced first. The most commonly used coordinate frames that are utilized in the description of UAV states are presented next. Applying the kinematics of rotating frames to a set of specific coordinate frames builds the basis for a convenient description of the external forces and moments acting on a fixed-wing airplane. Understanding of reference frames and their rotations is essential for the eventual development of the guidance, navigation, and control systems architecture.

Next, the chapter provides a detailed derivation of the equations of motion using the classical Newtonian approach. Assuming that a fixed-wing UAV can be represented as a rigid body moving in an inertial space allows for the derivation of the linear and angular momentum equations. Starting in an inertial frame, it is shown how the final form of translational and rotational equations of motion can be written in a body-fixed coordinate frame. The development of both the kinematic and dynamic equations is carried out first in a general vector form, and then, using simplifying assumptions applicable to a generic fixed-wing symmetric UAV, the vector equations are expanded into a scalar form to better highlight the physical meaning of their components. Since the external forces and moments found on an airplane act in a number of coordinate frames including inertial, body-fixed, and wind frames, the chapter utilizes the concepts and tools built in the kinematics description to transform the forces and moments into the body-fixed frame. Thus, the complete derivation of linear and angular momentum equations, along with the forces and moments acting on a rigid body, results in the generalized set of 6 degrees of freedom (6DoF) equations of motion.

14.2 Reference Frames and Coordinate Transformations

In order to accurately describe a body motion, it is required to define (i) the forces and moments acting on the body and thus resulting in the body motion and (ii) the coordinate system that can be used as a reference for the motion states definition. It is important to note that there are two types of forces acting on a body in free motion. First, the inertial forces and moments that depend on the velocities and accelerations relative to an inertial reference frame; the classical Newtonian dynamics equations hold only in the inertial frame. The second group consists of the aerodynamic forces and moments resulting from interaction of the body with the surrounding airflow and therefore relative to the air. Since the airflow might not be stationary, it is therefore convenient to describe the resulting aerodynamics in the coordinate frames connected to the body and to the surrounding air. The resulting motion can be conveniently described in terms of the position, velocity, acceleration, and attitude coordinates which comprise the states of the moving body. Some of these states, in turn, need to be defined with respect to a reference frame which choice is defined by the specifics of the UAV application. Thus, the information carried by various reference frames is what facilitates the complete and convenient definition of the free body motion.

Therefore, this section starts with a definition of a coordinate frame and the description of the coordinate frame rotation. The reference frames required to represent the aerodynamic forces and moments and facilitating the solution of the navigation states are introduced next. Communication of the states information occurring during the coordinate frame transformation is presented for the major coordinate frames typical for UAV applications. The section ends with a set of kinematic equations required to represent the transition of linear and angular accelerations.

Fig. 14.1 The same plane rotation considered with respect to two and three axes. (a) Two-dimensional coordinates. (b) Three-dimensional coordinates

14.2.1 Kinematics of Moving Frames

The objective of this subsection is to define a coordinate frame transformation and the associated mathematical formalism. Namely, the direct cosine matrix (DCM) is introduced, and its key properties are presented. The DCM matrix formalism is then followed by a differential rotation that defines the rate of change of the DCM matrix. A fundamental property of the simple summation of angular rates is introduced next. The section ends with a detailed presentation of the coordinate frames used to describe the 6DoF motion of a rigid body. The results of this development are heavily utilized throughout the entire chapter.

An arbitrary motion of a rigid body can be described by a transformation that consists of (Goldstein 1980) translational and rotational components. First, a pure rotation of a rigid body is addressed. Consider a vector \mathbf{p} defined in two orthogonal coordinate frames rotated with respect to their mutual origin by angle α , as shown in Fig. 14.1a.

From this geometrical setup, it can be demonstrated that vector $\mathbf{p} = [x_0, y_0]$ can be uniquely defined in both frames as follows:

$$\begin{aligned} x_1 &= x_0 \cos \alpha + y_0 \sin \alpha \\ y_1 &= -x_0 \sin \alpha + y_0 \cos \alpha \end{aligned} \quad (14.1)$$

where 0 and 1 subscripts refer to the coordinates of \mathbf{p} in the original and rotated frames correspondingly.

Introducing the matrix notation for the linear transformation above results in a simple form that relates the vector \mathbf{p} components in (x_0, y_0) frame to the corresponding components in (x_1, y_1) frame:

$$\begin{bmatrix} x_1 \\ y_1 \end{bmatrix} = R_0^1 \begin{bmatrix} x_0 \\ y_0 \end{bmatrix}, \quad R_0^1 = \begin{bmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{bmatrix}. \quad (14.2)$$

The resulting rotation matrix is called a DCM matrix. The DCM matrix R_0^1 consists of the cosine and sine functions which are the direction cosines between the matching axes of the new and old coordinate systems denoted in the superscript and the subscript correspondingly. Following the same approach, it can be demonstrated that for the case of right-handed coordinate system represented by three orthogonal axes (see Fig. 14.1b), the same right-hand rotation results in transformation

$${}_z R_0^1 = \begin{bmatrix} \cos \alpha & \sin \alpha & 0 \\ -\sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (14.3)$$

where for clarity, the subscript z denotes the axes of rotation. Proceeding similarly, right-handed rotations of the coordinate frame about the y_0 and x_0 axis give

$${}_y R_0^1 = \begin{bmatrix} \cos \alpha & 0 & -\sin \alpha \\ 0 & 1 & 0 \\ \sin \alpha & 0 & \cos \alpha \end{bmatrix}, \quad {}_x R_0^1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \alpha & \sin \alpha \\ 0 & -\sin \alpha & \cos \alpha \end{bmatrix}. \quad (14.4)$$

It is worth noting that the DCM transformation has the following easy-to-remember properties that simplify its application (see more details in Rogers 2003):

1. The transformed vector components along the axis of rotation remain unchanged with the rotation about that axis; elements of DCM are either 0 or 1.
2. The remaining elements of DCM are either sin or cos functions of the angle of rotation.
3. The cos elements are on the main diagonal with sin elements on off-diagonal.
4. The negative sin component corresponds to the component rotated “outside” of the quadrant formed by the original frames.
5. Columns (rows) of a DCM matrix form an orthonormal set.

It is straightforward to verify that a DCM matrix corresponding to the right-handed frames has the following properties:

$$\det(R) = 1; \quad R^T = R^{-}; \quad R^T R = I; \quad R = [c_1, c_2, c_3] \Rightarrow c_i \cdot c_j = \begin{cases} 0, & i \neq j \\ 1, & i = j \end{cases} \quad (14.5)$$

Fig. 14.2 Three consecutive rotations

and therefore it belongs to a general class of orthonormal transformation matrices. For a sequence of rotations performed with respect to each orthogonal axis, the resulting transformation can be obtained by a matrix composed of three sequential rotations, called Euler angle rotations, starting from the original frame of reference; see Fig. 14.2.

Formally, this transformation is accomplished by rotating through the ordered sequence of Euler angles $[\psi, \theta, \phi]$, where the numerical indexes define the ordered sequence of rotations and the corresponding axis of rotations:

$$R_{x_0}^y = R_{x_2}^y R_{x_1}^{x_2} R_{x_0}^{x_1} \quad (14.6)$$

It is worth mentioning that the corresponding Euler angles are also widely used to express elementary rotation matrices so that in (14.6), the following notation $R_\phi = R_{x_2}^y, R_\theta = R_{x_1}^{x_2}, R_\psi = R_{x_0}^{x_1}$ is possible. As an example, $R_\psi = R_{x_0}^{x_1}$ defines a rotation of the axis x_0 to x_1 and z_0 to z_1 performed with respect to the axis y_0 by the angle ψ . From now, the same approach to denoting the rotations and vectors is used throughout this chapter. In the case of rotations, the subscript refers to the original frame while the superscript refers to the rotated frame; in the case of vectors denoted in bold face, the subscript defines the frame where the vector is resolved and the superscript refers to a specific meaning of the vector when necessary, and the frames are indicated by the brace as in $\{frame\}$. Therefore, a vector $\mathbf{p}_0 = [x_0, y_0, z_0]^T$ given in $\{0\}$ coordinate frame can be resolved in another coordinate frame $\{1\}$ of arbitrary orientation with respect to the original frame by a transformation matrix R_0^1 composed of three sequential rotations as follows:

$$\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \underbrace{\begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \phi & \sin \phi \\ 0 & -\sin \phi & \cos \phi \end{bmatrix} \begin{bmatrix} \cos \theta & 0 & -\sin \theta \\ 0 & 1 & 0 \\ \sin \theta & 0 & \cos \theta \end{bmatrix} \begin{bmatrix} \cos \psi & \sin \psi & 0 \\ -\sin \psi & \cos \psi & 0 \\ 0 & 0 & 1 \end{bmatrix}}_{R_0^1} \begin{bmatrix} x_0 \\ y_0 \\ z_0 \end{bmatrix} \quad (14.7)$$

$$R_0^1 = \begin{bmatrix} \cos \theta \cos \psi & \cos \theta \sin \psi & -\sin \theta \\ -\cos \theta \sin \psi + \sin \phi \sin \theta \cos \psi & \cos \phi \cos \psi + \sin \phi \sin \theta \sin \psi & \sin \phi \cos \theta \\ \sin \phi \sin \psi + \cos \phi \sin \theta \cos \psi & -\sin \phi \cos \psi + \cos \phi \sin \theta \sin \psi & \cos \phi \cos \theta \end{bmatrix} \quad (14.8)$$

This matrix, which represents a transformation resulting from three sequential Euler angle rotations, will be used throughout the chapter.

Overall, any rotation matrix has a number of properties. They are summarized here for completeness; an interested reader is referred to references (Goldstein 1980; Murray et al. 1994) for thorough details:

- Rotation matrices are orthogonal.
- The determinant of a rotation matrix is unity.
- Successive rotations can be represented by the ordered product of the individual rotation matrices.
- Rotation matrices are not commutative; hence, in general case, $R_b^c R_a^b \neq R_a^b R_b^c$.
- A nontrivial rotation matrix has only one eigenvalue equal to unity with other two, being a complex conjugate pair with unity magnitude; a trivial rotation is described by an identity matrix.

The time rate of change of the DCM matrix that defines the dynamics of the attitude states is important in derivation of the kinematic equations of motion. As it will be shown shortly, it enables relating the sensor (e.g., given by the rate gyros) measurements obtained in a body-fixed frame to the time derivatives of the Euler angles describing the attitude of a body in an inertial frame.

In general case, the time derivative of a rotation matrix that is considered as a function of time can be obtained based on its key properties. Let $R(t) = R_0^1(t)$ be a rotation matrix given as a function of time. Since $R \cdot R^T = I$, taking the time derivative of both sides yields

$$\frac{d(R \cdot R^T)}{dt} = \dot{R} \cdot R^T + R \cdot \dot{R}^T = \dot{R} \cdot R^T + (\dot{R} \cdot R^T)^T = \mathbf{0}.$$

First, it can be observed that $\dot{R} \cdot R^T = S$ is a skew symmetric matrix. Next, let $\mathbf{p}_1 = R(t)\mathbf{p}_0$, where \mathbf{p}_0 is a vector of constant length rotated over time with an angular velocity vector $\boldsymbol{\Omega}$. Comparing two expressions of the absolute time derivatives of \mathbf{p}_1

$$\dot{\mathbf{p}}_1 = \dot{R}(t)\mathbf{p}_0 = S(t)R(t) \cdot \mathbf{p}_0 = S(t) \cdot \mathbf{p}_1,$$

$$\dot{\mathbf{p}}_1 = \boldsymbol{\Omega} \times \mathbf{p}_1 = S(\boldsymbol{\Omega}(t)) \cdot \mathbf{p}_1$$

leads to

$$\dot{R} = S(\mathbf{\Omega})R, \quad S(\mathbf{\Omega}) = \dot{R}R^T. \quad (14.9)$$

Thus, the skew symmetric matrix $S(\mathbf{\Omega})$ in (14.9) is used to represent the vector cross product between the vectors $\mathbf{\Omega}$ and the $R(t)\mathbf{p}_0$. The matrix $S(\mathbf{\Omega})$, where vector $\mathbf{\Omega} = [\omega_x, \omega_y, \omega_z]^T$ is represented by its components, can be written in the form

$$S(\mathbf{\Omega}) = \begin{bmatrix} 0 & \omega_z & -\omega_y \\ -\omega_z & 0 & \omega_x \\ \omega_y & -\omega_x & 0 \end{bmatrix}.$$

Another useful general property of angular velocities is called the *angular velocities addition theorem* (Rogers 2003). The theorem states that for angular velocity vectors coordinated in a common frame, the resulting angular velocity of the cumulative rotation is a plain sum of the contributing rotations. Now, if a rotating frame is given by a set of time varying Euler angles $[\psi, \theta, \phi]$ defined with respect to a stationary frame, then it is straightforward to determine the components of the angular velocity vector $\mathbf{\Omega} = [\omega_x, \omega_y, \omega_z]^T$ as though measured in the rotating frame. Starting from an initial stationary frame (see Fig. 14.2) and using two intermediate frames whose relative angular velocities are defined by the Euler angle rates $[\dot{\psi}, \dot{\theta}, \dot{\phi}]$ and utilizing the angular velocities addition theorem, the following kinematic equation can be obtained:

$$\begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} = R_\phi R_\theta \begin{bmatrix} 0 \\ 0 \\ \dot{\psi} \end{bmatrix} + R_\phi \begin{bmatrix} 0 \\ \dot{\theta} \\ 0 \end{bmatrix} + \begin{bmatrix} \dot{\phi} \\ 0 \\ 0 \end{bmatrix}. \quad (14.10)$$

Substituting the corresponding DCM matrices from (14.7) results in

$$\begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} = \begin{bmatrix} 1 & 0 & -\sin \theta \\ 0 & \cos \phi & \cos \theta \sin \phi \\ 0 & -\sin \phi & \cos \theta \cos \phi \end{bmatrix} \begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix}. \quad (14.11)$$

Inverting the last equation results in equation

$$\begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} = \begin{bmatrix} 1 & \sin \phi \frac{\sin \theta}{\cos \theta} & \cos \phi \frac{\sin \theta}{\cos \theta} \\ 0 & \cos \phi & -\sin \phi \\ 0 & \sin \phi \frac{1}{\cos \theta} & \cos \phi \frac{1}{\cos \theta} \end{bmatrix} \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} \quad (14.12)$$

that defines the derivatives of the Euler angles in terms of the angles themselves and the angular velocity vector $\mathbf{\Omega} = [\omega_x, \omega_y, \omega_z]^T$ as it was measured in the rotated frame. These equations define the rotational kinematics of a rigid body; they contribute to the final set of 6DoF equations of motion.

Analysis of the (14.12) shows that four elements of the inverted matrix become singular when the second rotation angle θ approaches $\pi/2$. This problem is usually called a *kinematic singularity* or a *gimbal lock* in navigation and is one of the

issues associated with the use of Euler angles for the attitude determination. For differently ordered Euler rotation sequences, the kinematic singularity will occur at a different point. Therefore, one way to avoid the singularity is to switch or change the Euler angle sequences when approaching the singularity. Next, depending on the available computing power, the integration of the kinematic equation (14.12) can be computationally expensive because it involves calculation of trigonometric functions. Furthermore, it can be observed that the Euler angle-based DCM matrix is redundant; it requires only 3 out of 9 elements of the DCM matrix to uniquely define the Euler angles. These shortcomings usually result in applying different parameters describing the attitude and its dynamic transformation.

In applications to the fixed-wing UAV attitude determination, the Rodrigues–Hamilton parameter, or quaternion, is one of the most widely used alternatives (Goldstein 1980). Utilizing the quaternion approach is very powerful because it gives a singularity-free attitude determination at any orientation of a rigid body. Next, since it can be shown that the equations of motion of a rigid body are linear differential equations in the components of quaternion, then it (linearity) is a desirable property, especially when developing estimation and control algorithms. Furthermore, the quaternion is a relatively computationally efficient approach since it does not involve trigonometric functions to compute the attitude matrix and has only one redundant parameter, as opposed to the six redundant elements of the attitude matrix. However, it is also worth noting that the quaternion and Euler angle techniques are both widely used in various UAV applications; the equations connecting both representations are well developed, thus enabling complementary definition of the DCM matrix and Euler angles through the parameters of quaternion and vice versa. An interested reader is referred to an extensive historical survey of attitude representations (Shuster 1993) and references (Rogers 2003; Goldstein 1980; Murray et al. 1994) for more details in the alternative methods of attitude determination.

14.2.2 Generalized Motion

In the development of dynamic equations of motion, it will be necessary to calculate the absolute time derivative of a vector defined in coordinate frames that rotate and move with respect to each other. In an application to the UAV kinematics, this can be justified by a necessity to relate the absolute time derivative of a position vector in inertial space (inertial velocity) that is defined based on the measurements taken in a body frame. Similarly, the second time derivative defines the body inertial acceleration.

Consider two coordinate frames $\{F_i\}$ and $\{F_r\}$, where i stands for an inertial not rotating frame and r stands for the rotating frame. The first objective is to calculate the derivative of a unity vector \mathbf{r}_r defined in $\{F_r\}$ attached to a rigid body rotating with respect to the $\{F_i\}$ with angular speed $\boldsymbol{\omega}$; see Fig. 14.3. Denote the rotation from $\{F_r\}$ to $\{F_i\}$ as R :

$$\mathbf{r}_i = R\mathbf{r}_r$$

Fig. 14.3 Deriving the time derivative of a vector

Taking the derivative results in

$$\dot{\mathbf{r}}_i = \dot{\mathbf{R}}\mathbf{r}_r + \mathbf{R}\dot{\mathbf{r}}_r = \dot{\mathbf{R}}\mathbf{r}_r = S(\boldsymbol{\omega})\mathbf{r}_r = \boldsymbol{\omega} \times \mathbf{r}_r, \quad (14.13)$$

where the time derivative $\dot{\mathbf{r}}_r$ is zero due to the rigid body assumption.

Next, using the same setup, calculate the absolute time derivative of an arbitrary time varying vector \mathbf{r} defined in $\{F_r\}$. Defining the vector in terms of its components in both frames and taking its time derivative in the inertial frame result in

$$\mathbf{r} = r_{xi}\mathbf{i} + r_{yi}\mathbf{j} + r_{zi}\mathbf{k} = r_{xr}\mathbf{l} + r_{yr}\mathbf{m} + r_{zr}\mathbf{n}.$$

Taking the absolute time derivative of both expressions gives

$$\begin{aligned} \frac{d\mathbf{r}}{dt} &= \dot{r}_{xi}\mathbf{i} + \dot{r}_{yi}\mathbf{j} + \dot{r}_{zi}\mathbf{k} \\ \frac{d\mathbf{r}}{dt} &= \dot{r}_{xr}\mathbf{l} + \dot{r}_{yr}\mathbf{m} + \dot{r}_{zr}\mathbf{n} + r_{xr}\dot{\mathbf{l}} + r_{yr}\dot{\mathbf{m}} + r_{zr}\dot{\mathbf{n}}. \end{aligned}$$

Applying (14.13) allows rewriting the last equation as

$$\frac{d\mathbf{r}}{dt} = \frac{\delta\mathbf{r}}{\delta t} + \boldsymbol{\omega} \times \mathbf{r} = \dot{\mathbf{r}}_r + \boldsymbol{\omega} \times \mathbf{r}, \quad (14.14)$$

which expresses the derivative of the vector \mathbf{r} in the inertial frame $\{F_i\}$ in terms of its change ($\dot{\mathbf{r}}_r$) calculated in a rotating frame $\{F_r\}$ and its relative rotation defined by the angular velocity $\boldsymbol{\omega}$. The result in (14.14) is known as the *Coriolis theorem*. The second derivative of \mathbf{r} defines the body acceleration and is used in the development of the dynamic equations. It is obtained in a similar manner by recursively applying the Coriolis theorem, thus leading to

$$\begin{aligned}
\ddot{\mathbf{r}} &= \frac{\delta}{\delta t}(\dot{\mathbf{r}}_r + \boldsymbol{\omega} \times \mathbf{r}) + \boldsymbol{\omega} \times (\dot{\mathbf{r}}_r + \boldsymbol{\omega} \times \mathbf{r}) \\
&= \ddot{\mathbf{r}}_r + \frac{\delta \boldsymbol{\omega}}{\delta t} \times \mathbf{r} + \boldsymbol{\omega} \times \frac{\delta \mathbf{r}}{\delta t} + \boldsymbol{\omega} \times \dot{\mathbf{r}}_r + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}), \\
\ddot{\mathbf{r}} &= \ddot{\mathbf{r}}_r + \dot{\boldsymbol{\omega}} \times \mathbf{r} + 2\boldsymbol{\omega} \times \dot{\mathbf{r}}_r + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}).
\end{aligned} \tag{14.15}$$

Similarly to (14.14) where $\dot{\mathbf{r}}_r$ denotes the local derivative taken in a rotating frame $\{F_r\}$, the $\frac{\delta \boldsymbol{\omega}}{\delta t}$ refers to the derivative of angular velocity $\boldsymbol{\omega}$ taken in $\{F_r\}$ frame. However, it can be easily demonstrated

$$\frac{d\boldsymbol{\omega}}{dt} = \frac{\delta \boldsymbol{\omega}}{\delta t} + \boldsymbol{\omega} \times \boldsymbol{\omega} = \frac{\delta \boldsymbol{\omega}}{\delta t} \tag{14.16}$$

that the derivative of $\boldsymbol{\omega}$ is independent on the coordinate frame. In turn, this justifies omitting the subscript in $\boldsymbol{\omega}$ referring to $\{F_r\}$. The last two terms in (14.15) are commonly known as *Coriolis* and the *centripetal accelerations* correspondingly. The following chapter heavily relies on the results in (14.14) and (14.15) when it develops the dynamic equations of motion.

14.2.3 Coordinate Frames

Deriving equations of motion of a fixed-wing UAV requires a definition of coordinate frames where forces and moments acting on the airplane can be conveniently defined and where the states including the position, velocity, acceleration, and attitude can be suitably described. It is worth noting that with the latest advances in power technologies and novel materials, a mission of long duration becomes a reality. As an example, solar power technology is one of the alternatives that can make the 24/7 flight of a fixed-wing solar powered autonomous soaring gliders feasible. Thus, the long duration and great operational distances might require considering the UAV flight operations with respect to the rotating Earth. This consideration would extend the set of coordinate frames used in long-endurance UAV applications. The primary reason for such an extension would lie in the necessity to resolve the inertial angular velocity of rotation of a body frame in a “true” inertial frame where the Earth rotation can be resolved. Those frames would include the Earth-centered inertial, Earth-centered Earth-fixed, and a geodetic coordinate frames. Consequently, the angular velocities addition theorem mentioned above would be used to resolve the angular velocity vector of body rotation with respect to the inertial frame as a vector sum of angular velocities of the intermediate frames. An interested reader is referred to (Rogers 2003) for more details in the coordinate frames and transformations used in inertial navigation.

Therefore, in addition to the body and wind frames that define dynamics of the body–fluid interaction, this subsection defines the following set of coordinate frames used in various UAV applications:

1. Earth-centered inertial frame $\{i\}$
2. Earth-centered Earth-fixed frame $\{e\}$

3. Geodetic coordinate system $\{\lambda, \varphi, h\}$
4. Tangent plane coordinate system $\{u\}$
5. Body-carried frame $\{n\}$
6. Body-fixed frame $\{b\}$
7. Wind frame $\{w\}$

Depending on the duration of flight and operational range, both dictated by a specific UAV application, the first four frames can be considered inertial frames, with the remaining three frames body fixed. The positioning of inertial and body frames is related by a plain translation, while the orientation of body frames relates to each other by pure rotations. Details of the frames definition and their relations are the subject of this section.

14.2.3.1 Earth-Centered and Geodetic Coordinate Frames

It is convenient to consider two coordinate frames connected to the Earth. The *Earth-centered Earth-fixed* (ECEF) coordinate system is fixed to the Earth, and therefore, it rotates at the Earth's sidereal rate with respect to the *Earth-centered inertial* (ECI) frame that represents nonrotating inertial frame. The ECI frame is usually denoted $\{i\}$ while the ECEF frame is denoted $\{e\}$. Both frames are right-handed orthogonal and have their origins at the center of the Earth. The ECI frame has its z_i axis aligned with the direction of the Earth's rotation vector and x_i and y_i axes placed in the equatorial plane with x_i fixed in some celestial reference direction, for example, a line connecting the Sun's center and the Earth's position at vernal equinox (Kaplan 1981). The ECEF has x_e and y_e axes placed in the equatorial plane and z_e axis aligned with z_i axis; see Fig. 14.4 where the Earth is modeled as a spheroid. The x_e axis is usually attached to the intersection of the Greenwich meridian and the equator, and the y_e axis completes the right-hand system.

It is worth noting that the ECEF axes definition may vary; however, the definition always states the attachment of two vectors to the direction of the Earth rotation and the Greenwich meridian as the inherent Earth properties. The sidereal rate Ω_i^e is the vector defining the ECEF rotation with respect to the ECI; the latter one is often called the true inertial frame. If necessary, for the purpose of UAV flight description, the magnitude Ω_i^e of the rate can be approximated by one full rotation in 23h56'4.099'', thus resulting in $\Omega_i^e = 15.04106718$ deg/h. Therefore, the transformation from ECI to ECEF frame is a plain rotation around the z_i axis defined by a single rotation by an angle $\Omega_i^e \cdot t$, where t is the time interval.

The *local geodetic* $\{\lambda, \varphi, h\}$ frame is usually associated with the ECEF frame, see Fig. 14.4. It has the same origin placed at the center of the Earth. The frame defines the orientation of a line normal to Earth's surface and passing through the point of interest. The orientation of the line is defined by two angles, λ (geodetic latitude) and φ (geodetic longitude), with the height h above the Earth's surface; eventually these three parameters, along with the components of the UAV velocity vector, become the major navigation states. For most UAV applications, it is sufficiently accurate to model Earth's surface as an oblate spheroid with given r_e (equatorial) and r_p (polar radiuses) or one of the radiuses and the e (ellipticity) (Kaplan 1981). Last revisited in 2004, the datum of World Geodetic System (WGS-84) provides

Fig. 14.4 ECI, ECEF, and geodetic coordinate frames

the following parameters for the oblate spheroid modeling: $r_e = 6,378,137.00$ m, $r_p = 6,356,752.314$ m. The resulting transformation from the geodetic $\{\lambda, \varphi, h\}$ to the ECEF frame is as follows:

$$\begin{aligned} x_e &= (r_\lambda + h) \cos \varphi \cos \lambda \\ y_e &= (r_\lambda + h) \cos \varphi \sin \lambda \\ z_e &= ((1 - \varepsilon^2)r_\lambda + h) \sin \varphi \end{aligned} \quad (14.17)$$

where ε the eccentricity of oblate ellipsoid is defined as

$$\begin{aligned} r_\lambda &= \frac{r_e}{\sqrt{1 - \varepsilon^2 \sin^2 \varphi}}; \\ \varepsilon &= \sqrt{1 - \frac{r_p^2}{r_e^2}}. \end{aligned}$$

14.2.3.2 Local Tangent Plane Coordinate System

The origin of the *local tangent plane* (LTP) is fixed to the surface of the Earth with two of its axes attached to the plane tangent to the surface; see Fig. 14.5. The frame is usually marked with the subscript $\{u\}$ and serves the purpose of an inertial frame in most short-duration low-speed UAV applications. The frame's x_u and y_u axes are in the tangent plane and most often aligned with the north and east directions correspondingly; the z_u axis completes the right-hand coordinate system, thus pointing down. Quite often the order and alignment of the LTP frame principal

Fig. 14.5 Definition of the local tangent plane; NED

axes change. In such cases, the LTP coordinate system explicitly specifies its type; in the nominal case presented above, it can be also defined as an NED frame indicating the north–east down alignment of the coordinate axes.

When the origin of the LTP frame is defined in terms of its geodetic latitude, longitude, and altitude above the ground surface, then the equations (14.17) can be applied to define the kinematics of navigation states.

14.2.3.3 Body-Carried and Fixed Frames

In flight dynamics, the body-attached reference frames usually have their origin at the center of gravity (CG) of an airplane; therefore, these frames are moving. The *body-carried* frame $\{n\}$ is an orthogonal frame originated at the CG of the UAV. All its axes are permanently stabilized and aligned with the LTP frame axes as it was connected to the CG; see Fig. 14.6; the frame is usually utilized in defining the navigation equations thus assigning its subscript $\{n\}$. This frame is connected to the LTP frame by means of a plain translation $\mathbf{r} = [r_n, r_e, r_d]^T$.

The *body-fixed* frame is an orthogonal frame defined with respect to the body-carried frame. Its origin is at the CG of UAV, and its axes are rigidly connected to the body; therefore, the frame also rotates with the body. The frame is usually marked with the subscript $\{b\}$. The alignment of the $\{b\}$ frame axes is a degree of freedom that can exploit the body symmetry. It can be proven (Goldstein 1980) that for every rigid body, there is always an orthogonal coordinate system, usually called principal, in which the cross products of inertia terms are zero. Assuming that a typical UAV has at least one plane of symmetry (geometric and mass symmetry) results in two of the body-fixed axes laying in the plane of symmetry. When the axes are aligned along the principal axes of inertia of the body, as will be shown in the following chapter, the dynamic equations of motion become significantly simpler. In a majority of fixed-wing UAV configurations, the axes of $\{b\}$ frame match the principal axes of inertia. The typical orientation of the body-fixed axes is as follows (see Fig. 14.6): if the UAV has a vertical plane of symmetry, then x_b and z_b lie in that plane of symmetry; x_b points toward the direction of flight and z_b points downward and y_b points right, thus completing the right-hand system.

Fig. 14.6 Definition of the body-fixed frame with respect to LTP frame

As the body moves, its attitude is defined with reference to the body-carried frame $\{n\}$ by three consecutive Euler rotations by ψ (yaw), θ (pitch), and ϕ (roll) angles. See their graphical illustration in Fig. 14.2 where frames $\{0\}$ and $\{1\}$ relate to the frames $\{n\}$ and $\{b\}$ correspondingly. The formal definition of the Euler angles in the application to an airplane attitude specification is presented here for completeness:

- ψ – yaw is the angle between x_n and the projection of x_b on the local horizontal plane.
- θ – pitch is the angle between the local horizon and the x_b axis measured in the vertical plane of symmetry of the UAV.
- ϕ – roll is the angle between the body-fixed y_b axis and the local horizon measured in the plane $y_b z_b$.

As it follows from the attitude representation section, the DCM matrix R_u^b transforming the body-carried $\{n\}$ to the body-fixed $\{b\}$ frame can be constructed as in (14.8). Now the subscripts ($u \rightarrow b$) denote the rotation from the LTP $\{u\}$ to the body-fixed frame; $\{u\}$ and $\{n\}$ frames are always aligned by the definition of body-carried frame.

The application of the rotation matrix (14.8) immediately follows from the need to describe the UAV translational motion in an inertial frame of reference by utilizing the inertial velocity measurements taken in the body-fixed frame at

$\text{CG} - \mathbf{V}_b^g = [u, v, w]^T$. To this end, consider Fig. 14.6 where vector $\mathbf{r} = [r_n, r_e, r_d]^T$ denotes the position of an airplane CG with respect to the LTP (NED) frame attached to the Earth. Relating the translational velocity and position and accounting for the fact that *body-carried* frame $\{n\}$ is stabilized with respect to the nonrotating $\{u\}$ frame results in

$$\begin{aligned} \frac{d\mathbf{r}}{dt} &= R_b^u \mathbf{V}_b^g \\ \frac{d}{dt} \begin{bmatrix} r_n \\ r_e \\ r_d \end{bmatrix} &= R_b^u \begin{bmatrix} u \\ v \\ w \end{bmatrix}. \end{aligned} \quad (14.18)$$

The relation between the Euler angles defining the relation between the stabilized $\{n\}$ frame and the body-fixed frame $\{b\}$ was already derived in (14.11) and (14.12). They define the dynamics of Euler angles defined in an inertial frame with respect to the rates measured in the body-fixed frame. Thus, the kinematic equations (14.12) and (14.18) represent the dynamics of translational and rotational coordinates and therefore are part of the final set of equations of motion.

14.2.3.4 Wind Frame

Aerodynamic forces and moments resulting from the body–air interaction as the airframe moves through the air depend on the body orientation with respect to the surrounding air. In other words, they depend on the vector representing the wind. The velocity vector of the possibly moving air (wind) resolved in the inertial frame $\{u\}$ is denoted \mathbf{V}_u^a ; see Fig. 14.7. The magnitude of \mathbf{V}_u^a is called an *airspeed* V_a , as opposed to the velocity vector defined in LTP with respect to the ground – *ground speed* vector \mathbf{V}_u^g . The orientation of the wind frame $\{w\}$ defined by the direction of \mathbf{V}_u^a with respect to the body-fixed $\{b\}$ is defined by two angles.

To generate the lift force in flight, the wing of the UAV must be oriented at a usually positive angle α with respect to the \mathbf{V}_u^a vector. This angle is called the *angle of attack*. The angle of attack α is also one of the key parameters that define

Fig. 14.7 Wind frame and body-fixed frames. Definition of the angle of attack and the sideslip

the longitudinal stability of an airplane. Therefore, quite often, the coordinate frame that results from a single rotation from the body-fixed $\{b\}$ frame on angle α is called a stability frame (Beard and McLain 2012; Etkin and Reid 1995). As illustrated in Fig. 14.7, the angle of attack is defined by the projection of \mathbf{V}_u^a into a vertical plane of symmetry of the UAV (spanned by axes x_b, z_b in frame $\{b\}$) and the longitudinal axis x_b of the UAV. It is positive when a leading edge of the wing rotates upward with respect to the \mathbf{V}_u^a . In turn, the angle between the velocity vector \mathbf{V}_u^a projected into the “wing-level” plane (spanned by axes x_b, y_b in frame $\{b\}$) and the longitudinal axis x_b of UAV is called the *sideslip angle*. It is denoted by β .

Then the transformation from the body-fixed frame $\{b\}$ to the wind frame $\{w\}$ is given by

$$\begin{aligned} R_b^w &= \begin{bmatrix} \cos \beta & \sin \beta & 0 \\ -\sin \beta & \cos \beta & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos \alpha & 0 & \sin \alpha \\ 0 & 1 & 0 \\ -\sin \alpha & 0 & \cos \alpha \end{bmatrix} \\ &= \begin{bmatrix} \cos \alpha \cos \beta & \sin \beta & \sin \alpha \cos \beta \\ -\cos \alpha \sin \beta & \cos \beta & -\sin \alpha \sin \beta \\ -\sin \alpha & 0 & \cos \alpha \end{bmatrix}. \end{aligned} \quad (14.19)$$

The inverse transformation from the wind frame $\{w\}$ to the body-fixed frame $\{b\}$ is the transpose of (14.19): $R_w^b = (R_b^w)^T$.

The importance of the wind frame in application to the UAVs flying in wind conditions that might contribute up to 100% of the nominal airplane speed cannot be overestimated. As an example, imagine an autonomous glider that is designed to utilize the wind energy to sustain the long duration of flight. Therefore, it is necessary to understand the difference between the airspeed, represented by the air velocity vector \mathbf{V}_u^a and the ground speed \mathbf{V}_u^g , both resolved with respect to the LTP frame. Consider the graphical representation of the relation between these vectors in Fig. 14.8. In the presence of constant wind, these velocities are related by the equation that is often called the *wind triangle*:

$$\mathbf{V}_u^a = \mathbf{V}_u^g - \mathbf{V}_u^w \quad (14.20)$$

where \mathbf{V}_u^w is the wind velocity defined in the LTP frame.

The objective of the following development is to define the relations among these velocities defined in three different frames, while being measured or estimated by the sensors installed in the body-fixed and in the inertial frame. First, define the components of all three vectors in the body-fixed frame $\{b\}$. Let the UAV velocity in the LTP (inertial) frame expressed in the body frame be $\mathbf{V}_b^g = [u, v, w]^T$, and let the wind velocity in the LTP frame expressed in body frame be $\mathbf{V}_b^w = [u_w, v_w, w_w]^T$. Observe that \mathbf{V}_u^a can be expressed in $\{w\}$ frame as $\mathbf{V}_w^a = [V_a \ 0 \ 0]^T$, and let $\mathbf{V}_b^a = [u_a \ v_a \ w_a]^T$ be its components expressed in the body frame. Utilizing the definition of the angles of attack and sideslip relating the wind frame to the body-fixed frame and the “wind triangle” (14.20) expressed in the body frame results in the following:

Fig. 14.8 Wind triangle in 2D plane and the yaw (ψ), sideslip (β), and course (χ) angles

$$\mathbf{V}_b^a = \mathbf{V}_b^g - \mathbf{V}_b^w = \begin{bmatrix} u \\ v \\ w \end{bmatrix} - \begin{bmatrix} u_w \\ v_w \\ w_w \end{bmatrix}$$

$$\mathbf{V}_b^a = \begin{bmatrix} u_a \\ v_a \\ w_a \end{bmatrix} = R_w^b \begin{bmatrix} V_a \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} \cos \alpha \cos \beta & \sin \beta & \sin \alpha \cos \beta \\ -\cos \alpha \sin \beta & \cos \beta & -\sin \alpha \sin \beta \\ -\sin \alpha & 0 & \cos \alpha \end{bmatrix} \begin{bmatrix} V_a \\ 0 \\ 0 \end{bmatrix}.$$

$$\begin{bmatrix} u_a \\ v_a \\ w_a \end{bmatrix} = V_a \begin{bmatrix} \cos \alpha \cos \beta \\ \sin \beta \\ \sin \alpha \cos \beta \end{bmatrix} \quad (14.21)$$

This last equation relates the airspeed components of \mathbf{V}_b^a resolved in the body frame with the airspeed and the angles of attack and sideslip. In turn, if the wind components resolved in the body frame are known, then inverting the last equation allows for calculation of the airspeed V_a and the α , β angles:

$$V_a = \sqrt{u_a^2 + v_a^2 + w_a^2}, \quad \alpha = a \tan \left(\frac{w_a}{u_a} \right), \quad \beta = a \sin \left(\frac{v_a}{V_a} \right). \quad (14.22)$$

14.2.3.5 Summary of Kinematics

This section developed the fundamental kinematic equations that not only define the kinematics of states and contribute to the final set of 6DoF equations of motion but also serve as the basis for the design of the guidance and navigation tasks. There are numerous publications describing the kinematics of moving frames. Most of the publications originate in the area of classical mechanics and rigid body

dynamics (Murray et al. 1994; Goldstein 1980). The publications in the area of flight dynamics and control always contain material addressing the attitude representation techniques and differential rotations and thus can be a good source of reference information. The most recent and thorough presentation of these topics can be found in (Beard and McLain 2012) where the authors specifically address the kinematics and dynamics of small UAVs.

14.3 Rigid Body Dynamics

This section addresses the development of the dynamics of a rigid body. The discussion is based on the application of the Newton's laws in the cases of linear and angular motion. In particular, the Newton's second law of motion states that the sum of all external forces acting on a body in an inertial frame must be equal to the time rate of change of its linear momentum. On the other hand, the sum of the external moments acting on a body must be equal to the time rate of change of its angular momentum. The application of these laws is the objective of this chapter.

Thus, a fixed-wing UAV is considered as the rigid body, and its dynamics is defined with respect to the body-fixed coordinate system. The approach considers a typical fixed-wing UAV operating in a small region of the Earth thus justifying the assumption of LTP frame as an inertial frame. Relations necessary to translate the inertial forces to the body-fixed frame are also presented. Before proceeding to the derivation, it is necessary to present some assumptions typical for the fixed-wing UAVs:

A1. The mass of the UAV remains constant during flight.

A2. The UAV is a rigid body.

The relations derived in this chapter are general and can be applied to any rigid body; however, the treatment of the aerodynamic forces and moments acting on the body will be specific to the aerodynamically controlled fixed-wing UAVs.

14.3.1 Conservation of Linear Momentum

First, assume that a rigid body consists of a set of i “isolated” elementary particles with mass m_i exposed to the external force \mathbf{F}_u^i while being connected together by the internal forces \mathbf{R}_u^i . Since the set of N particles comprises a rigid body structure (see **A2**), the net force exerted by all the particles is $\sum_i^N \mathbf{R}_u^i = 0$. The set of external forces acting on the body is a combination of the gravity force acting in an inertial frame $\{u\}$ and the aerodynamic and propulsion forces defined with respect to the body-fixed frame $\{b\}$ but expressed in the inertial frame $\{u\}$. Thus, the linear momentum of a single particle expressed in an inertial frame obeys the equality

$$\mathbf{F}_u^i + \mathbf{R}_u^i = \frac{d}{dt}(m_i \mathbf{V}_u^i), \quad (14.23)$$

where the time derivative is taken in an inertial frame. Summing up all the N particles comprising the body gives the linear momentum equation of the entire body

$$\sum_{i=1}^N \mathbf{F}_u^i = \sum_{i=1}^N \frac{d}{dt} (m_i \mathbf{V}_u^i). \quad (14.24)$$

The left-hand side of this equation represents the sum of all forces (gravitational, propulsion, and aerodynamic) expressed in an inertial frame, with the right side depending on the velocity of the body defined in an inertial frame. First, observe that the individual inertial velocities \mathbf{V}_u^i are not independent. Since they comprise a rigid body, their vectors can be represented as a sum of \mathbf{V}_b^g the inertial velocity vector resolved in $\{b\}$ frame with respect to CG plus the velocity vector induced by the body rotation with respect to the CG and defined by the radius vector \mathbf{r}_b^i of the i th particle in $\{b\}$ frame; thus $\mathbf{V}_u^i = \mathbf{V}_b^g + \boldsymbol{\omega} \times \mathbf{r}_b^i$. Next, using an assumption **A1** and utilizing the result in (14.14) for the total velocity of the i th particle in an inertial frame, allows for the calculation of the absolute time derivatives in an inertial frame in the following form:

$$\begin{aligned} \sum_{i=1}^N \mathbf{F}_u^i &= \sum_{i=1}^N \frac{d}{dt} (m_i \mathbf{V}_u^i) = \sum_{i=1}^N \frac{d}{dt} (m_i (\mathbf{V}_b^g + \boldsymbol{\omega} \times \mathbf{r}_b^i)) \\ &= \sum_{i=1}^N m_i \frac{d\mathbf{V}_b^g}{dt} + \sum_{i=1}^N m_i \frac{d}{dt} (\boldsymbol{\omega} \times \mathbf{r}_b^i) \\ &= \sum_{i=1}^N m_i \frac{d\mathbf{V}_b^g}{dt} + \frac{d}{dt} \left[\boldsymbol{\omega} \times \sum_{i=1}^N m_i \mathbf{r}_b^i \right]. \end{aligned} \quad (14.25)$$

Here $\boldsymbol{\omega}$ represents the angular velocity of the UAV body resolved in the inertial frame; see (14.14). Defining \mathbf{r}_b^{cg} the vector of CG location in $\{b\}$ frame as $m\mathbf{r}_b^{cg} = \sum_{i=1}^N m_i \mathbf{r}_b^i$, where $m = \sum_{i=1}^N m_i$ is the total mass of the body, simplifies the linear momentum equation:

$$\sum_{i=1}^N \mathbf{F}_u^i = m \frac{d\mathbf{V}_b^g}{dt} + m \frac{d}{dt} [\boldsymbol{\omega} \times \mathbf{r}_b^{cg}].$$

Resolving all external forces in $\{b\}$ frame and assuming that the location of CG does not change with time and applying the result in (14.14) to the absolute derivatives of the vectors \mathbf{V}_b^g and $\boldsymbol{\omega}$ result in

$$\mathbf{F}_b = m(\dot{\mathbf{V}}_b^g + \dot{\boldsymbol{\omega}} \times \mathbf{r}_b^{cg} + \boldsymbol{\omega} \times \mathbf{V}_b^g + \boldsymbol{\omega} \times [\boldsymbol{\omega} \times \mathbf{r}_b^{cg}]), \quad (14.26)$$

where the vector quantities can be represented in the following scalar form:

$\mathbf{F}_b = [X, Y, Z]^T$ – the externally applied forces expressed in the body frame
 $\mathbf{V}_b^g = [u, v, w]^T$ – the inertial velocity components defined in the body frame
 $\boldsymbol{\omega} = [p, q, r]^T$ – the inertial angular velocity resolved in the body frame
 $\mathbf{r}_b^{cg} = [x_{cg}, y_{cg}, z_{cg}]^T$ – the body referenced location of the center of gravity.

The translation of the inertial forces to the body frame is justified by the convenience of calculating the local body frame derivatives of the \mathbf{V}_b^g and $\boldsymbol{\omega}$ expressed in the body frame; the first one results in $\dot{\mathbf{V}}_b^g$, while the derivative of $\boldsymbol{\omega}$ is independent on the coordinate frame; see (14.16).

Utilizing the double vector product identity $\boldsymbol{\omega} \times [\boldsymbol{\omega} \times \mathbf{r}_b^{cg}] = (\boldsymbol{\omega} \cdot \mathbf{r}_b^{cg}) \cdot \boldsymbol{\omega} - (\boldsymbol{\omega} \cdot \boldsymbol{\omega}) \cdot \mathbf{r}_b^{cg}$ allows for the expansion of the linear momentum equation in the scalar form as follows:

$$\begin{aligned}
 X &= m [\dot{u} + qw - rv + \dot{q}z_{cg} - \dot{r}y_{cg} + (qy_{cg} + rz_{cg})p - (q^2 + r^2)x_{cg}] \\
 Y &= m [\dot{v} + ru - pw + \dot{r}x_{cg} - \dot{p}z_{cg} + (rz_{cg} + px_{cg})q - (r^2 + p^2)y_{cg}] \\
 Z &= m [\dot{w} + pv - qu + \dot{p}y_{cg} - \dot{q}x_{cg} + (px_{cg} + qy_{cg})r - (p^2 + q^2)z_{cg}].
 \end{aligned} \tag{14.27}$$

The last set of equations allows for an arbitrary choice of the body frame origin $\{b\}$ with respect to the CG. However, if the origin of the body-fixed frame $\{b\}$ is chosen at the CG, the last set of equations can be significantly simplified by substituting $\mathbf{r}_b^{cg} = [0, 0, 0]^T$, thus leading to

$$\mathbf{F}_b = m (\dot{\mathbf{V}}_b^g + \boldsymbol{\omega} \times \mathbf{V}_b^g). \tag{14.28}$$

Expanding the cross product results in the following simplified form of the linear momentum equation:

$$\begin{aligned}
 X &= m [\dot{u} + qw - rv] \\
 Y &= m [\dot{v} + ru - pw] \\
 Z &= m [\dot{w} + pv - qu].
 \end{aligned} \tag{14.29}$$

Resolving equations (14.29) with respect to the derivatives (accelerations in the body frame) leads to the standard form of differential equations suitable for immediate mathematical modeling:

$$\begin{aligned}
 \dot{u} &= \frac{X}{m} + [rv - qw] \\
 \dot{v} &= \frac{Y}{m} + [pw - ru] \\
 \dot{w} &= \frac{Z}{m} + [qu - pv].
 \end{aligned} \tag{14.30}$$

14.3.2 Conservation of Angular Momentum

Applying the law of conservation of angular momentum to an i th particle in a moving frame is very similar to the approach used above. Consider an i th particle subjected to the internal (\mathbf{M}_u^i) and external ($\mathbf{r}_u^i \times \mathbf{F}_u^i$) moments acting on the body in inertial frame. Similar to the linear momentum case, the sum of internal moments acting on the particle of a rigid body (A2) should be equal to zero $\left(\sum_{i=1}^N \mathbf{M}_u^i = 0\right)$, while the external moments arise from the inertial gravity and the body-attached forces, such as aerodynamic and propulsion. Thus, the conservation of angular momentum calculated across the entire rigid body results in

$$\sum_{i=1}^N (\mathbf{M}_u^i + \mathbf{r}_b^i \times \mathbf{F}_u^i) = \sum_{i=1}^N \mathbf{M}_u^i + \sum_{i=1}^N \mathbf{r}_b^i \times \mathbf{F}_u^i = \sum_{i=1}^N \mathbf{r}_b^i \times \frac{d}{dt}(m_i \mathbf{V}_u^i), \quad (14.31)$$

where the sum of internal moments cancel each other out. Then, applying the Coriolis theorem (14.14) leads to

$$\begin{aligned} \sum_{i=1}^N \mathbf{r}_b^i \times \frac{d}{dt}(m_i \mathbf{V}_u^i) &= \sum_{i=1}^N m_i \mathbf{r}_b^i \times \frac{d}{dt}(\mathbf{V}_u^i) \\ &= \sum_{i=1}^N m_i \mathbf{r}_b^i \times \left(\frac{\delta \mathbf{V}_b^g}{\delta t} + \boldsymbol{\omega} \times \mathbf{V}_b^g + \frac{\delta \boldsymbol{\omega}}{\delta t} \times \mathbf{r}_b^i + \boldsymbol{\omega} \times [\boldsymbol{\omega} \times \mathbf{r}_b^i] \right) \\ &= \sum_{i=1}^N m_i \mathbf{r}_b^i \times \left(\frac{\delta \mathbf{V}_b^g}{\delta t} + \boldsymbol{\omega} \times \mathbf{V}_b^g \right) + \sum_{i=1}^N m_i \mathbf{r}_b^i \times \left[\frac{\delta \boldsymbol{\omega}}{\delta t} \times \mathbf{r}_b^i \right] \\ &\quad + \sum_{i=1}^N m_i \mathbf{r}_b^i \times [\boldsymbol{\omega} \times [\boldsymbol{\omega} \times \mathbf{r}_b^i]]. \end{aligned} \quad (14.32)$$

The first term can be expanded by utilizing the definition of the CG:

$$\begin{aligned} \sum_{i=1}^N m_i \mathbf{r}_b^i \times \left(\frac{\delta \mathbf{V}_b^g}{\delta t} + \boldsymbol{\omega} \times \mathbf{V}_b^g \right) &= m \mathbf{r}_{cg} \times \left(\frac{\delta \mathbf{V}_b^g}{\delta t} + \boldsymbol{\omega} \times \mathbf{V}_b^g \right) \\ &= \begin{bmatrix} m [y_{cg}(\dot{w} + pv - qu) - z_{cg}(\dot{v} + ru - pw)] \\ m [z_{cg}(\dot{u} + qw - rv) - x_{cg}(\dot{w} + pv - qu)] \\ m [x_{cg}(\dot{v} + ru - pw) - y_{cg}(\dot{u} + qw - rv)] \end{bmatrix}. \end{aligned} \quad (14.33)$$

Utilizing the double vector product identity allows for the expansion of the second term as follows:

$$\begin{aligned}
 \sum_{i=1}^N m_i \mathbf{r}_b^i \times \left(\frac{\delta \boldsymbol{\omega}}{\delta t} \times \mathbf{r}_b^i \right) &= \sum_{i=1}^N m_i \left(\frac{\delta \boldsymbol{\omega}}{\delta t} (\mathbf{r}_b^i \cdot \mathbf{r}_b^i) - \mathbf{r}_b^i \left(\frac{\delta \boldsymbol{\omega}}{\delta t} \cdot \mathbf{r}_b^i \right) \right) \\
 &= \begin{bmatrix} \sum_{i=1}^N m_i ((y_i^2 + z_i^2) \dot{p} - (y_i \dot{q} + z_i \dot{r}) x_i) \\ \sum_{i=1}^N m_i ((z_i^2 + x_i^2) \dot{q} - (z_i \dot{r} + x_i \dot{p}) y_i) \\ \sum_{i=1}^N m_i ((x_i^2 + y_i^2) \dot{r} - (x_i \dot{p} + y_i \dot{q}) z_i) \end{bmatrix} = \begin{bmatrix} I_{xx} \dot{p} + I_{xy} \dot{q} + I_{xz} \dot{r} \\ I_{yx} \dot{p} + I_{yy} \dot{q} + I_{yz} \dot{r} \\ I_{zx} \dot{p} + I_{zy} \dot{q} + I_{zz} \dot{r} \end{bmatrix} \\
 &= \begin{bmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{bmatrix} \begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} = \mathbf{I} \cdot \dot{\boldsymbol{\omega}}. \tag{14.34}
 \end{aligned}$$

The equation (14.34) is obtained by recognizing the moments of inertia and their symmetrical properties:

$$\begin{aligned}
 I_{xx} &= \sum_{i=1}^N m_i (y_i^2 + z_i^2) & I_{yy} &= \sum_{i=1}^N m_i (z_i^2 + x_i^2) & I_{zz} &= \sum_{i=1}^N m_i (x_i^2 + y_i^2) \\
 I_{xy} &= I_{yx} = - \sum_{i=1}^N m_i x_i y_i & I_{xz} &= I_{zx} = - \sum_{i=1}^N m_i x_i z_i & I_{yz} &= I_{zy} = - \sum_{i=1}^N m_i y_i z_i
 \end{aligned}$$

Combining them into a matrix form defines the inertia tensor \mathbf{I} that allows the conversion of the entire double vector product into a very compact form as in (14.34). The diagonal terms of \mathbf{I} are called the moments of inertia. The off-diagonal terms are called the products of inertia; they define the inertia cross coupling. The moments of inertia are directly proportional to the UAV's tendency to resist angular acceleration with respect to a specific axis of rotation. For a body with axes of symmetry, the inertia tensor can be resolved (Goldstein 1980) with zero off-diagonal terms that significantly simplify its form and the final equations of angular momentum.

The last term in (14.32) utilizes twice the same double cross product expansion, thus leading to

$$\begin{aligned} \sum_{i=1}^N m_i \mathbf{r}_b^i \times [\boldsymbol{\omega} \times [\boldsymbol{\omega} \times \mathbf{r}_b^i]] &= \sum_{i=1}^N m_i \mathbf{r}_b^i \times ((\boldsymbol{\omega} \cdot \mathbf{r}_b^i) \boldsymbol{\omega} - (\boldsymbol{\omega} \cdot \boldsymbol{\omega}) \mathbf{r}_b^i) \\ &= \begin{bmatrix} I_{yz}(q^2 - r^2) + I_{xz}pq - I_{xy}pr \\ I_{xz}(r^2 - p^2) + I_{xy}rq - I_{yz}pq \\ I_{xy}(p^2 - q^2) + I_{yz}pr - I_{xz}qr \end{bmatrix} + \begin{bmatrix} (I_{zz} - I_{yy})rq \\ (I_{xx} - I_{zz})rp \\ (I_{yy} - I_{xx})qp \end{bmatrix}. \end{aligned} \quad (14.35)$$

Resolving the total inertial moment acting on the UAV in body frame and denoting the components as $\mathbf{M}_b = [L, M, N]^T$ and combining the results in (14.33)–(14.35) lead to the following complete angular momentum equations in an expanded form:

$$\begin{aligned} L &= I_{xx}\dot{p} + I_{xy}\dot{q} + I_{xz}\dot{r} \\ &\quad + I_{yz}(q^2 - r^2) + I_{xz}pq - I_{xy}pr + (I_{zz} - I_{yy})rq \\ &\quad + m[y_{cg}(\dot{w} + pv - qu) - z_{cg}(\dot{v} + ru - pw)] \\ M &= I_{yx}\dot{p} + I_{yy}\dot{q} + I_{yz}\dot{r} \\ &\quad + I_{xz}(r^2 - p^2) + I_{xy}rq - I_{yz}pq + (I_{xx} - I_{zz})rp \\ &\quad + m[z_{cg}(\dot{u} + qw - rv) - x_{cg}(\dot{w} + pv - qu)] \\ N &= I_{zx}\dot{p} + I_{zy}\dot{q} + I_{zz}\dot{r} \\ &\quad + I_{xy}(p^2 - q^2) + I_{yz}pr - I_{xz}qr + (I_{yy} - I_{xx})qp \\ &\quad + m[x_{cg}(\dot{v} + ru - pw) - y_{cg}(\dot{u} + qw - rv)]. \end{aligned} \quad (14.36)$$

If the origin of the body-fixed frame $\{b\}$ is chosen at the CG ($\mathbf{r}_b^{cg} = [0, 0, 0]^T$), then in the case of a typical UAV with a vertical plane of symmetry spanned by the body-fixed axes x_b, z_b , the two pairs of the off-diagonal terms of \mathbf{I} matrix become zero, namely, $I_{xy} = I_{yx} = 0$ and $I_{yz} = I_{zy} = 0$. This significantly simplifies the above equations:

$$\begin{aligned} L &= I_{xx}\dot{p} + (I_{zz} - I_{yy})rq + I_{xz}(\dot{r} + pq) \\ M &= I_{yy}\dot{q} + (I_{xx} - I_{zz})rp + I_{xz}(r^2 - p^2) \\ N &= I_{zz}\dot{r} + (I_{yy} - I_{xx})qp + I_{zx}(\dot{p} - qr). \end{aligned} \quad (14.37)$$

These equations represent the complete rotational dynamics of a typical fixed-wing UAV modeled as a rigid body with a longitudinal plane of symmetry.

14.3.3 Complete Set of 6DoF Equations of Motion

The final set of 6DoF equations of motion describing the kinematics and dynamics of a generic UAV with a longitudinal plane of symmetry modeled as a rigid body can be summarized as follows:

$$\begin{aligned} X &= m [\dot{u} + qw - rv] \\ Y &= m [\dot{v} + ru - pw] \\ Z &= m [\dot{w} + pv - qu] \end{aligned} \quad (14.38)$$

$$\begin{aligned} L &= I_{xx} \dot{p} + (I_{zz} - I_{yy})rq + I_{xz}(\dot{r} + pq) \\ M &= I_{yy} \dot{q} + (I_{xx} - I_{zz})rp + I_{xz}(r^2 - p^2) \\ N &= I_{zz} \dot{r} + (I_{yy} - I_{xx})qp + I_{xz}(\dot{p} - qr) \end{aligned} \quad (14.39)$$

$$\begin{aligned} \dot{\mathbf{r}} &= \mathbf{R}^u \mathbf{V}_b^g = \\ &\begin{bmatrix} \cos \theta \cos \psi & -\cos \theta \sin \psi + \sin \phi \sin \theta \cos \psi & \sin \phi \sin \psi + \cos \phi \sin \theta \cos \psi \\ \cos \theta \sin \psi & \cos \phi \cos \psi + \sin \phi \sin \theta \sin \psi & -\sin \phi \cos \psi + \cos \phi \sin \theta \sin \psi \\ -\sin \theta & \sin \phi \cos \theta & \cos \phi \cos \theta \end{bmatrix} \mathbf{V}_b^g \end{aligned} \quad (14.40)$$

$$\begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} = \begin{bmatrix} 1 & \sin \phi \frac{\sin \theta}{\cos \theta} & \cos \phi \frac{\sin \theta}{\cos \theta} \\ 0 & \cos \phi & -\sin \phi \\ 0 & \sin \phi \frac{1}{\cos \theta} & \cos \phi \frac{1}{\cos \theta} \end{bmatrix} \begin{bmatrix} p \\ q \\ r \end{bmatrix}. \quad (14.41)$$

Analysis of the above differential equations shows that these equations are nonlinear and coupled, that is, each differential equation depends upon variables which are described by other differential equations. In general case, their analytical solutions are not known, and they can only be solved numerically. There are 12 states describing the free motion of a rigid body subject to external forces ($\mathbf{F}_b = [X, Y, Z]^T$) and moments ($\mathbf{M}_b = [L, M, N]^T$). In the control system design, these variables are called state variables because they completely define the state of a rigid body at any instance of time. The state variables are summarized in Table 14.1 for completeness.

What remains in the description of 6DoF equations of motion is to define the external forces and moments acting on the airplane. This will be the objective of the next section.

Table 14.1 State variables of the 6DoF equations of motion

| State variable | Definition |
|-------------------------------------|--|
| $\mathbf{r} = [r_x, r_y, r_z]^T$ | Vector of inertial position of the UAV and its components |
| $\mathbf{V}_b^g = [u, v, w]^T$ | Vector of inertial velocity components resolved in the body-fixed frame |
| $[\phi, \theta, \psi]$ | Euler angles that define the attitude of body-fixed frame with respect to the inertial frame |
| $\boldsymbol{\omega} = [p, q, r]^T$ | The inertial angular rates resolved in the body-fixed frame |

14.4 Forces and Moments Acting on the Airplane

The objective of this section is to present a generalized approach to defining the external forces and moments acting on a fixed-wing UAV as functions of its states. The primary forces and moments acting on an airplane are the gravitational, thrust of the propulsion system, aerodynamic, and disturbances due to the flight in unsteady atmosphere. The most challenging task here is in defining the aerodynamic forces and moments resulting from the air–body interaction. Although the aerodynamic description of airfoils defining a fixed wing is not a new subject, the varieties of shapes, aspect ratios, and aerodynamic configurations of modern fixed-wing UAVs do not allow thorough presentation of all configurations. As an example, possible aerodynamic configurations of aerodynamic surfaces include tandem, variable span wings, joined wings, twin boom, and V-tail configuration, just to name a few. However, a generalization is possible. An interested reader is referred to the most relevant survey (Mueller and DeLaurier 2003) of aerodynamics of small UAV that describes the modeling approaches and their limitations.

14.4.1 Gravitation

Assuming that the flight altitude is negligible in comparison to the radius of the Earth, it is sufficient to consider the gravity’s magnitude constant. Then, the effect of the Earth’s gravitation can be naturally modeled in the body-carried frame by the force applied to the CG of the UAV of mass m ; the gravitational force is proportional to the gravitational constant g and is called the weight of the UAV

$$\mathbf{F}_u^{gr} = \begin{bmatrix} 0 \\ 0 \\ mg \end{bmatrix}. \quad (14.42)$$

Before substituting this force expression into the equations of motion (14.39), it needs to be resolved in the body frame. The inertial to body rotation R_u^b enables this transformation:

$$\mathbf{F}_b^{gr} = R_u^b \begin{bmatrix} 0 \\ 0 \\ mg \end{bmatrix} = mg \begin{bmatrix} -\sin \theta \\ \sin \phi \cos \theta \\ \cos \theta \cos \phi \end{bmatrix}. \quad (14.43)$$

Assuming that the frame $\{b\}$ origin is chosen at the CG and since the gravitational force acts through the CG of the airplane, the corresponding moment contribution is zero, $\mathbf{M}_b^{gr} = [0, 0, 0]^T$.

14.4.2 Propulsion

The configuration of the propulsion system of modern fixed-wing UAVs varies greatly. The architectures can be categorized by the number of engines, their type, and their installation arrangement in the airframe. A thorough review of the existing configurations along with some future projections and trends in the modern and future UAV systems can be found in reference (OSD 2001). However, what is common across all possible configurations is that the vector of thrust in all systems is set parallel to the existing axes of symmetry; the thrust vectoring is not a common feature of fixed-wing UAVs yet.

The thrust is naturally represented in the body-fixed reference system. The direction of the thrust vector \mathbf{F}_b^{tr} is usually fixed and lies in the plane of symmetry or is parallel to it; however, it may not be aligned with the longitudinal x_b -axis. If the orientation of the thrust vector \mathbf{F}_b^{tr} varies in its reference to the airframe, then a separate coordinate system analogous to the wind axes should be defined, thus introducing the required rotation of the thrust vector to the body-fixed coordinate system. It is a common design requirement that the installation of multiple engines should not introduce any unbalanced moments, thus not inducing any loss of control efforts for the UAV stabilization. For the analysis of a nominal flight regime, the thrust vector \mathbf{F}_b^{tr} is considered fixed with respect to the body-fixed frame.

For the sake of simplicity, consider a typical fixed-wing UAV architecture where the installation of one or multiple engines results in the cumulative thrust vector \mathbf{F}_b^{tr} passing through the CG and the only moment being the torque generated primarily by the reactive force from the rotating propeller; depending on the type and the power of the propulsion system, there might be three more components (Illman 1999) of the torque, namely, the spiraling slipstream, the gyroscopic precession, and the asymmetric propeller loading (“P-factor”). Thus, in the case of a typical UAV, the net force X_{tr} of thrust in x_b direction and the moment L around x_b axis can be considered proportional to the thrust control command δ_{tr} . Moreover, thrust characteristics of most conventional engines are always functions of the air density and the airspeed. Thus, the contributing force and moment resulting from the propulsion system can be presented as follows:

$$\mathbf{F}_b^{tr} = \begin{bmatrix} F_{tr}(V_a, h, \delta_{tr}) \\ 0 \\ 0 \end{bmatrix}; \mathbf{M}_b^{tr} = \begin{bmatrix} M_{tr}(V_a, h, \delta_{tr}) \\ 0 \\ 0 \end{bmatrix}. \quad (14.44)$$

A particular example of modeling the propulsion force for the case of a micro UAV can be found in Beard and McLain (2012).

14.4.3 Unsteady Atmosphere

In the previous discussion of the wind frame, it was assumed that the wind \mathbf{V}_u^w defined in the LTP frame is constant; thus, the velocities are related by the “wind triangle” equation $\mathbf{V}_u^a = \mathbf{V}_u^g - \mathbf{V}_u^w$.

The most common approach (McRuer et al. 1999) in wind modeling is to consider two components contributing to the wind. The first component $\mathbf{V}_u^{wsteady}$ defines the steady wind resolved in the inertial frame, and therefore it can be presented by the measurements in the LTP frame. The second component \mathbf{V}_b^{wgust} is stochastic, which represents the short-period disturbances or gusts resolved in the body-fixed frame. Since the equations of motion are written in the body-fixed frame, then

$$\mathbf{V}_b^w = R_u^b \mathbf{V}_u^{wsteady} + \mathbf{V}_b^{wgust}. \quad (14.45)$$

From the components of the wind and the UAV velocity, both resolved in the body frame, it is therefore possible to find the body frame components of the air velocity as

$$\mathbf{V}_b^a = \begin{bmatrix} u_a \\ v_a \\ w_a \end{bmatrix} = \begin{bmatrix} u \\ v \\ w \end{bmatrix} - R_u^b \begin{bmatrix} u^{wsteady} \\ v^{wsteady} \\ w^{wsteady} \end{bmatrix} - \begin{bmatrix} u^{wgust} \\ v^{wgust} \\ w^{wgust} \end{bmatrix}. \quad (14.46)$$

These body frame components of the air velocity enable straightforward calculation of the airspeed and the angles of attack and sideslip as in (14.22).

Modeling of the stochastic and steady components of wind is based primarily on a history of experimental observations expressed using linear filters. The most widely used techniques are represented by von Karman and Dryden wind turbulence models (Hoblit 2001). Both methods are well supported with their numerical implementations.

14.4.4 Aerodynamics

Aerodynamic forces and moments depend on the interaction of an aircraft with the airflow, which may also be in motion relative to the Earth. However, for the purpose of representing the nominal aerodynamic effects, the large-scale motion of the atmosphere is not critical and therefore will be considered constant; in fact, it will only affect the navigation of the UAV.

The small perturbation theory (Ashley and Landahl 1985) is one of the approaches used in describing the aerodynamic interaction of a given aerodynamic shape with airflow. The perturbation in aerodynamic forces and moments are

functions of variations in state variables and control inputs. The control inputs here are the deflections of the control surfaces of an airplane that modify the airflow around the body, thus generating the desired aerodynamic effects. The nomenclature of the control surfaces and their control mechanization depends on the particular aerodynamic composition of the airplane. Nevertheless, the principles describing the effects of the control surface deflection on the generated forces and moments are the same. Consider the following control effectors of a classical aerodynamic configuration: the elevator, the aileron, and the rudder (see Fig. 14.9). In this configuration, the ailerons are used to control the roll angle ϕ , the elevator is used to control the pitch angle θ , and the rudder controls the yaw angle ψ .

Their deflections are denoted as δ_a for the aileron, δ_e for the elevator, and δ_r for the rudder. The positive deflection of a control surface is defined by applying the right-hand rule to the rotation axis of the surface. The positive direction of the aileron, elevator, and rudder deflections is also depicted in Fig. 14.9.

Deflection of the control surfaces modifies the pressure distribution around the control surfaces or the entire body thus producing corresponding forces. The forces acting with respect to the CG of the body result in aerodynamic moments. For example, deflecting the elevator primarily changes the pitching moment acting on the airplane. In turn, this results in changing the angle of attack of the wing that increases the lifting power of the airplane. The calculation of aerodynamic characteristics of one or more lifting surfaces with variable deflections of the control surfaces at various attitudes with respect to the airflow can be accomplished by utilizing well-developed linear panel methods (Hess 1990; Henne 1990) conveniently implemented in various software packages (Fearn 2008; Kroo 2012).

The panel methods capture the effect of pressure distribution in the form of parameterized forces and moments versus the angles of attack and sideslip, and airspeed; they play a role of states here. For example, considering the longitudinal plane, the effect of aerodynamic pressure acting on a fixed wing can be modeled using a total force \mathbf{F}_b^Σ and pitching moment \mathbf{M}_b^Σ acting on the wing both resolved in the body frame. It is common to project the total force to the wind axes, thus resulting in the lift F_{lift} and drag F_{drag} force components. Figure 14.10

Fig. 14.9 Control surfaces of a classical aerodynamic configuration

Fig. 14.10 Definition of the lift and drag forces and the pitching moment in the wind frame

demonstrates the approach to modeling aerodynamic effects in the wind and body-fixed frames with respect to the vector of free airstream \mathbf{V}_∞ .

As shown in Fig. 14.10, the lift F_{lift} and drag F_{drag} forces act in the wind frame and are applied at the aerodynamic center of the lifting surface that is located at the quarter-chord point (c is the length of the mean aerodynamic chord). The pitching component M of moment \mathbf{M}_b^Σ acts around the aerodynamic center. Then, the values of forces and moments are represented in a form connecting a number of surface-specific parameters and the states in the following form:

$$\begin{aligned} F_{lift} &= 1/2 \rho V_a^2 S C_L \\ F_{drag} &= 1/2 \rho V_a^2 S C_D, \\ M &= 1/2 \rho V_a^2 S c C_m \end{aligned} \quad (14.47)$$

where C_L, C_D, C_m are the nondimensional aerodynamic coefficients (to be parameterized), S is the planform area of the wing surface, and c and b are the mean aerodynamic chord and the wing span. The same approach is applied to each of the aerodynamic surfaces comprising the airplane. Then by using the parallel axis theorem (Goldstein 1980), the elementary moments from all the lifting and control surfaces can be transferred to the CG of the rigid body, thus resolving the actions with respect to one unifying center.

It is common practice to consider the total aerodynamic forces and moments in projections to the longitudinal and lateral planes of the airplane. The benefit of this approach is in the simplicity of representing the aerodynamic effects and in providing a natural ground for the nonlinear model decomposition at the next step of the control system design. Thus, the longitudinal forces and moments (14.47) consist of lift, drag, and pitching moment acting in the vertical plane of symmetry. The lateral side force F_{side} , yawing N , and rolling L moments are caused by the asymmetric airflow around the airplane and control surfaces deflection; the asymmetry can be caused by the side wind or intentional deflection of the rudder. For the majority of fixed-wing UAVs, the key states that define the parameterization

Table 14.2

Parameterization of longitudinal and lateral aerodynamics

| Longitudinal channel | Lateral channel |
|---|---|
| $F_{drag} = 1/2\rho V_a^2 S C_D(\alpha, q, \delta_e)$ | $F_{side} = 1/2\rho V_a^2 S C_Y(\beta, p, r, \delta_r, \delta_a)$ |
| $F_{lift} = 1/2\rho V_a^2 S C_L(\alpha, q, \delta_e)$ | $L = 1/2\rho V_a^2 S b C_l(\beta, p, r, \delta_r, \delta_a)$ |
| $M = 1/2\rho V_a^2 S c C_m(\alpha, q, \delta_e)$ | $N = 1/2\rho V_a^2 S b C_n(\beta, p, r, \delta_r, \delta_a)$ |

of the aerodynamic coefficient are the angle of attack α , the sideslip β , body rates $[p, q, r]$, and the controls which are the surface deflections $[\delta_e, \delta_r, \delta_a]$. The most general functional form of the longitudinal and lateral aerodynamics can be presented as follows (Table 14.2):

Without delving deeper into the intricacies of aerodynamic parameterization, it is sufficient to demonstrate the final form of forces and moments defined in the wind coordinate frame:

- Longitudinal plane

$$\begin{aligned}
 F_{drag} &= 1/2\rho V_a^2 S \left(C_{D_0} + C_D^\alpha \alpha + C_D^q \frac{c}{2V_a} \cdot q + C_D^{\delta_e} \cdot \delta_e \right) \\
 F_{lift} &= 1/2\rho V_a^2 S \left(C_{L_0} + C_L^\alpha \alpha + C_L^q \frac{c}{2V_a} \cdot q + C_L^{\delta_e} \cdot \delta_e \right) \\
 M &= 1/2\rho V_a^2 S c \left(C_{M_0} + C_M^\alpha \alpha + C_M^q \frac{c}{2V_a} \cdot q + C_M^{\delta_e} \cdot \delta_e \right)
 \end{aligned} \tag{14.48}$$

- Lateral plane

$$\begin{aligned}
 F_{side} &= 1/2\rho V_a^2 S \left(C_{Y_0} + C_Y^\beta \beta + C_Y^p \frac{b}{2V_a} \cdot p + C_Y^r \frac{b}{2V_a} \cdot r + C_Y^{\delta_r} \cdot \delta_r + C_Y^{\delta_a} \cdot \delta_a \right) \\
 L &= 1/2\rho V_a^2 S b \left(C_{l_0} + C_l^\beta \beta + C_l^p \frac{b}{2V_a} \cdot p + C_l^r \frac{b}{2V_a} \cdot r + C_l^{\delta_r} \cdot \delta_r + C_l^{\delta_a} \cdot \delta_a \right) \\
 N &= 1/2\rho V_a^2 S b \left(C_{n_0} + C_n^\beta \beta + C_n^p \frac{b}{2V_a} \cdot p + C_n^r \frac{b}{2V_a} \cdot r + C_n^{\delta_r} \cdot \delta_r + C_n^{\delta_a} \cdot \delta_a \right)
 \end{aligned} \tag{14.49}$$

The presented parameterization is a simple linear approximation of the aerodynamics given by the Taylor series expansion taken with respect to the given trim conditions. The coefficients $C_{f/m}^{state}$ are the nondimensional partial derivatives of the corresponding forces and moments (denoted in the subscript) defined with respect to the corresponding state or control (denoted in the superscript). The coefficients with zero in the subscript denote the forces and moments calculated when all states, including the control surface deflection, are zero; for example, C_{l_0} denotes the roll moment coefficient estimated at $\beta = p = r = 0$ and $\delta_r = \delta_a = 0$. The common naming convention suggests that those derivatives defined with respect to states $[\alpha, \beta, p, q, r]$ are called the stability derivatives and those with respect to controls $[\delta_e, \delta_r, \delta_a]$ are called the control derivatives. The static stability of an aircraft

with respect to disturbances in some variable is directly reflected in the sign of a particular derivative. For example, the sign of C_M^α should be negative to guarantee static stability in pitching motion, while the sign of C_N^β should be positive for the directional static stability.

Each of the presented coefficients is usually a function of states. The precision requirement of the linear parameterization greatly depends on the operational envelop of the UAV and its intended use; the higher the maneuverability of the UAV, the more terms necessary to accurately represent the aerodynamics. Each of the coefficients has very intuitive physical meaning and is usually studied separately. An interested reader is referred to Beard and McLain (2012) for a detailed discussion of the aerodynamic coefficients of small and micro fixed-wing UAVs.

One last step needs to be performed before the aerodynamics (14.48) and (14.49) defined in the wind coordinates can be plugged into the equations of motion (14.38) and (14.39) resolved in the body-fixed frame. The transformation (14.19) from the wind to the body frame serves this purpose.

Therefore, the total forces and moments acting on the fixed-wing UAV can be presented as follows:

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = R_u^b \begin{bmatrix} 0 \\ 0 \\ mg \end{bmatrix} + \begin{bmatrix} F_{tr}(V_a, h, \delta_{tr}) \\ 0 \\ 0 \end{bmatrix} + \frac{1}{2} \rho V_a^2 S \cdot R_w^b \begin{bmatrix} C_D(\alpha, q, \delta_e) \\ C_Y(\beta, p, r, \delta_r, \delta_a) \\ C_L(\alpha, q, \delta_e) \end{bmatrix} \quad (14.50)$$

$$\begin{bmatrix} L \\ M \\ N \end{bmatrix} = \begin{bmatrix} M_{tr}(V_a, h, \delta_{tr}) \\ 0 \\ 0 \end{bmatrix} + \frac{1}{2} \rho V_a^2 S \cdot \begin{bmatrix} bC_l(\beta, p, r, \delta_r, \delta_a) \\ cC_M(\alpha, q, \delta_e) \\ bC_n(\beta, p, r, \delta_r, \delta_a) \end{bmatrix}. \quad (14.51)$$

14.5 Accounting for the Earth Rotation Rate

The complete set of 6DoF equations of motion presented above is an approximation of the rigid body kinematics and dynamics and is valid as long as the assumption of the flat Earth model satisfies the task at hand. During the high-speed flight or in long-duration and extended range missions, the precision of the derived states will suffer from omitting the sidereal rate of the rotating Earth. The key reason for the error is in the accumulation over time of the Coriolis and centripetal accelerations induced by the rotating Earth. Thus, the following derivation outlines how the Earth rotation can be accounted for in the definition of the inertial velocity and acceleration vectors.

First, consider the ECI as the true inertial frame $\{i\}$. Next, by using the simplifying properties of defining the free motion of a rigid body with respect to the CG and utilizing the Coriolis theorem, resolve the absolute time derivative of the CG position vector \mathbf{r}_i^{cg} in the true inertial frame as follows:

$$\mathbf{V}_i^{cg} = \dot{\mathbf{r}}_i^{cg} = \mathbf{V}_e^{cg} + \boldsymbol{\Omega}_i^e \times \mathbf{r}_i^{cg}. \quad (14.52)$$

Taking the second time derivative and assuming that the sidereal rate of the Earth rotation is constant ($\dot{\boldsymbol{\Omega}}_i^e = 0$) results in

$$\begin{aligned}\dot{\mathbf{V}}_i^{cg} &= \dot{\mathbf{V}}_b^{cg} + \boldsymbol{\omega} \times \mathbf{V}_e^{cg} + \boldsymbol{\Omega}_i^e \times \dot{\mathbf{r}}_i^{cg} = \dot{\mathbf{V}}_b^{cg} + \boldsymbol{\omega} \times \mathbf{V}_e^{cg} + \boldsymbol{\Omega}_i^e \times (\mathbf{V}_e^{cg} + \boldsymbol{\Omega}_i^e \times \mathbf{r}_i^{cg}) \\ &= \dot{\mathbf{V}}_b^{cg} + (\boldsymbol{\omega} + \boldsymbol{\Omega}_i^e) \times \mathbf{V}_e^{cg} + \boldsymbol{\Omega}_i^e \times (\boldsymbol{\Omega}_i^e \times \mathbf{r}_i^{cg})\end{aligned}\quad (14.53)$$

In (14.53), the $\boldsymbol{\omega}$ denotes the vector of inertial angular velocity resolved in the body frame, and \mathbf{V}_b^{cg} is the same as $\mathbf{V}_b^g = \mathbf{V}_b^g$. The equation (14.52) updates the kinematic dead reckoning equation in (14.39), while the vector of inertial acceleration in (14.53) should be used in the application of the second Newtonian law.

Applying the angular velocities addition theorem, the vector $\boldsymbol{\omega}$ can be represented as a sum of the angular velocity vector $\boldsymbol{\omega}_n^b$ of body frame $\{b\}$ resolved in the body-carried frame $\{n\}$, the angular velocity vector $\boldsymbol{\omega}_e^n$ of body-carried frame $\{n\}$ resolved in ECEF frame $\{e\}$, and the sidereal rate of the Earth rotation vector $\boldsymbol{\Omega}_i^e$ resolved in the true inertial frame $\{i\}$. Thus, the last equation can be also written as

$$\dot{\mathbf{V}}_i^{cg} = \dot{\mathbf{V}}_b^{cg} + (\boldsymbol{\omega}_n^b + \boldsymbol{\omega}_e^n + 2\boldsymbol{\Omega}_i^e) \times \mathbf{V}_e^{cg} + \boldsymbol{\Omega}_i^e \times (\boldsymbol{\Omega}_i^e \times \mathbf{r}_i^{cg}). \quad (14.54)$$

What remains is to define the elements of (14.54) that enable calculation of the vector cross products.

As before, the term $2\boldsymbol{\Omega}_i^e \times \mathbf{V}_e^{cg}$ is the Coriolis, and the term $\boldsymbol{\Omega}_i^e \times (\boldsymbol{\Omega}_i^e \times \mathbf{r}_i^{cg})$, is the centripetal accelerations. The angular velocity vector $\boldsymbol{\omega}_e^n$, can be obtained from the geodetic latitude ($\dot{\phi}$) and longitude ($\dot{\lambda}$) rates, which in turn can be calculated from the NED components of $\mathbf{V}_e^{cg} = [V_N, V_E, V_D]^T$. The transformation of rates of the geodetic system ($\dot{\phi}, \dot{\lambda}$) to the body-carried stabilized frame $\{n\}$ can be obtained similarly to (14.10) by a left-handed rotation around the east axis through the latitude angle ϕ

$$\boldsymbol{\omega}_e^n = \begin{bmatrix} 0 \\ -\dot{\phi} \\ 0 \end{bmatrix} + \begin{bmatrix} \cos \phi & 0 & \sin \phi \\ 0 & 1 & 0 \\ -\sin \phi & 0 & \cos \phi \end{bmatrix} \begin{bmatrix} \dot{\lambda} \\ 0 \\ 0 \end{bmatrix}. \quad (14.55)$$

The rate of change of latitude and longitude can be calculated from the V_n northern and V_e eastern components of the velocity vector as follows:

$$\dot{\phi} = \frac{V_n}{r_m + h}, \quad \dot{\lambda} = \frac{V_E}{(r_n + h) \cos \varphi}, \quad (14.56)$$

where h is the height of CG above the reference oblate spheroid and

$$r_m = \frac{r_e(1 - \varepsilon^2)}{(1 - \varepsilon^2 \sin^2 \varphi)^{\frac{3}{2}}}, \quad r_n = \frac{r_e}{\sqrt{1 - \varepsilon^2 \sin^2 \varphi}}$$

are the estimates of the reference spheroid radius in the meridian and normal directions at given latitude and longitude. Substituting (14.56) into the (14.55) results in the estimate of ω_e^n as follows:

$$\omega_e^n = \left[\frac{V_E}{r_n + h}, -\frac{V_N}{r_m + h}, -\frac{V_E}{r_n + h} \tan \phi \right]^T. \quad (14.57)$$

Observe that the Earth sidereal rotation vector Ω_i^e has only one component in ECEF frame $\Omega_i^e = [0, 0, \Omega_i^e]^T$. Resolving for convenience Ω_i^e in the $\{n\}$ frame by a single φ rotation produces

$$\Omega_i^n = [\Omega_i^e \cos \phi, 0, -\Omega_i^e \sin \phi]^T, \quad (14.58)$$

thus completing the definition of all terms in (14.54). Obviously, the result of substituting of all the vectors into (14.54) is cumbersome; however it demonstrates how the Earth sidereal rate can be accounted for.

The corresponding linear and angular momentum equations can be obtained by applying the second Newtonian law; the procedure is similar to the simplified case presented above and resulted in the (14.26) and (14.32). Utilizing the same set of assumptions (A1–A2) and resolving all the external forces and moments with respect to the CG in the body frame results in the same angular momentum equation; however, the kinematic and the linear momentum equations need to be modified. Applying the second Newtonian law to the linear motion of the CG and accounting for a new result in (14.52) and (14.53) gives

$$\mathbf{V}_i^{cg} = R_b^e \mathbf{V}_b^{cg} + \Omega_i^e \times \mathbf{r}_i^{cg} \quad (14.59)$$

$$\mathbf{F}_b = m [\dot{\mathbf{V}}_b^{cg} + (\omega + \Omega_b^e) \times R_b^e \mathbf{V}_b^{cg} + \Omega_b^e \times (\Omega_b^e \times R_b^e \mathbf{r}_i^{cg})], \quad (14.60)$$

where \mathbf{F}_b , as before, is the sum of all externally applied forces applied at CG resolved in the body frame. Equations (14.59) and (14.60) are the new relations derived in a true inertial frame $\{i\}$, thus accounting for the rotating Earth.

To give a reader a sense of numerical significance of the resulting acceleration, the following numerical example compares the contribution of the Coriolis and the centripetal terms with an assumption that a UAV is at the constant altitude in the wing-level flight due east and is not maneuvering; therefore, $\omega_n^b = 0$ and $\mathbf{V}_e^{cg} = [0, V_E, 0]^T$. In these conditions, the centripetal term becomes equal to the Coriolis term at the speed of 914 m/s. In turn, when at the equator latitude, the third vertical component of the Coriolis acceleration is about 0.27 m/s^2 , that is, 2.7 % of the acceleration due to gravity (9.8 m/s^2). Thus, the applicability of the simplifying flat Earth assumption becomes justified for a case of a short-duration and relatively low-speed flight of an airplane. Therefore, this new set of equations should be used when accurate modeling is required for a UAV moving faster than 600 m/s over the Earth or when long distance and duration navigation is considered.

14.6 Conclusion

The objective of this chapter was to provide a review of the theoretical material required to enable accurate mathematical representation of the free and controlled motion of a generic fixed-wing UAV modeled as a rigid body. The key building blocks presented were the coordinate frames and their transformations, kinematics of rotation, dynamics of motion, and the definition of forces and moments acting on the airplane. The kinematics of spatial rotation is what connects the three building blocks of the “kinematics–dynamics–actions” triad. In addition to the 6DoF equations of motion describing the kinematics and dynamics of a rigid body motion, the tools and methods developed in this chapter contribute significantly into the UAV flight dynamics, system identification, control, guidance, and navigation.

Abstract

A nonlinear dynamic model of a miniature aerobatic helicopter is presented in detail. A component buildup was applied in devising the model, using simplified analytical expressions for the component forces and moments. Flight-test experiments were used to estimate several key parameters, such as the equivalent torsional stiffness in the hub. The model was used to design control logic for aerobatic maneuvers performed entirely under computer control.

15.1 Introduction

Miniature helicopters with hingeless rotors are extremely agile compared to their full-scale counterparts due to fast shrinking of moments of inertia with size and therefore growth of control authority Mettler (2002). These vehicles can be used for tasks requiring aggressive maneuvering, such as pursuit and evasion in urban or mountainous environment, or aerial stunts for movie industry. Precise autonomous execution of aggressive maneuvers, coupled with online motion planning, can further expand utility of agile miniature rotorcraft. This created the need for an adequate nonlinear model of an aerobatic miniature helicopter.

An extensive body of literature has been devoted to the dynamics of full-scale helicopters, and step-by-step procedures for creating a first-principles dynamic model were outlined (Padfield 1996; Bramwell 2001; Talbot et al. 1982). Frequency-domain system identification techniques are widely used to evaluate accuracy of linearized models at different operating conditions (NASA Ames Research Center 2000; Tischler 1996). Due to a wide range of flow conditions and their complex interaction with the wake, cross-axis coupling in the hub, and sometimes interaction of the structural modes with the rigid body modes, the models of full-scale helicopters used in simulators tend to be complex and contain a large number of states.

Recent years have seen an increase in modeling efforts for small-scale helicopters. Mettler (2002) performed a comprehensive study of the features common to the dynamics of small-scale helicopters and applied frequency-domain methods for identification of linearized models. Most of the small-scale helicopters have Bell-Hiller stabilizer bars, which slow down rotor dynamics and mitigate gust response. It was shown (Mettler 2002) that this creates relatively low-frequency lateral and longitudinal pendulum-like flapping modes, which involve fuselage, rotor, and stabilizer bar. The same effect was observed on a full-size UH-1H helicopter, equipped with a stabilizer bar with mechanical dampers instead of aerodynamic surfaces. The modes are lightly damped and must be accounted for to develop a high-bandwidth control system required for autonomous aggressive maneuvering.

LaCivita et al. (2002b) developed a technique for integrating first-principles modeling and frequency-domain system identification to yield a nonlinear model for small-scale helicopters. The resulting model of the Yamaha R-50 helicopter employed 30 states and was used for H_∞ -based control system design for the helicopter in steady-state hovering or slow forward and backward flight (LaCivita et al. 2002a). The authors further compared accuracy of full linearized models and reduced-order linear models and came to similar conclusions with those previously noted by Mettler (2002), which advocated the use of first-order models for tip-path-plane flapping dynamics.

Abbeel et al. (2006) built a nonlinear model of a small-scale aerobatic helicopter, using a combination of first-principles modeling and data fitting based on reinforcement learning. The model used fewer states than the one described in this chapter: it included rigid body states and main rotor speed only. The authors used the model and apprenticeship learning algorithms to develop control laws that enabled tracking

of highly aggressive aerobatic trajectories (Abbeel et al. 2010) and autonomous autorotation landing (Abbeel et al. 2008). Under this approach, time histories from aerobatic flights conducted by an expert pilot were used to refine the model and tailor control law parameters to a particular task.

This chapter presents a development of a first-principles-based nonlinear dynamic model of a miniature helicopter, which proved sufficiently accurate to predict helicopter dynamics in a wide range of conditions, including aerobatic flight. This work is closely based on a modeling chapter in the author's doctoral dissertation (Gavrilets 2003), devoted to human-inspired approach to autonomous helicopter aerobatics. Most of the model parameters were measured directly, and several were estimated using data from flight-test experiments. Analytical linearization of the model with respect to forward speed yields simple models, directly used for design of feedback control laws for autonomous execution of aerobatic maneuvers. The helicopter used in the study is X-Cell .60 SE by Miniature Aircraft (1999), equipped with a 0.90 size engine and an electronic governor. This helicopter features a particularly stiff hub, which gives large control authority to cyclic actuators. The coupling in the hub for this helicopter was also shown to be negligible, which further simplified model development.

The helicopter flew a fully autonomous mission that included an axial roll, a hammerhead, and a Split-S and sequences of these maneuvers (Gavrilets et al. 2002). An artist representation of a Split-S maneuver is shown in Fig. 15.1. The state trajectories in both open loop and closed loop flights were well predicted by the nonlinear model that used a single set of parameters, invariant of the task being performed.

The work on the dynamic model was performed using a custom-designed and built avionics suite, which was concurrently developed. The avionics suite is described in detail in the author's Ph.D. dissertation (Gavrilets 2003).

The model has typical rigid body states with the quaternion attitude representation used in order to enable simulation of extreme attitudes (Rolfe and Staples 1986), two states for the lateral and longitudinal flapping angles, one for the rotor speed, and one for the integral of the rotor speed tracking error. This last state comes from the governor action, modeled with a proportional-integral feedback from the rotor speed tracking error to the throttle command. The model covers a large portion of the X-Cell's natural flight envelope: from hover flight to about 20 m/s forward flight. The maximum forward speed corresponds to an advance ratio $\mu = 0.15$, which is considered as relatively low (Padfield 1996), and permits a number of assumptions (e.g., thrust perpendicular to the rotor disk; see Chen (1979)). The cross-coupling effects in the rotor hub were also shown to be negligible for this helicopter, which further simplified model development. The mathematical model was developed using basic helicopter theory, accounting for the particular characteristics of a miniature helicopter. Most of the parameters were measured directly, and several were estimated using data collected from simple flight-test experiments, involving step and pulse responses in various actuator inputs. No formal system identification procedures are required for the proposed model structure. The model's accuracy was verified using comparison between model predicted responses and responses

Fig. 15.1 Miniature helicopter undergoing a Split-S maneuver. The same maneuver was performed fully autonomously under control laws, developed based on the dynamic model described in this chapter (Drawing courtesy of Popular Mechanics magazine)

collected during flight-test data. The model was also “flown” in simulator by an expert RC pilot to determine how well it reproduces the piloted flying qualities.

Analytical linearization of the model with respect to forward speed was used to derive simple linear models. These were subsequently used for a model-based design of the controllers used for the automatic execution of aerobatic maneuvers. The actual aggressive trajectories flown by the helicopter were adequately predicted by the simulation based on the developed nonlinear model.

The remainder of the chapter contains a full list of model parameters with the numerical values, dynamics equations of motion, and expressions for forces and moments exerted on the helicopter by its components. Flight-test data used to validate the model for various flight regimes, including aerobatics, is provided throughout the chapter.

15.2 Helicopter Parameters

The physical helicopter parameters used for the model are given in Table 15.1. The moments of inertia around the aircraft body axes passing through the vehicle center of gravity were determined using torsional pendulum tests (Harris 1996). The cross-axis moments of inertia are hard to measure without a balancing device, and since they are usually small, they were neglected. The X-Cell main and tail rotors, as well as the stabilizer bar, have symmetric airfoils. The lift curve slopes of these surfaces were estimated according to their respective aspect ratios (Kueth and Chow 1986).

Table 15.1 Parameters of MIT instrumented X-Cell 60 SE helicopter

| Parameter | Description |
|---|--|
| $m = 8.2 \text{ kg}$ | Helicopter mass |
| $I_{xx} = 0.18 \text{ kg m}^2$ | Rolling moment of inertia |
| $I_{yy} = 0.34 \text{ kg m}^2$ | Pitching moment of inertia |
| $I_{zz} = 0.28 \text{ kg m}^2$ | Yawing moment of inertia |
| $K_\beta = 54 \text{ N-m/rad}$ | Hub torsional stiffness |
| $\gamma_{fb} = 0.8$ | Stabilizer bar Lock number |
| $B_{\delta_{lat}}^{\text{nom}} = 4.2 \text{ rad/rad}$ | Lateral cyclic to flap gain at nominal rpm |
| $A_{\delta_{lon}}^{\text{nom}} = 4.2 \text{ rad/rad}$ | Longitudinal cyclic to flap gain at nominal rpm |
| $K_\mu = 0.2$ | Scaling of flap response to speed variation |
| $\Omega_{\text{nom}} = 167 \text{ rad/s}$ | Nominal m.r. speed |
| $R_{\text{mr}} = 0.775 \text{ m}$ | m.r. radius |
| $c_{\text{mr}} = 0.058 \text{ m}$ | m.r. chord |
| $a_{\text{mr}} = 5.5 \text{ rad}^{-1}$ | m.r. blade lift curve slope |
| $C_{D_0}^{\text{mr}} = 0.024$ | m.r. blade zero lift drag coefficient |
| $C_{T_{\text{max}}}^{\text{mr}} = 0.0055$ | m.r. max thrust coefficient |
| $I_{\beta_{\text{mr}}} = 0.038 \text{ kg m}^2$ | m.r. blade flapping inertia |
| $R_{\text{tr}} = 0.13 \text{ m}$ | t.r. radius |
| $c_{\text{tr}} = 0.029 \text{ m}$ | t.r. chord |
| $a_{\text{tr}} = 5.0 \text{ rad}^{-1}$ | t.r. blade lift curve slope |
| $C_{D_0}^{\text{tr}} = 0.024$ | t.r. blade zero lift drag coefficient |
| $C_{T_{\text{max}}}^{\text{tr}} = 0.05$ | t.r. max thrust coefficient |
| $n_{\text{tr}} = 4.66$ | Gear ratio of t.r. to m. r. |
| $n_{\text{es}} = 9.0$ | Gear ratio of engine shaft to m. r. |
| $\delta_r^{\text{trim}} = 0.1 \text{ rad}$ | t.r. pitch trim offset |
| $S_{\text{vf}} = 0.012 \text{ m}^2$ | Effective vertical fin area |
| $C_{L_{\alpha}}^{\text{vf}} = 2.0 \text{ rad}^{-1}$ | Vertical fin lift curve slope |
| $\epsilon_{\text{vf}}^{\text{tr}} = 0.2$ | Fraction of vertical fin area exposed to t.r. induced velocity |
| $S_{\text{ht}} = 0.01 \text{ m}^2$ | Horizontal fin area |
| $C_{L_{\alpha}}^{\text{ht}} = 3.0 \text{ rad}^{-1}$ | Horizontal tail lift curve slope |
| $P_{\text{eng}}^{\text{idle}} = 0.0 \text{ W}$ | Engine idle power |
| $P_{\text{eng}}^{\text{max}} = 2,000.0 \text{ W}$ | Engine max power |
| $K_p = 0.01 \text{ s/rad}$ | Proportional governor gain |
| $K_i = 0.02 \text{ 1/rad}$ | Integral governor gain |
| $S_x^{\text{fus}} = 0.1 \text{ m}^2$ | Frontal fuselage drag area |
| $S_y^{\text{fus}} = 0.22 \text{ m}^2$ | Side fuselage drag area |
| $S_z^{\text{fus}} = 0.15 \text{ m}^2$ | Vertical fuselage drag area |
| $h_{\text{mr}} = 0.235 \text{ m}$ | m.r. hub height above c.g. |
| $l_{\text{tr}} = 0.91 \text{ m}$ | t.r. hub location behind c.g. |
| $h_{\text{tr}} = 0.08 \text{ m}$ | t.r. height above c.g. |
| $l_{\text{ht}} = 0.71 \text{ m}$ | Stabilizer location behind c.g. |

The effective torsional stiffness in the hub was estimated from angular rate responses to step commands in cyclic, as described in Sect. 15.4.1.3.

Note that in the table, “m.r.” stands for the main rotor, and “t.r.” stands for the tail rotor.

15.3 Equations of Motion

The rigid body equations of motion for a helicopter are given by the Newton-Euler equations shown below. Here the cross products of inertia are neglected:

$$\dot{u} = vr - wq - g \sin \theta + (X_{mr} + X_{fus}) / m$$

$$\dot{v} = wp - ur + g \sin \phi \cos \theta + (Y_{mr} + Y_{fus} + Y_{tr} + Y_{vf}) / m$$

$$\dot{w} = uq - vp + g \cos \phi \cos \theta + (Z_{mr} + Z_{fus} + Z_{ht}) / m$$

$$\dot{p} = qr(I_{yy} - I_{zz}) / I_{xx} + (L_{mr} + L_{vf} + L_{tr}) / I_{xx}$$

$$\dot{q} = pr(I_{zz} - I_{xx}) / I_{yy} + (M_{mr} + M_{ht}) / I_{yy}$$

$$\dot{r} = pq(I_{xx} - I_{yy}) / I_{zz} + (-Q_e + N_{vf} + N_{tr}) / I_{zz}$$

The set of forces and moments acting on the helicopter are organized by components: $()_{mr}$ for the main rotor, $()_{tr}$ for the tail rotor, $()_{fus}$ for the fuselage (includes fuselage aerodynamic effects), $()_{vf}$ for the vertical fin, and $()_{ht}$ for the horizontal stabilizer. These forces and moments are shown along with the main helicopter variables in Fig. 15.2. Q_e is the torque produced by the engine to counteract the aerodynamic torque on the main rotor blades. The helicopter blades rotate clockwise when viewed from above; therefore, $Q_e \geq 0$. In the above equations, it was assumed that the fuselage center of pressure coincides with the c.g.; therefore, the moments created by the fuselage aerodynamic forces were neglected.

Fig. 15.2 Moments and forces acting on helicopter

The rotational kinematic equations were mechanized using quaternions (Rolfe and Staples 1986). The inertial velocities are derived from the body-axis velocities by a coordinate transformation (flat-Earth equations are used) and integrated to obtain inertial position. A fourth-order Runge-Kutta integration method is used, with an integration step of 0.01 s.

15.4 Component Forces and Moments

15.4.1 Main Rotor Forces and Moments

15.4.1.1 Thrust

For the main rotor thrust, it was assumed that the inflow is steady and uniform. According to Padfield (1996, p. 126), the time constant for settling of the inflow transients at hover is given by

$$\tau_\lambda = \frac{0.849}{4\lambda_{\text{trim}}\Omega_{\text{mr}}} \quad (15.1)$$

Induced velocity at hover trim condition can be determined from simple momentum theory:

$$V_{\text{imr}} = \sqrt{\frac{mg}{2\rho\pi R_{\text{mr}}^2}} = 4.2 \text{ m/s} \quad (15.2)$$

The tip speed of the main rotor is $V_{\text{mr}}^{\text{tip}} = \Omega_{\text{mr}} R_{\text{mr}} = 125.7 \text{ m/s}$, from which the inflow ratio is $\lambda_{\text{imr}} = V_{\text{imr}}/V_{\text{mr}}^{\text{tip}} = 0.033$. Therefore, the time it takes for the inflow to settle is $\tau_\lambda = 0.038 \text{ s}$, which is significantly faster than the rigid body dynamics. During the maneuvers requiring large thrust variations, the time constant may change substantially. However, as shown in the section on the main rotor flapping dynamics, the X-Cell cyclic control authority is dominated by the hub torsional stiffness, which makes the modeling of the inflow transients less critical.

A momentum theory-based iterative scheme given by Padfield (1996, p. 123) was adapted to compute the thrust coefficient and inflow ratio as a function of airspeed, rotor speed, and collective setting. Flapping angles were neglected in the computation of the rotor thrust. The blades of the main rotor have no twist. The influence of the cyclics and the roll rate on thrust are of second order for advance ratio range $\mu < 0.15$ and were neglected as well. An empirically determined maximum thrust coefficient was introduced, since momentum theory does not take into account the effect of blade stall.

The thrust coefficient is given by (omitting the “mr” index)

$$C_T = \frac{T}{\rho (\Omega R)^2 \pi R^2} \quad (15.3)$$

where T is the main rotor thrust. Then, the following system of equations can be solved iteratively:

$$\lambda_0 = \frac{C_T}{2\eta_w \sqrt{\mu^2 + (\lambda_0 - \mu_z)^2}} \quad (15.4)$$

$$C_T^{\text{ideal}} = \frac{a\sigma}{2} \left(\theta_0 \left(\frac{1}{3} + \frac{\mu^2}{2} \right) + \frac{\mu_z - \lambda_0}{2} \right) \quad (15.5)$$

$$C_T = \begin{cases} C_T^{\text{ideal}} & \text{if } -C_T^{\text{max}} \leq C_T^{\text{ideal}} \leq C_T^{\text{max}} \\ -C_T^{\text{max}} & \text{if } C_T^{\text{ideal}} < -C_T^{\text{max}} \\ C_T^{\text{max}} & \text{if } C_T^{\text{max}} < C_T^{\text{ideal}} \end{cases} \quad (15.6)$$

$$C_T^{\text{max}} = \frac{T^{\text{max}}}{\rho (\Omega R)^2 \pi R^2} \quad (15.7)$$

Here

$$\mu = \frac{\sqrt{(u - u_{\text{wind}})^2 + (v - v_{\text{wind}})^2}}{\Omega R} - \text{advance ratio}$$

$$\mu_z = \frac{w - w_{\text{wind}}}{\Omega R} - \text{normal airflow component}$$

$$\sigma = \frac{2c}{\pi R} - \text{solidity ratio}$$

a – lift curve slope

θ_0 – commanded collective angle

η_w – coefficient of nonideal wake contraction

$T^{\text{max}} = 2.5 \text{ mg}$ – maximum rotor thrust

Based on momentum theory, the rotor wake far downstream contracts by a factor of 2 (Padfield 1996, p. 116). A coefficient η_w was introduced to account for nonideal wake contraction and the power lost due to the nonuniform velocity and pressure distribution in the wake. An approximate value for this coefficient was determined to be $\eta_w = 0.9$. Hence, the iterative scheme given in Padfield (1996, p. 123) is modified as follows. First, define the zero function:

$$g_0 = \lambda_0 - \frac{C_T}{2\eta_w \Lambda^{1/2}}, \text{ where}$$

$$\Lambda = \mu^2 + (\lambda_0 - \mu_z)^2$$

and thrust coefficient C_T is given by Eq. (15.5). Apply Newton's iterative scheme:

$$\lambda_{0_{j+1}} = \lambda_{0_j} + f_j h_j (\lambda_{0_j})$$

$$h_j = - \left(\frac{g_0}{dg_0/d\lambda_0} \right)_{\lambda_0=\lambda_{0_j}}$$

An explicit expression for h_j :

$$h_j = - \frac{(2\eta_w \lambda_{0_j} \Lambda^{1/2} - C_T) \Lambda}{2\eta_w \Lambda^{3/2} + \frac{a\sigma}{4} \Lambda - C_T (\mu_z - \lambda_{0_j})}$$

Padfield (1996, p. 123) suggests a constant value of the convergence rate coefficient $f_j = 0.6$.

Note that at hover the denominator of Eq. (15.4) is zero when the vertical velocity is equal to the inflow velocity. This condition corresponds to a vortex-ring state, which cannot be modeled adequately by the momentum theory. Instead, the denominator is numerically separated from zero. In general, this condition is avoided in flight because it leads to a loss of control. One has to keep in mind that the simulation does not adequately represent the helicopter dynamics when vortex-ring conditions exist on either the main or the tail rotor. Furthermore, strictly speaking, the momentum theory applies only to a fully developed steady-state flow in ascending flight. Empirical corrections for descending flight, cited by Padfield (1996, p. 118), could be used to make thrust prediction somewhat more accurate.

The momentum theory approach was previously shown to be adequate for estimating steady-state main rotor thrust both at hover and in fast forward flight. Results of the wind tunnel tests with a 5-ft-diameter rotor are given by Harris (1972) and summarized by Bramwell (2001, pp. 109–114). It was shown that the blade lift curve slope coefficient a can be determined from experiments such that the momentum theory accurately predicts thrust for a wide range of advance ratios and collective pitch angles. To test the applicability of momentum theory-based thrust calculation to transient response, flight data was gathered for collective pitch pulse responses at hover. At hover, the vertical acceleration can be represented by a linear relation:

$$a_z = Z_w w + Z_{\text{col}} \delta_{\text{col}} \quad (15.8)$$

The vertical speed damping stability derivative Z_w and the collective pitch control derivative Z_{col} can be obtained analytically by linearization of the momentum theory equations (Padfield 1996, pp. 219, 229). For hover,

Fig. 15.3 Modeling vertical acceleration response at hover

$$Z_w = -\frac{\rho (\Omega R) \pi R^2}{m} \frac{2a\sigma\lambda_0}{16\lambda_0 + a\sigma} \quad (15.9)$$

$$Z_{col} = -\frac{\rho (\Omega R)^2 \pi R^2}{m} \frac{8}{3} \frac{a\sigma\lambda_0}{16\lambda_0 + a\sigma} \quad (15.10)$$

The same value for the blade lift curve slope was used as the one determined for the particular airfoil used in the tests summarized by Harris (1972), $a = 5.5$. This value is consistent with the high aspect ratio of the main rotor blades, if the blades are considered as a wing (Kuethe and Chow 1986). The mean values were subtracted from the collective command and the vertical acceleration measurement; the signals were filtered with a first-order low-pass filter with time constant of 0.2 s. The digital models of the analog low-pass filter and the servomechanism were applied to the collective command for consistency. Figure 15.3 shows the comparison of the computed vertical acceleration from Eq. (15.8) and actual acceleration. As can be seen, the model, based on linearization of the momentum theory, agrees well with flight data.

15.4.1.2 Torque

The main rotor torque can be approximated as a sum of induced torque due to generated thrust and torque due to profile drag on the blades (Padfield 1996, p. 116):

$$C_Q = \frac{Q}{\rho (\Omega R)^2 \pi R^3} = C_T (\lambda_0 - \mu_z) + \frac{C_{D_0}\sigma}{8} \left(1 + \frac{7}{3}\mu^2\right) \quad (15.11)$$

where C_Q is the torque coefficient and C_{D_0} is the profile drag coefficient of the main rotor blade. The profile drag is not significantly affected by changes in the collective setting. Thus, the yawing moment produced by the main rotor is given by

$$Q_{mr} = C_Q \rho (\Omega R)^2 \pi R^3 \quad (15.12)$$

Profile drag coefficient of the main rotor blade was estimated as $C_{D_0} = 0.024$. Underestimation of the profile drag coefficient would lead to overprediction of the main rotor speed in windmilling flight conditions, which occur during autorotation and some agile maneuvers.

Except for the hover condition, the rotor in-plane force, which contributes to the drag and side force, is substantially smaller than the drag provided by the fuselage and the side force from the fuselage and the empennage. This force was neglected in the calculations; effectively it was lumped with the fuselage forces, estimated in Sect. 15.4.3. The moments due to the in-plane force are much smaller than those due to the blade flapping, since the torsional stiffness of the hub retention is high on the X-Cell.

15.4.1.3 Main Rotor Moments and Flapping Dynamics

The main rotor flapping angle β can be represented as a Fourier series of the blade azimuth angle ψ , with only the first three coefficients retained (Padfield 1996, p. 32):

$$\beta(\psi) = a_0 + a_1 \cos \psi + b_1 \sin \psi \quad (15.13)$$

Flapping of the teetering stabilizer bar can be represented by a similar equation without the constant term since no coning takes place:

$$\beta_s(\psi) = a_{1s} \sin \psi + b_{1s} \cos \psi \quad (15.14)$$

Stabilizer bar flapping contributes to the change of the main rotor blade pitch angle through a mechanical linkage:

$$\theta(\psi) = \theta_0 + \theta_{lon} \sin \psi + \theta_{lat} \cos \psi + k_s \beta_s \quad (15.15)$$

The swashplate deflections change the cyclic pitch angle of both the main rotor and the stabilizer bar. Coupled second-order differential equations can be developed for Fourier coefficients of the main rotor and stabilizer bar flapping. It can be shown (Padfield 1996, pp. 33–35) that the undamped natural frequency of the flapping motion is close to the rotor speed Ω_{mr} and the damping ratio can be approximated by $\gamma/8$, where γ is the Lock number of the blades being considered (main rotor or stabilizer bar). The Lock number represents the ratio of aerodynamic to inertial forces and is defined as

$$\gamma = \frac{\rho c a R^4}{I_\beta} \quad (15.16)$$

For the main rotor blades, the Lock number is relatively high, $\gamma_{mr} \approx 3.7$; therefore, the flapping motion is well damped. For a step response, this corresponds to the settling time (to within 5 % of the steady-state value) of $24/\gamma\Omega = 0.039$ s. For the stabilizer bar, with its small aerodynamic surfaces, the Lock number is low, $\gamma_{tb} \approx 0.8$, and the corresponding settling time is 0.144 s. Earlier work on modeling of small-scale rotorcraft with Bell-Hiller stabilizer bars (Mettler et al. 2002b; Mettler 2002; LaCivita et al. 2002b) showed that the main rotor and stabilizer bar flapping dynamics can be lumped and represented by tip-path plane (TPP) flapping dynamics with only two states. This result was based on frequency-domain identification and comparison of reduced and full order transfer functions for attitude dynamics. Furthermore, coupling of the lumped flapping dynamics and rigid body pitch and roll motions leads to pronounced second-order characteristics (von Grunhagen et al. 1996; Talbot et al. 1982; Mettler 2002; LaCivita et al. 2002b). These modes are lightly damped and should be explicitly accounted for in designing high-bandwidth attitude or rate control systems (Mettler et al. 2000, 2002a). The lateral and longitudinal flapping dynamics were represented by the first-order equations:

$$\dot{b}_1 = -p - \frac{b_1}{\tau_e} - \frac{1}{\tau_e} \frac{\partial b_1}{\partial \mu_v} \frac{v - v_w}{\Omega R} + \frac{B_{\delta_{lat}}}{\tau_e} \delta_{lat} \quad (15.17)$$

$$\dot{a}_1 = -q - \frac{a_1}{\tau_e} + \frac{1}{\tau_e} \left(\frac{\partial a_1}{\partial \mu} \frac{u - u_w}{\Omega R} + \frac{\partial a_1}{\partial \mu_z} \frac{w - w_w}{\Omega R} \right) + \frac{A_{\delta_{lon}}}{\tau_e} \delta_{lon} \quad (15.18)$$

where $B_{\delta_{lat}}$ and $A_{\delta_{lon}}$ are effective steady-state lateral and longitudinal gains from the cyclic inputs to the main rotor flap angles; δ_{lat} and δ_{lon} are the lateral and longitudinal cyclic control inputs (pilot stick or control system outputs); u_w , v_w , and w_w are the wind components along, respectively, X, Y, and Z helicopter body axes; and τ_e is the effective rotor time constant for a rotor with the stabilizer bar. Frequency-domain identification showed that the pitch and roll cross-coupling flapping coefficients are approximately an order of magnitude less than the direct coefficients for the X-Cell (Mettler 2002) and were neglected. This result holds for large-amplitude inputs as well. For example, during an axial roll maneuver, the pitch rate remains close to zero with no pilot compensation, similarly to the roll rate during a loop. This natural decoupling of the cyclic responses makes the X-Cell a particularly attractive helicopter for aerobatics.

The dominant rotor moments are the control moments produced by the rotor flapping. In the following pages, the moments in the roll direction are described (resulting from the lateral TPP flapping b_1). Figure 15.4 shows the rotor moments that are acting on the fuselage. The first contribution results from the restraint in the blade attachment to the rotor head. The restraint can be approximated using a linear torsional spring with a constant stiffness coefficient K_β , resulting in a roll moment $M_{k,lat} = K_\beta b_1$. The second contribution results from the tilting of the thrust vector. Assuming that the thrust vector is perpendicular to the TPP, the thrust vector will tilt proportionally to the rotor flapping angles. The moment arm is the distance h_{mr}

Fig. 15.4 Rotor moments acting on the helicopter fuselage

between the rotor head and the helicopter center of gravity, resulting in a lateral moment $M_{h,lat} = T h_{mr} b_1$. The total main rotor rolling moment, entering the rigid body equations of motion, is represented by Eq. (15.19):

$$L_{mr} = (K_\beta + T h_{mr}) b_1 \quad (15.19)$$

Similarly, the pitching moment is given by Eq. (15.20):

$$M_{mr} = (K_\beta + T h_{mr}) a_1 \quad (15.20)$$

To determine the parameters entering the flapping equations, one can split up the problem into “slow” and “fast” dynamics. First, one can notice that the dihedral derivatives are important only at the low-frequency spectrum of the dynamics. At high frequencies (above 0.5 Hz), the transfer functions from cyclic inputs to angular rates can be approximated by second-order transfer functions, derived by omitting the translational flapping derivatives in Eqs. (15.17) and (15.18) and combining it with Eqs. (15.19) and (15.20):

$$\frac{q}{\delta_{lon}} \approx \frac{A_{\delta_{lon}}}{\tau_e} \frac{\omega_{nq}^2}{s^2 + 1/\tau_e s + \omega_{nq}^2} \quad (15.21)$$

$$\frac{p}{\delta_{lat}} \approx \frac{B_{\delta_{lat}}}{\tau_e} \frac{\omega_{np}^2}{s^2 + 1/\tau_e s + \omega_{np}^2} \quad (15.22)$$

Pitching dynamics in fast forward flight is significantly influenced by the horizontal tail, which provides a stabilizing effect, and the main rotor flapping due to vertical speed, which provides a destabilizing effect. Therefore, the longitudinal cyclic to pitch rate transfer function given in Eq. (15.21) is valid in low-speed flight only. Here the undamped natural frequencies of the longitudinal and lateral fuselage-rotor modes are

$$\omega_{nq} = \sqrt{\frac{T_{mr}h_{mr} + K_\beta}{I_{yy}}}$$

$$\omega_{np} = \sqrt{\frac{T_{mr}h_{mr} + K_\beta}{I_{xx}}}$$

Note that for hover and straight and level flight, $T_{mr} \approx mg$. The distance between the main rotor hub and the helicopter center of gravity can be measured. The moments of inertia were determined with the torsional pendulum tests (Harris 1996). The natural frequencies of the lightly damped second-order systems can be easily determined by counting oscillation periods in a recorded step response, thereby providing an estimate of the hub torsional stiffness. These parameters are given in Table 15.1. An approximate value of the damping time constant for the flapping motion (Mettler 2002) is given in Eq. (15.23):

$$\tau_e = \frac{16}{\gamma_{fb}\Omega_{mr}} \approx 0.1 \text{ s} \quad (15.23)$$

Note that the damping is proportional to the stabilizer bar Lock number, making it small. The steady-state cyclic to rate gains depend on the swashplate gearing. Experiments have also indicated that the values of $B_{\delta_{lat}}$ and $A_{\delta_{lon}}$ grow with the rotor speed. This effect was approximated as a function of effective dynamic pressure, or square of the rotor speed:

$$B_{\delta_{lat}} = B_{\delta_{lat}}^{\text{nom}} \left(\frac{\Omega}{\Omega_{\text{nom}}} \right)^2 \text{ rad/rad}$$

$$A_{\delta_{lon}} = A_{\delta_{lon}}^{\text{nom}} \left(\frac{\Omega}{\Omega_{\text{nom}}} \right)^2 \text{ rad/rad}$$

$$\Omega_{\text{nom}} = 167 \text{ rad/s}$$

These gains were determined by matching DC gain of the angular rate responses to steps in cyclics. Final verification of the derived parameters is provided by simulation of the linear systems described in Eqs. (15.21) and (15.22) and comparison with the flight-test data. Figure 15.5 shows the actual and simulated roll rates for a segment including an axial roll maneuver. The helicopter undergoes negative rotor loading during inverted portion of the maneuver, leading to 15% lower roll rate in that segment than predicted by the simplified linear model. Figure 15.6 shows the actual and simulated pitch rates for a segment of 15 m/s forward flight with pulse commands on longitudinal cyclic. Note that the linearized models of angular rate dynamics are adequate for both small- and large-amplitude motion.

The flapping due to translational velocity is described by the flapping derivatives $\partial a_1/\partial \mu$ and $\partial b_1/\partial \mu_v$. The longitudinal flapping due to the forward speed increase

Fig. 15.5 Actual and model roll rate response during axial roll maneuver

Fig. 15.6 Actual and model pitch rate response in low-speed flight

is caused by an increased lift on the advancing blade with respect to the retreating blade, which turns into a flap-back moment on the main rotor due to the 90° gyroscopic phase lag. A theoretical value for the steady-state longitudinal flapping for a rotor without a stabilizer bar is given by Bramwell (2001, p. 107)

$$a_1 = \frac{2\mu (4\delta_{col}/3 - \lambda_0)}{1 + 3\mu^2/2} \approx 2\mu (4\delta_{col}/3 - \lambda_0) \quad (15.24)$$

While this expression is valid for a teetering rotor at hover, theoretical approximation for a hingeless rotor without a stabilizer bar is very close (Padfield 1996). The stabilizer bar dramatically reduces flapping response to gusts, and

Eq. (15.24) cannot be used for predicting dihedral effect on a rotor equipped with one. Since this derivative plays a primary role in the frequency and damping of the phugoid mode, which is very slow, it is difficult to estimate with the frequency-domain identification methods (Mettler 2002). An open loop excitation would have to last for much longer than it takes for the helicopter to diverge; therefore, the necessary pilot's feedback would bias an estimate of the derivative (Ljung 1999). A scaling coefficient was introduced in Eq. (15.24), which was linearized to yield

$$\frac{\partial a_1}{\partial \mu} = 2K_\mu \left(\frac{4\delta_{\text{col}}}{3} - \lambda_0 \right) \quad (15.25)$$

A rough estimate for the scaling coefficient K_μ can be obtained by matching the steady-state cyclic input in forward flight at constant speed (maintained with the velocity-tracking feedback controller) with that predicted by the simulation in the same conditions. An estimate for X-Cell 60 yielded $K_\mu = 0.2$, which implies that the stabilizer bar reduces steady-state flapping response to forward speed by a factor of 5. From Eq. (15.24) and the rotor symmetry, one can conclude that the longitudinal and lateral dihedral derivatives are equal in magnitude and, in both cases, cause the rotor to flap away from the incoming air:

$$\frac{\partial b_1}{\partial \mu_v} = -\frac{\partial a_1}{\partial \mu} \quad (15.26)$$

Positive Z-axis velocity causes higher lift on advancing blade, which results in a flap back of the rotor; this effect is captured by the stability derivative $\partial a_1 / \partial \mu_z$ in Eq. (15.17). An analytical estimate of the derivative is adapted (Bramwell 2001, p. 159) to accommodate backward flight and scaled by the same coefficient K_μ to reflect the effect of the stabilizer bar:

$$\frac{\partial a_1}{\partial \mu_z} = K_\mu \frac{16\mu^2}{(1 - \mu^2/2)(8|\mu| + a\sigma)} \text{sign } \mu \approx K_\mu \frac{16\mu^2}{8|\mu| + a\sigma} \text{sign } \mu \quad (15.27)$$

15.4.1.4 Rotor Forces

For small advance ratio flight ($\mu < 0.15$), one can assume that the thrust vector is perpendicular to the TPP. The small flapping angles (below 10°) allow one to use linear approximation for the main rotor force components along the helicopter body axes. As was stated above, the in-plane rotor force was lumped with the fuselage forces and is not accounted for in the equations below:

$$X_{\text{mr}} = -T_{\text{mr}}a_1$$

$$Y_{\text{mr}} = T_{\text{mr}}b_1$$

$$Z_{\text{mr}} = -T_{\text{mr}}$$

15.4.2 Engine, Governor, and Rotor Speed Model

The rotor speed dynamics is modeled by the following equation:

$$\dot{\Omega} = \dot{r} + \frac{1}{I_{\text{rot}}} [Q_e - Q_{\text{mr}} - n_{\text{tr}} Q_{\text{tr}}] \quad (15.28)$$

where Q_e is the engine torque (positive clockwise), $Q_{\text{mr}} = C_Q \rho (\Omega R)^2 \pi R^3$ is the main rotor torque (positive counterclockwise), Q_{tr} is the tail rotor torque, n_{tr} is the tail rotor gear ratio, I_{rot} is the total rotating inertia referenced to the main rotor speed, and Ω is the rotor speed. The engine torque depends on the throttle setting δ_t and rotor speed and is usually represented by engine maps or lookup tables. The maps for the engine were not available, and a simplified representation of the engine torque is suggested. Assume that engine power is proportional to the throttle setting:

$$P_e = P_e^{\max} \delta_t \quad (15.29)$$

where $0 < \delta_t < 1$. Then, the torque is

$$Q_e = \frac{P_e}{\Omega} \quad (15.30)$$

The engine torque response to throttle changes can be considered instantaneous, since the time lags associated with air intake, fuel flow, and combustion are very small compared to vehicle dynamics.

In the absence of manufacturer data, the governor can be modeled as a proportional-integral feedback controller, maintaining commanded rotor speed by changing the throttle:

$$\begin{aligned} \delta_t &= K_p \cdot (\Omega_c - \Omega) + K_i \cdot \omega_i \\ \dot{\omega}_i &= \Omega_c - \Omega \end{aligned} \quad (15.31)$$

where Ω_c is the rotor speed command and K_p and K_i are proportional and integral feedback gains. The anti-windup logic resets the integrator state value ω_i in case computed throttle command is saturated. Throttle servo dynamics is much faster than the rotor speed dynamics and was neglected in the model.

To determine the parameters of the given engine/governor model, time response to the rotor speed step command was analyzed. Consider linearization of Eqs. (15.28)–(15.31) around a nominal operating point, for example, hovering flight, neglecting the yawing acceleration and the tail rotor torque. The states of the linear system will be the rotor speed deviation from the nominal ω and an integral of the rotor speed tracking error ω_i . The inputs are ω_c , a variation of the rotor speed command, and δ_c , a variation of the collective angle from the trim setting. The resulting linear system is given in Eq. (15.32):

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} \omega \\ \omega_i \end{bmatrix} = & \begin{bmatrix} -\frac{1}{\Omega I_{\text{rot}}} (3Q_{\text{mr}}^0 + P_e^{\text{max}} K_p) & \frac{P_e^{\text{max}} K_i}{\Omega I_{\text{rot}}} \\ -1 & 0 \end{bmatrix} \begin{bmatrix} \omega \\ \omega_i \end{bmatrix} \\ & + \begin{bmatrix} \frac{P_e^{\text{max}} K_p}{\Omega I_{\text{rot}}} & -\frac{1}{I_{\text{rot}} C_Q} \frac{\partial C_Q}{\partial \delta_c} Q_{\text{mr}}^0 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} \omega_c \\ \delta_c \end{bmatrix} \end{aligned} \quad (15.32)$$

From Eq. (15.11), the main rotor torque at hover Q_{mr}^0 can be computed, and for the X-Cell with the parameters given in Table 15.1, $Q_{\text{mr}}^0 \approx 6.3 \text{ Nm}$. The characteristic polynomial of the system is given in Eq. (15.33):

$$\chi(\lambda) = \lambda^2 + \lambda \frac{3Q_{\text{mr}}^0 + P_e^{\text{max}} K_p}{\Omega I_{\text{rot}}} + \frac{P_e^{\text{max}} K_i}{\Omega I_{\text{rot}}} \quad (15.33)$$

To estimate the coefficients of the characteristic polynomial, the following test was performed (Sprague et al. 2001). The helicopter was kept at hover at 1,600 rpm, and a 100 rpm step input in rotor speed was commanded to the governor from a remote control. The rotor speed measurement was not available directly in the instrumentation package. Instead, the sound of the engine was recorded with a handheld camcorder. Next, a time-frequency decomposition analysis (Feron et al. 1998) was applied to determine frequency content of the engine noise as a function of time. In such an analysis, a signal of limited duration and frequency, called a wavelet, defined by its central frequency and width, is convoluted in the time domain with the data. The output in the time domain will have a larger magnitude when the wavelet's central frequency is present in the signal than when the central frequency is missing. The spectral content of the signal as a function of time can then be determined by repeating this computation over a range of frequencies. Many frequency bands appear in the sound spectrum of the engine noise, representing harmonics. Figure 15.7 (top) shows the result of the Morlet wavelet time-frequency analysis performed on the engine noise during a step change in RPM setting; two harmonics are indicated. The same behavior appears on each harmonic, providing the opportunity to fine-tune the model to a number of step responses, thereby reducing measurement error due to external noise. The governor/engine system was approximated with a second-order system, whose response to a commanded RPM step input appears at the bottom of Fig. 15.7. The system's damping ratio is $\zeta = 0.63$, and its natural frequency is $\omega_n = 1.3 \text{ rad/s}$. By matching the coefficients of the characteristic polynomials, one can obtain the expressions given in Eq. (15.34):

$$\begin{aligned} 2\zeta\omega_n &= \frac{3Q_{\text{mr}}^0 + P_e^{\text{max}} K_p}{\Omega I_{\text{rot}}} \\ \omega_n^2 &= \frac{P_e^{\text{max}} K_i}{\Omega I_{\text{rot}}} \end{aligned} \quad (15.34)$$

Fig. 15.7 (top) Two frequency bands in the engine noise spectrum; (bottom) simulated response to rotor speed step command

A total kinetic energy of all rotating components is $2I_{\beta_{mr}}\Omega^2 + I_{es}(n_{es}\Omega)^2 + 2I_{\beta_{tr}}(n_{tr}\Omega)^2 = (2I_{\beta_{mr}} + I_{es}n_{es}^2 + 2I_{\beta_{tr}}n_{tr}^2)\Omega^2$, where $I_{\beta_{mr}}$ and $I_{\beta_{tr}}$ are, respectively, the main and the tail rotor blade inertias, I_{es} is the inertia of the engine shaft and all components rotating at the engine speed, n_{tr} is the tail rotor gear ratio, and n_{es} is the engine gear ratio. Therefore, the rotating inertia referenced to the main rotor speed can be represented as $I_{rot} = 2I_{\beta_{mr}} + I_{es}n_{es}^2 + 2I_{\beta_{tr}}n_{tr}^2$. The most important contribution comes from the main rotor blades. The tail rotor inertia, after scaling with the gear ratio squared, amounts to 5 % of the main rotor inertia. The rotating inertia referenced to the engine speed is harder to estimate, but an upper bound can be found by estimating the total mass of rotating components (0.2 kg) and its effective radius of inertia (0.04 m). One thus arrives at an estimate for I_{rot} equal to 2.5 inertias of the main rotor blade. Using this value, and matching coefficients of the characteristic polynomial according to Eq. (15.34), estimates for the proportional and integral governor gains were obtained. The model could be further refined if real-time rotor speed data were available, or the actual governor gain and the engine maps were available from the manufacturer datasheets.

This engine/governor model is simplified. However, it reflects the trends which are important in some very aggressive maneuvers which involve large and rapid variation of the aerodynamic torque on the rotor. First, tight governor feedback keeps the rotor speed close to the nominal setting. Second, an increase in the aerodynamic torque leads to a temporary decrease in rotor speed and a lagged application of the yawing torque to the airframe. The reverse is true for windmilling flight, in which the rotor extracts energy from the air, and leads to an increase in rotor speed, and lagged decrease in torque applied to the airframe. The inaccuracies in the model can make feedforward compensation of the main rotor torque with the tail rotor difficult to tune; a tight yaw rate feedback to the tail rotor pitch is much more effective and is routinely used by R/C pilots in the form of a yaw rate gyro.

15.4.3 Fuselage Forces

For hover flight and forward speeds well below the induced velocity at hover (≈ 4.5 m/s for X-Cell), the rotor downwash is deflected by the forward and side velocity. This deflection creates a force opposing the movement. One can express the X and Y drag forces created by the fuselage in this flight regime by

$$X_{\text{fus}} = S_x^{\text{fus}} \frac{1}{2} \rho V_{\text{imr}}^2 \frac{u}{V_{\text{imr}}}$$

$$Y_{\text{fus}} = S_y^{\text{fus}} \frac{1}{2} \rho V_{\text{imr}}^2 \frac{v}{V_{\text{imr}}}$$

where S_x^{fus} and S_y^{fus} are effective drag areas of the fuselage in the X and Y directions.

When the forward speed is higher than the rotor induced velocity, the fuselage drag can be modeled as the drag of a flat plate exposed to dynamic pressure. In this case, the perturbations to the fuselage forces can be expressed as

$$X_{\text{fus}} = S_x^{\text{fus}} \frac{1}{2} \rho U_e^2 \frac{u}{U_e}$$

$$Y_{\text{fus}} = S_y^{\text{fus}} \frac{1}{2} \rho U_e^2 \frac{v}{U_e}$$

where U_e is the trim airspeed.

Considering the above equations, fuselage forces can be approximated by

$$V_{\infty} = \sqrt{u_a^2 + v_a^2 + (w_a + V_{\text{imr}})^2}$$

$$X_{\text{fus}} = -0.5 \rho S_x^{\text{fus}} u_a V_{\infty}$$

$$Y_{\text{fus}} = -0.5\rho S_y^{\text{fus}} v_a V_\infty$$

$$Z_{\text{fus}} = -0.5\rho S_z^{\text{fus}} (w_a + V_{\text{imr}}) V_\infty$$

where S_x^{fus} , S_y^{fus} , and S_z^{fus} are effective frontal, side, and vertical drag areas of the fuselage and u_a , v_a , and w_a are fuselage center of pressure velocities with respect to air (i.e., $u_a = u - u_w$, where u_w is the projection of wind velocity vector on the X body axis). One can neglect small moments generated by the fuselage and assume that the fuselage center of pressure coincides with the helicopter center of gravity. Based on the fuselage projection areas, one can assume that $S_y^{\text{fus}} \approx 2.2S_x^{\text{fus}}$, $S_z^{\text{fus}} \approx 1.5S_x^{\text{fus}}$. Effective frontal drag area can be determined from the average pitch angle required to maintain a certain forward speed. This is best done under automatic control in velocity hold mode. In a steady trimmed flight, $\text{mg}\theta \approx -0.5\rho U^2 S_x^{\text{fus}}$. A pitch angle of -10° was required to maintain 14.5 m/s forward speed, which resulted in the estimate $S_x^{\text{fus}} = 0.1 \text{ m}^2$.

15.4.4 Vertical Fin Forces and Moments

The side force generated by the vertical fin can be approximated as follows:

$$Y_{\text{vf}} = -0.5\rho S_{\text{vf}} (C_{L_\alpha}^{\text{vf}} V_\infty^{\text{tr}} + |v_{\text{vf}}|) v_{\text{vf}} \quad (15.35)$$

where S_{vf} is the vertical fin area, $C_{L_\alpha}^{\text{vf}}$ is its lift curve slope, $V_\infty^{\text{tr}} = \sqrt{u_a \cdot u_a + w_{\text{tr}} \cdot w_{\text{tr}}}$ is the axial velocity at the location of the tail rotor hub, v_{vf} is the side velocity relative to air at the location of the vertical fin, and w_{tr} is the vertical velocity (same as for the tail rotor):

$$v_{\text{vf}} = v_a - \epsilon_{\text{vf}}^{\text{tr}} V_{\text{itr}} - l_{\text{tr}} r \quad (15.36)$$

$$w_{\text{tr}} = w_a + l_{\text{tr}} q - K_\lambda \cdot V_{\text{imr}} \quad (15.37)$$

Here V_{itr} is the induced velocity of the tail rotor (see Eq. (15.50)), r is yaw rate, $\epsilon_{\text{vf}}^{\text{tr}}$ is the fraction of the vertical fin area exposed to full induced velocity from the tail rotor, l_{tr} is the vertical distance between the c.g. and tail rotor hub, which is about the same distance to the center of pressure of the vertical fin, V_{imr} is the main rotor induced velocity, and K_λ is the wake intensity factor, calculated in the tail rotor section.

To accommodate for stall of the vertical fin (McConley 1998), the absolute value of the vertical fin side force is limited by

$$|Y_{\text{vf}}| \leq 0.5\rho S_{\text{vf}} \left((V_\infty^{\text{tr}})^2 + v_{\text{vf}}^2 \right) \quad (15.38)$$

The vertical fin side force creates a yawing moment and a small rolling moment due to the offsets from the c.g.:

$$\begin{aligned} N_{vf} &= -Y_{vf}l_{tr} \\ L_{vf} &= Y_{vf}h_{tr} \end{aligned}$$

15.4.5 Horizontal Stabilizer Forces and Moments

The destabilizing effect of the main rotor flapping due to vertical speed is offset by the weathervaning provided by the horizontal tailplane. The horizontal tail produces lift and a stabilizing pitching moment around the center of gravity. An effective vertical speed at the horizontal tail location is determined, assuming that the stabilizer may be fully or partially submerged in the downwash of the main rotor:

$$w_{ht} = w_a + l_{ht}q - K_\lambda \cdot V_{imr} \quad (15.39)$$

The same wake intensity factor is used for the horizontal fin as for the vertical fin and the tail rotor. Next, the Z-force generated by the horizontal stabilizer is determined according to

$$Z_{ht} = 0.5\rho S_{ht} (C_{L_\alpha}^{ht} |u_a| w_{ht} + |w_{ht}| w_{ht}) \quad (15.40)$$

where S_{ht} is the horizontal stabilizer area and $C_{L_\alpha}^{ht} = 3.0$ is its lift curve slope. To accommodate for the stall of the horizontal stabilizer (McConley 1998), the absolute value of the horizontal stabilizer lift is limited by

$$|Z_{ht}| \leq 0.5\rho S_{ht} (u_a^2 + w_{ht}^2) \quad (15.41)$$

Finally, the pitching moment generated by the horizontal stabilizer is

$$M_{ht} = Z_{ht} \cdot l_{ht} \quad (15.42)$$

15.4.6 Tail Rotor

The tail rotor is subjected to a wide range of flow conditions, including those where the thrust-inflow iteration algorithm (given for the main rotor in Eqs. (15.4) and (15.5)) would fail (e.g., when the tail rotor operates in its own wake at a low in-plane airspeed). The thrust-inflow iteration equations for the tail rotor were linearized around the trim conditions corresponding to a no-sideslip flight at a range of forward speeds. The tail rotor thrust at such trim conditions is always nonzero to compensate for the main rotor torque, and zero sideslip implies that there is no airflow component normal to the rotor disk; therefore, Eqs. (15.4) and (15.5) are applicable:

Fig. 15.8 Linearized tail rotor side force due to side velocity

$$C_{T_{\mu_z}^{tr}} = \frac{\partial C_T^{tr}}{\partial \mu_z^{tr}} (|\mu_{tr}|, \mu_z^{tr} = 0, \delta_r^{trim}) \quad (15.43)$$

$$C_{T_{\delta_r}^{tr}} = \frac{\partial C_T^{tr}}{\partial \delta_r} (|\mu_{tr}|, \mu_z^{tr} = 0, \delta_r^{trim}) \quad (15.44)$$

The partial derivatives in Eqs. (15.43) and (15.44) were computed numerically. Simple approximate analytical expressions for the tail rotor coefficients can be obtained by adapting those used for the main rotor coefficients (Padfield 1996, pp. 219, 229). They fall within 15 % of those computed via numerical or exact analytical linearization. The resulting nondimensional coefficients were used to calculate the corresponding dimensional stability derivatives:

$$Y_v^{tr} = -C_{T_{\mu_z}^{tr}} \frac{f_t \rho \Omega_{tr} R_{tr} \pi R_{tr}^2}{m} \quad (15.45)$$

$$Y_{\delta_r}^{tr} = -C_{T_{\delta_r}^{tr}} \frac{f_t \rho (\Omega_{tr} R_{tr})^2 \pi R_{tr}^2}{m} \quad (15.46)$$

where f_t is the fin blockage factor, as suggested in Padfield (1996, p. 142):

$$f_t = 1.0 - \frac{3}{4} \frac{S_{vf}}{\pi R_{tr}^2}$$

The tail rotor speed is given by $\Omega_{tr} = n_{tr} \Omega_{mr}$, where n_{tr} is the gear ratio given in Table 15.1. For reference, the computed dimensional derivatives are provided in Figs. 15.8 and 15.9. Finally, the side force generated by the tail rotor is given in Eq. (15.47):

$$Y_{tr} = m Y_{\delta_r}^{tr} \delta_r + m Y_v^{tr} \mu_z^{tr} \Omega_{tr} R_{tr} \quad (15.47)$$

Fig. 15.9 Linearized tail rotor side force due to tail rotor pitch

In order to calculate Y_{tr} , one needs to determine the normal (μ_z^{tr}) and the in-plane (μ_{tr}) tail rotor inflow components. The main rotor wake affects the tail rotor thrust in a complex way; to model this influence accurately, an extensive modeling of the wake is required. It was decided to approximate just the increase in an apparent in-plane velocity seen by the tail rotor. For this, determine the main rotor wake intensity factor K_λ . The geometry calculations are equivalent to those given in Leishman (2000), but computationally more efficient since an explicit evaluation of the trigonometric functions is avoided. Calculate the following variables (tangents of the angles determining the geometry):

$$g_i = \frac{l_{tr} - R_{mr} - R_{tr}}{h_{tr}}$$

$$g_f = \frac{l_{tr} - R_{mr} + R_{tr}}{h_{tr}}$$

First, the tail rotor is out of the downwash if $V_{imr} \leq w_a$, in which case there is an effective upwash. Next, at low enough forward speed with respect to air, the tail rotor is out of the wake as well. This can be represented by the condition:

$$\frac{u_a}{V_{imr} - w_a} \leq g_i$$

In both of these cases, $K_\lambda = 0$. The tail rotor is fully in the wake if

$$\frac{u_a}{V_{imr} - w_a} \geq g_f \quad (15.48)$$

In the far wake, the downwash is twice the value at the rotor. It was assumed that $K_\lambda = 1.5$ when the tail rotor is fully immersed. In the remaining case, when the tail rotor is partially immersed, assume a linear growth of the wake intensity factor with the forward speed:

$$K_\lambda = 1.5 \frac{\frac{u_a}{V_{\text{mr}} - w_a} - g_i}{g_f - g_i} \quad (15.49)$$

The derived expression is used to calculate the vertical component of airspeed at the tail rotor location, as shown in Eq. (15.37). Next, determine an advance ratio for the tail rotor:

$$\mu_{\text{tr}} = \frac{u_a^2 + w_{\text{tr}}^2}{\Omega_{\text{tr}} \cdot R_{\text{tr}}}$$

Velocity component normal to the tail rotor is given by

$$v_{\text{tr}} = v_a - l_{\text{tr}} \cdot r + h_{\text{tr}} \cdot p$$

and in nondimensional form

$$\mu_{z_{\text{tr}}} = \frac{v_{\text{tr}}}{\Omega_{\text{tr}} \cdot R_{\text{tr}}}$$

The magnitude of the resulting tail rotor thrust is limited based on the assumed maximum thrust coefficient to model stall of the blades and other viscous losses:

$$Y_{\text{max}}^{\text{tr}} = f_t C_{T_{\text{max}}}^{\text{tr}} \rho (\Omega_{\text{tr}} R_{\text{tr}})^2 \pi R_{\text{tr}}^2$$

$$|Y_{\text{tr}}| \leq Y_{\text{max}}^{\text{tr}}$$

The yawing and small rolling moments due to offsets from the c.g. are computed as follows:

$$N_{\text{tr}} = -Y_{\text{tr}} l_{\text{tr}}$$

$$L_{\text{tr}} = Y_{\text{tr}} h_{\text{tr}}$$

The tail rotor induced velocity, used in the calculation of the vertical fin side force (see Eq. (15.36)), needs to be computed. Using the same derivation as for the main rotor (Padfield 1996, pp. 115–123), the inflow ratio is approximated by Eq. (15.50):

$$\lambda_0^{\text{tr}} = \mu_{z_{\text{tr}}} - 2 \left[\frac{2C_T^{\text{tr}}}{a_{\text{tr}} \sigma_{\text{tr}}} - \delta_r \left(\frac{1}{3} + \frac{\mu_{\text{tr}}^2}{2} \right) \right] \quad (15.50)$$

where C_T^{tr} is the computed tail rotor thrust coefficient, a_{tr} is the tail rotor blade lift curve slope given in Table 15.1, and $\sigma_{\text{tr}} = \frac{2C_{\text{tr}}}{\pi R_{\text{tr}}}$ is the tail rotor solidity ratio.

Finally, the tail rotor torque Q_{tr} is computed similarly to Eqs. (15.11) and (15.12) using the tail rotor parameters in place of the main rotor parameters.

15.5 Actuator Models

The command ranges for the cyclics and collective blade pitch are symmetric around the center point. The tail rotor blade pitch is offset by the trim value given in Table 15.1 such that the tail rotor pitch is computed as

$$\delta_r = \delta_r^{\text{cmd}} + \delta_r^{\text{trim}} \quad (15.51)$$

The following maximum commanded deflections were set, in radians:

$$\delta_{\text{lat}}^{\text{max}} = 0.096$$

$$\delta_{\text{lon}}^{\text{max}} = 0.096$$

$$\delta_{\text{col}}^{\text{max}} = 0.183$$

$$\delta_{r_{\text{cmd}}}^{\text{max}} = 0.38$$

Here $\delta_{\text{lat}}^{\text{max}}$ and $\delta_{\text{lon}}^{\text{max}}$ are actual maximum cyclic pitch angles of the main rotor blades, measured statically. The gearing between servos and pitch angles of control surfaces is close to being linear. Linear functions are used to relate servo pulse-width commands to control surface deflections. Lookup tables can be used for a different gearing. Hobby servos and pulse-width generation electronics used on the helicopter result in significant quantization effects. On average, 150 steps were used to encode rail-to-rail deflection of each control surface. This results, for example, in a tail rotor command quantization of 0.3° . Linear transfer functions are used to model the servo dynamics. Futaba S9402 servos, used for collective and cyclic deflections of the main rotor blades, were subjected to small-amplitude frequency sweeps under 35 oz-in mean load and small inertia, which was assumed to be representative of the actual loads experienced by the servos during the flight. The following transfer function came up as a result:

$$H_{\text{servo}}(s) = \frac{s/T_z + 1}{s/T_p + 1} \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

where $T_z = 104$ s, $T_p = 33$ s, $\omega_n = 36$ rad/s, and $\zeta = 0.5$. Note that 90° phase lag occurs at roughly 30 rad/s, which also imposes a limitation on the control system bandwidth. A fast digital servo (Futaba S9450) was used for the tail rotor pitch. Since the torque required from the tail rotor servo is much lower than that required from the swashplate actuators, no-load small-signal bandwidth tests provide an

adequate model of the servo. As a result of the tests, the servo transfer function was approximated by a second-order system with the undamped natural frequency of 7 Hz and the damping ratio of 0.6.

Conclusion

A representative nonlinear dynamic model of a miniature aerobatic helicopter was developed with first-principles methods. In addition to the rigid body states, the model includes two states to represent lateral and longitudinal flapping angles of the main rotor, one state for the main rotor speed, and one state for the integral of the main rotor speed tracking error. Flight-test data were used for determining several key parameters. The model is valid up to advance ratios $\mu < 0.15$ for a variety of maneuvering flight conditions, including negative rotor loading and high angular rates. The model can be used for developing and evaluating control design methods for demanding tasks, including aerobatics. This simplified modeling framework is suitable for a class of miniature helicopters with hingeless rotors.

Abstract

This chapter presents an overview of the rigid body dynamics of a quadrotor as well as several controllers for the quadrotor. First, the Newton-Euler equations of motion that govern the quadrotor motion are described, and it is shown that the quadrotor model is differentially flat. Next, two controllers for the quadrotor

are presented. The first is a linear controller based on a linearized model of the dynamics. The second is a nonlinear controller derived from the original dynamic model. The architecture of the GRASP quadrotor testbed at the University of Pennsylvania is also presented. Finally, experimental results which illustrate the dynamics and control of small quadrotors are presented.

16.1 Introduction

Aerial robotics is a growing field with tremendous civil and military applications. Potential applications for micro unmanned aerial vehicles include search and rescue tasks, environmental monitoring, aerial transportation and manipulation, and surveillance. Quadrotor designs, rotorcrafts whose propulsive force is provided by four rotors, make flexible and adaptable platforms for aerial robotics. Rotorcraft designs are not limited to quadrotors – vehicle designs range from helicopters with tail rotors as seen in vehicles used for transport, coaxial helicopter designs such as the Skybotix CoaX (Skybotix Technologies 2012) to the Falcon 8, a vehicle with 8 rotors sold by Ascending Technologies, GmbH (Ascending Technologies 2012). However, quadrotors have recently emerged as the platform of choice for research in micro aerial vehicles (Kumar and Michael 2011). They are highly maneuverable and enable safe and low-cost experimentation in mapping, navigation, and control algorithms in three dimensions. They can hover in place and take off and land vertically, unlike their fixed-wing counterparts. They also have sufficient payload and flight endurance to support a number of indoor and outdoor applications. Their ability to move in 3-dimensional space brings new research challenges compared to the wheeled mobile robots that have driven mobile robotics research over the last decade. In recent years, small quadrotors have been demonstrated for mapping three-dimensional environments (Shen et al. 2011), transporting and manipulating payloads (Lindsey et al. 2011), assembling structures (Michael et al. 2011), and for autonomous exploration (Shen et al. 2012).

The work in this chapter deals specifically with quadrotors that are on the order of 0.1–0.5 m in length and 0.1–0.5 kg in mass. As the length is scaled down, mass and inertia scale down much faster resulting in higher angular accelerations and superior maneuverability. As shown in Kushleyev et al. (2012), very small quadrotors (0.1 m in diameter) are remarkably agile. Another advantage is that the quadrotor design is easy to build and is quite robust. The blades have fixed pitch and the propellers rotate in one direction, allowing for simple motors and controllers. There are no hinges or flaps. As a result quadrotors are also easy to model and control.

However, quadrotors are inefficient compared to fixed-wing UAVs. While fixed-wing UAVs are able to exploit the lift generated by the structure of their wings, rotorcraft such as quadrotors must produce all of the energy they need to fly via their rotors, which is a much less efficient process. Because of limits on battery energy density and specific power, the battery represents close to 30 % of total mass, yielding flight times of less than 30 min. Another key challenge to creating autonomous quadrotors is the need to equip them with onboard sensors

and processors to enable 3-D state estimation. Sensors such as lidars are heavy and consume a lot of power, while cameras require significant processing power. The reader is referred to Kumar and Michael (2011) for a discussion of the challenges in developing autonomous quadrotors.

This chapter presents an overview of the dynamics, control, and planning for quadrotors. The next section describes a dynamic model of a quadrotor. The dynamic model is used to develop controllers for the system, which are described in Sect. 16.3. Experimental results with controllers on real platforms are discussed in Sect. 16.4. Two popular quadrotor platforms are used extensively for modeling and experimental results. The first is the Hummingbird quadrotor sold by Ascending Technologies, GmbH (Ascending Technologies 2012). The second platform is the Nano Quadrotor, a micro quadrotor designed by KMeI Robotics (KMeI Robotics 2011; Kushleyev et al. 2012). Both platforms will be described in detail throughout this chapter.

16.2 Modeling

16.2.1 Quadrotor Platforms

This section starts by describing two representative quadrotor platforms. Both platforms have onboard microcontrollers which allow low-level control and estimation to be done in flight by the robot. In addition, both platforms have onboard IMUs which provide feedback of accelerations and angular velocities. The Hummingbird quadrotor is shown in Fig. 16.1. The Hummingbird spans 55 cm from the tip of one rotor to the tip of the opposite rotor, has a height of 8 cm, and has a mass of about 500 g including a battery. The platform is durable enough to survive most crashes, while the blades are soft enough not to cause damage during such event. Furthermore, the 20 min battery life and 200 g payload capacity are also advantageous.

Fig. 16.1 A quadrotor platform with Vicon markers

The Nano Quadrotor spans 15 cm, has a height of 5 cm, and has a mass of about 75 g including battery. The platform is very small and maneuverable and safe due to the small size of the rotors.

16.2.2 Coordinate System and Reference Frames

A convenient description of the kinematics of a quadrotor can be provided using four reference frames. The inertial frame, \mathcal{A} , is defined by the triad \mathbf{a}_1 , \mathbf{a}_2 , and \mathbf{a}_3 with \mathbf{a}_3 pointing upward. Two intermediate frames \mathcal{E} and \mathcal{F} are produced by first rotating through an angle ψ about the \mathbf{a}_3 axis and then rotating about an angle ϕ about the \mathbf{e}_1 axis. Finally, the body frame \mathcal{B} of the quadrotor is defined by rotating about an angle θ about the \mathbf{f}_2 axis. The origin of the body frame is attached to the center of mass of the quadrotor with \mathbf{b}_3 perpendicular to the plane of the rotors pointing vertically up (aligned with \mathbf{a}_3) during perfect hover. The basis vectors of the body frame are parallel to the principal axes of inertia of the quadrotor. The center of mass is denoted as C (Fig. 16.2).

Fig. 16.2 The body-fixed frame and the inertial reference frame. A pair of motors (1 and 3) spins counterclockwise, while the other pair spins clockwise (2 and 4). The pitches on the corresponding propellers are reversed so that the thrust is always pointing in the \mathbf{b}_3 direction for all propellers. However, while the reaction moments on the frame of the robot are also in the vertical direction, the signs are such that they oppose the direction of the angular velocity of the propeller

16.2.3 Inertial Properties

Since \mathbf{b}_i are principal axes, the inertia matrix referenced to the center of mass along the \mathbf{b}_i reference triad, I , is a diagonal matrix. In practice, the three moments of inertia can be estimated by weighting individual components of the quadrotor and building a physically accurate model in SolidWorks or approximated using known inertia tensors of simple shapes (e.g., cylinders for the motors). The key parameters for the rigid body dynamics of the quadrotors used for simulation and experiments in this text are as follows:

- (a) Total mass of the quadrotor m
- (b) The distance from the center of mass to the axis of a motor: L
- (c) The components of the inertia dyadic using \mathbf{b}_i as the basis vectors:

$$[I_C]^{\mathbf{b}_i} = \begin{bmatrix} I_{xx} & 0 & 0 \\ 0 & I_{yy} & 0 \\ 0 & 0 & I_{zz} \end{bmatrix}.$$

The inertial properties of each of the quadrotor platforms are detailed in Table 16.1. Inspection of this table combined with reference to Kumar and Michael (2011) allows the reader to gain some insight into quadrotor scaling. Let L represent the characteristic length. The rotor radius R should scale linearly with L , the mass should as L^3 , and the moments of inertia should scale as L^5 . The force produced by the rotors, F , and the drag force D scale with the cross-sectional area and the square of the blade tip speed, v . Let the angular speed of the blades be denoted ω . Clearly, $\omega = \frac{v}{L}$. Thus $F \sim \omega^2 L^4$ and $D \sim \omega^2 L^4$. Linear acceleration $a = \frac{F}{m}$ scales as $a \sim \omega^2 L$.

16.2.4 Motor Model

Each rotor has an angular speed ω_i and produces a vertical force F_i according to

$$F_i = k_F \omega_i^2. \quad (16.1)$$

Table 16.1 Inertial properties of quadrotor platforms

| Platform | Hummingbird | Nano |
|--|-----------------------|-----------------------|
| $I_{xx}, \frac{\text{kg}}{\text{m}^2}$ | 2.32×10^{-3} | 4.28×10^{-5} |
| $I_{yy}, \frac{\text{kg}}{\text{m}^2}$ | 2.32×10^{-3} | 4.28×10^{-5} |
| $I_{zz}, \frac{\text{kg}}{\text{m}^2}$ | 4.00×10^{-3} | 8.36×10^{-5} |
| m, kg | 0.5 | 0.075 |
| L, m | 0.175 | 0.0635 |

The rotors also produce a moment according to

$$M_i = k_M \omega_i^2. \quad (16.2)$$

The constants k_M and k_F can be determined by experimentation with fixed rotors or by matching the performance of a simulation to the performance of the real system.

Data obtained from system identification experiments suggests that the rotor speed is related to the commanded speed by a first-order differential equation

$$\dot{\omega}_i = k_m(\omega_i^{\text{des}} - \omega_i).$$

This motor gain, k_m , is found from experimental data. The desired angular velocities, ω_i^{des} , are limited to a minimum and maximum value determined through experimentation. The response of a motor from the Nano Quadrotor to a step input is shown in Fig. 16.3.

However, as a first approximation, the motor controllers can be assumed to be perfect and the time constant k_m associated with the motor response to be arbitrarily small. In other words, assume that the actual motor velocities ω_i are equal to the commanded motor velocities, ω_i^{des} . Specific values for the Hummingbird and Nano Quadrotor platforms are given in Table 16.2.

Fig. 16.3 Experimental step response for motor on Nano Quadrotor. The commanded speed is a step from 0 to 10,000 RPM at time 0. Dots represent measured motor speeds. The motor reaches the desired speed in approximately 0.25 s

Table 16.2 Motor characteristics of quadrotor platforms

| Platform | Hummingbird | Nano Quadrotor |
|---------------------------------------|-----------------------|-------------------------|
| $k_M, \frac{\text{Nm}}{\text{rpm}^2}$ | 1.5×10^{-9} | 4.737×10^{-12} |
| $k_F, \frac{\text{N}}{\text{rpm}^2}$ | 6.11×10^{-8} | 1.9985×10^{-9} |
| k_m, s^{-1} | 20 | 200 |

16.2.5 Rigid Body Dynamics

Kinematics The $Z - X - Y$ Euler angle convention is used to model the rotation of the quadrotor in the world frame. As described in Sect. 16.2.2 to get from \mathcal{A} to \mathcal{B} , first rotate about \mathbf{a}_3 through the yaw angle, ψ , to get the triad \mathbf{e}_i . A rotation about the \mathbf{e}_1 through the roll angle, ϕ results in the triad \mathbf{f}_i (not shown in the figure). A third pitch rotation about \mathbf{f}_2 through θ results in the body-fixed triad \mathbf{b}_i . This convention produces the rotation matrix from \mathcal{A} to \mathcal{B} , ${}^{\mathcal{A}}R_{\mathcal{B}}$:

$${}^{\mathcal{A}}[R]_{\mathcal{B}} = \begin{bmatrix} c\psi c\theta - s\phi s\psi s\theta & -c\phi s\psi & c\psi s\theta + c\theta s\phi s\psi \\ c\theta s\psi + c\psi s\phi s\theta & c\phi c\psi & s\psi s\theta - c\psi c\theta s\phi \\ -c\phi s\theta & s\phi & c\phi c\theta \end{bmatrix}. \quad (16.3)$$

The components of angular velocity of the robot in the body frame are given by p , q , and r :

$${}^{\mathcal{A}}\omega_{\mathcal{B}} = p\mathbf{b}_1 + q\mathbf{b}_2 + r\mathbf{b}_3.$$

These values are related to the derivatives of the roll, pitch, and yaw angles according to

$$\begin{bmatrix} p \\ q \\ r \end{bmatrix} = \begin{bmatrix} c\theta & 0 & -c\phi s\theta \\ 0 & 1 & s\phi \\ s\theta & 0 & c\phi c\theta \end{bmatrix} \begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix}, \quad (16.4)$$

Newton's Equations of Motion Let \mathbf{r} denote the position vector of C in \mathcal{A} . The forces on the system are gravity, in the $-\mathbf{a}_3$ direction, and the forces from each of the rotors, F_i , in the \mathbf{b}_3 direction. The equations governing the acceleration of the center of mass are

$$m\ddot{\mathbf{r}} = \begin{bmatrix} 0 \\ 0 \\ -mg \end{bmatrix} + {}^{\mathcal{A}}R_{\mathcal{B}} \begin{bmatrix} 0 \\ 0 \\ F_1 + F_2 + F_3 + F_4 \end{bmatrix}. \quad (16.5)$$

The first input u_1 will be defined to be

$$u_1 = \sum_{i=1}^4 F_i,$$

which is the total force produced by the rotors in the \mathbf{b}_3 direction.

Euler's Equations of Motion In addition to forces, each rotor produces a moment perpendicular to the plane of rotation of the blade, M_i . Rotors 1 and 3 rotate in the $-\mathbf{b}_3$ direction, while 2 and 4 rotate in the $+\mathbf{b}_3$ direction. Since the moment produced on the quadrotor is opposite to the direction of rotation of the blades, M_1 and M_3 act in the \mathbf{b}_3 direction while, M_2 and M_4 act in the $-\mathbf{b}_3$ direction.

The angular acceleration determined by the Euler equations is

$$I \begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} = \begin{bmatrix} L(F_2 - F_4) \\ L(F_3 - F_1) \\ M_1 - M_2 + M_3 - M_4 \end{bmatrix} - \begin{bmatrix} p \\ q \\ r \end{bmatrix} \times I \begin{bmatrix} p \\ q \\ r \end{bmatrix}. \quad (16.6)$$

This can be rewritten as

$$I \begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} = \begin{bmatrix} 0 & L & 0 & -L \\ -L & 0 & L & 0 \\ \gamma & -\gamma & \gamma & -\gamma \end{bmatrix} \begin{bmatrix} F_1 \\ F_2 \\ F_3 \\ F_4 \end{bmatrix} - \begin{bmatrix} p \\ q \\ r \end{bmatrix} \times I \begin{bmatrix} p \\ q \\ r \end{bmatrix}. \quad (16.7)$$

where $\gamma = \frac{k_M}{k_F}$ is the relationship between lift and drag given by Eqs. (16.1) and (16.2). Accordingly, the second set of inputs is defined as the vector of moments \mathbf{u}_2 given by

$$\mathbf{u}_2 = \begin{bmatrix} 0 & L & 0 & -L \\ -L & 0 & L & 0 \\ \gamma & -\gamma & \gamma & -\gamma \end{bmatrix} \begin{bmatrix} F_1 \\ F_2 \\ F_3 \\ F_4 \end{bmatrix}.$$

Since u_1 and \mathbf{u}_2 are defined using a linear combination of the forces produced by the motors, they become the inputs to the system. Note that a rigid body in cartesian coordinates has six degrees of freedom, so the four inputs result in an underactuated system.

16.2.6 Differential Flatness

The quadrotor has six degrees of freedom in position and orientation but only four actuators. This means that it is an underactuated system. In order to plan dynamically feasible trajectories and feedforward control inputs, it must be shown that the quadrotor system is differentially flat. A system is differentially flat if the states and inputs can be written as algebraic functions of the flat outputs σ and their derivatives (van Nieuwstadt et al. 1994). This means that any trajectory $\sigma(t)$ in the space of flat outputs will be dynamically feasible for the quadrotor. In the case of the quadrotor, the four flat outputs can be shown to be $\sigma = [x, y, z, \psi]$.

The quadrotor is differentially flat if it can be shown that there exists a smooth map

$$(\mathbf{x}, \mathbf{u}) = \Phi(\sigma, \dot{\sigma}, \ddot{\sigma}), \quad (16.8)$$

where \mathbf{x} is the state of the quadrotor, defined as $\mathbf{x} = [x \ y \ z \ \phi \ \theta \ \psi \ \dot{x} \ \dot{y} \ \dot{z} \ p \ q \ r]$, and \mathbf{u} are the control inputs as defined in Sect. 16.2.5. From the above definition of σ , it is trivial to show that this condition is satisfied for position and velocity, with the acceleration proving that the map is smooth:

$$\begin{aligned} [x, y, z] &= [\sigma_1, \sigma_2, \sigma_3] \\ [\dot{x}, \dot{y}, \dot{z}] &= [\dot{\sigma}_1, \dot{\sigma}_2, \dot{\sigma}_3] \\ [\ddot{x}, \ddot{y}, \ddot{z}] &= [\ddot{\sigma}_1, \ddot{\sigma}_2, \ddot{\sigma}_3]. \end{aligned} \quad (16.9)$$

Next, the condition must be satisfied for rotation and angular velocity as well. Let the rotation matrix ${}^A R_B$ describe the rotation of the quadrotor, with the unit vectors in the body frame denoted by $\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3$. From the equations of motion,

$$\mathbf{b}_3 = \frac{\frac{1}{u_1}(\ddot{\mathbf{r}} - m\mathbf{g})}{|\frac{1}{u_1}(\ddot{\mathbf{r}} - m\mathbf{g})|} = \frac{(\ddot{\mathbf{r}} - m\mathbf{g})}{|\ddot{\mathbf{r}} - m\mathbf{g}|} \quad (16.10)$$

where the dependence on u_1 can be eliminated since it is a scalar and \mathbf{b}_3 is a unit vector. It has been shown above that $\ddot{\mathbf{r}}$ is a function of the flat outputs alone and the remaining terms are constant, so \mathbf{b}_3 is also a function of the flat outputs. A second unit vector in the body frame can be obtained using the following:

$$\mathbf{e}_1 = \cos \psi \mathbf{a}_1 + \sin \psi \mathbf{a}_2 \quad (16.11)$$

$$\mathbf{b}_3 \times \mathbf{e}_1 = \mathbf{b}_3 \times R' \mathbf{b}_1 = \mathbf{b}_3 \times (\cos \theta \mathbf{b}_1 - \sin \theta \mathbf{b}_3) = \cos \theta \mathbf{b}_2 \quad (16.12)$$

where R^T is a rotation of $-\theta$ about the \mathbf{b}_2 axis. Therefore the result of $\mathbf{b}_3 \times \mathbf{e}_1$ can be normalized to find \mathbf{b}_2 as a function of the flat outputs, provided that $\cos \theta$ is not zero. Finally, the cross product of \mathbf{b}_3 and \mathbf{b}_2 can be used to find \mathbf{b}_1 .

To show that the angular velocity is also a function of the flat outputs, use the derivative of acceleration given by the Newton-Euler equations in (16.5):

$$\mathbf{j} = \frac{1}{m} \dot{u}_1 \mathbf{b}_3 + \frac{1}{m} u_1 {}^A \omega^B \times \mathbf{b}_3. \quad (16.13)$$

Define $\mathbf{j} = \ddot{\mathbf{r}}$ to denote the jerk. Taking the dot product of the above equation with \mathbf{b}_3 shows that

$$\dot{u}_1 = m \mathbf{j} \cdot \mathbf{b}_3. \quad (16.14)$$

This can be substituted into (16.13) to find

$${}^A \omega^B \times \mathbf{b}_3 = \frac{m}{u_1} (\mathbf{j} - (\mathbf{j} \cdot \mathbf{b}_3) \mathbf{b}_3). \quad (16.15)$$

Expressing ${}^A \omega^B$ in terms of components p, q , and r means that the left-hand side of the equations above can be equated to $q \mathbf{b}_1 - p \mathbf{b}_2$ to find

$$p = -\mathbf{b}_2 \cdot \frac{m}{u_1}(\mathbf{j} - (\mathbf{j} \cdot \mathbf{b}_3)\mathbf{b}_3), q = \mathbf{b}_1 \cdot \frac{m}{u_1}(\mathbf{j} - (\mathbf{j} \cdot \mathbf{b}_3)\mathbf{b}_3). \quad (16.16)$$

For the third component of angular velocity, the derivatives of the Euler angles are related to the angular velocity using the following,

$${}^A\omega^B = [\mathbf{e}_1 \ \mathbf{b}_2 \ \mathbf{a}_3] \begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} = {}^A R_B \begin{bmatrix} p \\ q \\ r \end{bmatrix}. \quad (16.17)$$

This results in a system of three equations and three unknowns ($r, \dot{\phi}, \dot{\theta}$) which can be solved provided that \mathbf{e}_1 , \mathbf{b}_2 , and \mathbf{a}_3 are linearly independent.

The mapping between the flat outputs and the derivatives of angular velocity is found by taking another derivative of Newton's equation, giving

$$m\dot{\mathbf{j}} = \ddot{u}_1\mathbf{b}_3 + 2{}^A\omega^B \times \dot{u}_1\mathbf{b}_3 + {}^A\omega^B \times {}^A\omega^B \times u_1\mathbf{b}_3 + {}^A\alpha^B \times u_1\mathbf{b}_3. \quad (16.18)$$

\ddot{u}_1 can be found by projecting this equation along \mathbf{b}_3 . ${}^A\omega^B$, u_1 and \dot{u}_1 can be used to compute ${}^A\alpha^B \times \mathbf{b}_3$. This produces

$$\dot{p} = -({}^A\alpha^B \times \mathbf{b}_3) \cdot \mathbf{b}_2, \quad \dot{q} = ({}^A\alpha^B \times \mathbf{b}_3) \cdot \mathbf{b}_1. \quad (16.19)$$

For the last component of angular acceleration, the derivative of the relationship between Euler angles and angular velocity (16.17) can be used:

$${}^A R_B \left(\begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} + \begin{bmatrix} p \\ q \\ r \end{bmatrix} \times \begin{bmatrix} p \\ q \\ r \end{bmatrix} \right) = {}^\varepsilon\omega^A \times \dot{\phi}\mathbf{e}_1 + {}^B\omega^A \times \dot{\theta}\mathbf{b}_2 + [\mathbf{e}_1 \ \mathbf{b}_2 \ \mathbf{a}_3] \begin{bmatrix} \ddot{\phi} \\ \ddot{\theta} \\ \ddot{\psi} \end{bmatrix}. \quad (16.20)$$

If \mathbf{e}_1 , \mathbf{b}_2 , and \mathbf{a}_3 are linearly independent, then this equation is affine in the variables \dot{p} , \dot{q} and \dot{r} and results in a system of equations which can be solved for \dot{r} .

Finally the control inputs need to be expressed as a function of the flat outputs. This can be done by simply rearranging the Newton-Euler equations to solve for u_1 and \mathbf{u}_2 :

$$u_1 = m || [\ddot{\sigma}_1 \ \ddot{\sigma}_2 \ \ddot{\sigma}_3 + g] || \quad (16.21)$$

$$\mathbf{u}_2 = \mathcal{I} \begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} + \begin{bmatrix} p \\ q \\ r \end{bmatrix} \times \mathcal{I} \begin{bmatrix} p \\ q \\ r \end{bmatrix}. \quad (16.22)$$

Thus, the existence of the smooth map is shown in (16.9), (16.16), (16.17), and (16.19)–(16.22). However, as presented, the derivation is only valid provided that \mathbf{z}_B is never parallel to \mathbf{x}_C and \mathbf{y}_B is never parallel to \mathbf{z}_W .

16.3 Robot Controllers

16.3.1 Linearized Controller

For control at small angles, the position and attitude control of the quadrotor can be decoupled. This allows the use of nested feedback loops which allows the attitude control to run at a much faster rate than the position control.

The control problem is to determine the four inputs $\{u_1, \mathbf{u}_2\}$ required to follow a desired trajectory \mathbf{z}^{des} . As shown in Fig. 16.4, errors in the robot's position will drive a position controller which directly determines u_1 from (16.26). The model in (16.26) also leads to the desired orientation along the trajectory. The attitude controller for this orientation is derived from the model in (16.7).

The transformation of the forces F_1 to F_4 into $\{u_1, \mathbf{u}_2\}$ is straightforward and is described in Michael et al. (2010). The inner attitude control loop uses onboard accelerometers and gyroscopes to control the roll, pitch, and yaw and runs at approximately 1 kHz (Gurdan et al. 2007), while the outer position control loop uses estimates of position and velocity of the center of mass to control the trajectory in three dimensions at 100–200 Hz.

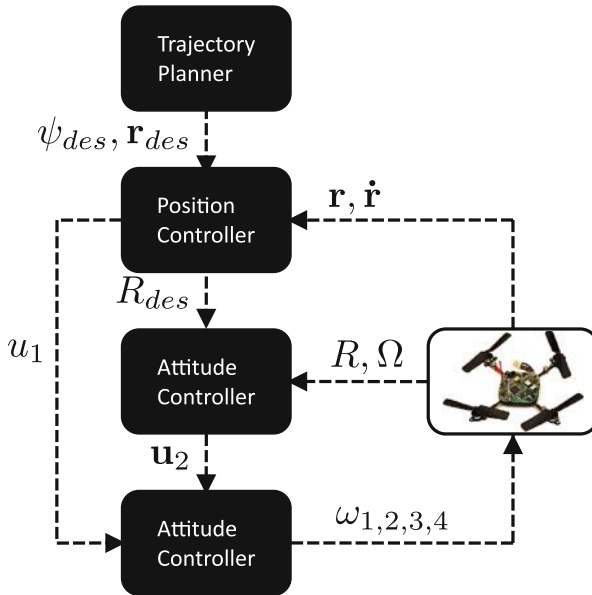

Fig. 16.4 The position and attitude control loops

16.3.1.1 Linearization

The controllers are derived by linearizing the equations of motion and motor model Eqs. (16.2)–(16.5) at an operating point that corresponds to the nominal hover state, \mathbf{x}_0 , with the inputs nominally required for hover, \mathbf{u}_0 . The hover configuration is given by $\mathbf{r} = \mathbf{r}_0$, $\theta = \phi = 0$, $\psi = \psi_0$, $\dot{\mathbf{r}} = 0$, and $\dot{\phi} = \dot{\theta} = \dot{\psi} = 0$. This approximation is valid where the roll and pitch angles are small ($c\phi \approx 1$, $c\theta \approx 1$, $s\phi \approx \phi$, and $s\theta \approx \theta$). Linearizing the equations of motion about the hover state results in an equation of the form

$$\dot{\mathbf{x}} = \frac{\partial}{\partial \mathbf{x}} f(\mathbf{x}, \mathbf{u})|_{(\mathbf{x}_0, \mathbf{u}_0)} (\mathbf{x} - \mathbf{x}_0) + \frac{\partial}{\partial \mathbf{u}} f(\mathbf{x}, \mathbf{u})|_{(\mathbf{x}_0, \mathbf{u}_0)} (\mathbf{u} - \mathbf{u}_0) = A\mathbf{x} + B\mathbf{u}.$$

At this state the lift from the propellers is given by

$$F_{i,0} = \frac{mg}{4},$$

The nominal values for the inputs at hover are $u_{1,0} = mg$, $\mathbf{u}_{2,0} = \mathbf{0}$. A and B are given by

$$A = \begin{bmatrix} 0_{3 \times 3} & I_{3 \times 3} & 0_{3 \times 6} \\ 0_{3 \times 6} & a_{3 \times 3} & 0_{3 \times 3} \\ 0_{3 \times 3} & 0_{3 \times 6} & I_{3 \times 3} \\ 0_{3 \times 3} & 0_{3 \times 6} & 0_{3 \times 3} \end{bmatrix} \quad (16.23)$$

$$a = \begin{bmatrix} g \cos \psi_0 & g \sin \psi_0 & 0 \\ g \sin \psi_0 & -g \cos \psi_0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (16.24)$$

$$B = \begin{bmatrix} 0_{4 \times 5} & & & \\ \frac{1}{m} & 0 & 0 & 0 \\ & 0_{4 \times 3} & & \\ 0 & \frac{1}{I_{xx}} & 0 & 0 \\ 0 & 0 & \frac{1}{I_{yy}} & 0 \\ 0 & 0 & 0 & \frac{1}{I_{zz}} \end{bmatrix}. \quad (16.25)$$

Specifically, the linearized equations for the acceleration are

$$\ddot{r}_1 = g(\Delta\theta \cos \psi_0 + \Delta\phi \sin \psi_0) \quad (16.26)$$

$$\ddot{r}_2 = g(\Delta\theta \sin \psi_0 - \Delta\phi \cos \psi_0)$$

$$\ddot{r}_3 = \Delta u_1 = u_1 - u_{1,0}$$

$$\Delta\theta = \theta - \theta_0$$

$$\Delta\phi = \phi - \phi_0.$$

Assuming that the rotor craft is symmetric so $I_{xx} = I_{yy}$,

$$\begin{aligned}\dot{p} &= \frac{u_{2,x}}{I_{xx}} = \frac{L}{I_{xx}}(F_2 - F_4) \\ \dot{q} &= \frac{u_{2,y}}{I_{yy}} = \frac{L}{I_{yy}}(F_3 - F_1), \\ \dot{r} &= \frac{u_{2,z}}{I_{zz}} = \frac{\gamma}{I_{zz}}(F_1 - F_2 + F_3 - F_4).\end{aligned}$$

In other words, the equations of motion for the angular accelerations are decoupled. Each component of angular acceleration depends only on the appropriate component of \mathbf{u}_2 .

16.3.1.2 Attitude Control

One attitude controller is a proportional plus derivative (PD) attitude controller which tracks a trajectory in $SO(3)$ specified in terms of a desired roll, pitch, and yaw angle. Since the development of the controller will be based on linearized equations of motion, the attitude must be close to the nominal hover state where the roll and pitch angles are small.

Near the nominal hover state the proportional plus derivative control laws take the form:

$$\mathbf{u}_2 = \begin{bmatrix} k_{p,\phi}(\phi^{\text{des}} - \phi) + k_{d,\phi}(p^{\text{des}} - p) \\ k_{p,\theta}(\theta^{\text{des}} - \theta) + k_{d,\theta}(q^{\text{des}} - q) \\ k_{p,\psi}(\psi^{\text{des}} - \psi) + k_{d,\psi}(r^{\text{des}} - r) \end{bmatrix}. \quad (16.27)$$

16.3.1.3 Position Control

In the next subsection, the dynamic model will be used to derive a position control method that uses the roll and pitch angles as inputs to drive the position of the quadrotor. The position control algorithm will determine the desired roll and pitch angles, θ^{des} and ϕ^{des} , which can be used to compute the desired speeds from (16.27). The controller tracks a specified trajectory, $\mathbf{r}_T(t)$, in three dimensions. The yaw angle, ψ , can be specified independently. It can either be constant, ψ_0 , or time varying, $\psi_T(t)$. Since the model is linearized, differential flatness is not necessary for trajectory planning here. Let \mathbf{r}_T denote the closest point on the desired trajectory to the current position \mathbf{r} , and let the desired velocity and acceleration obtained by differentiating the specified trajectory be given by $\dot{\mathbf{r}}_T$ and $\ddot{\mathbf{r}}_T$, respectively. The desired trajectory,

$$\mathbf{z}^{\text{des}} = \begin{bmatrix} \mathbf{r}_T(t) \\ \psi_T(t) \end{bmatrix},$$

will be provided by a trajectory planner as an input to specify the trajectory of the position vector and the yaw angle that the vehicle should track. These are the flat outputs which were discussed in Sect. 16.2.6. Any continuous trajectory in the flat outputs specifies the trajectory for the system and the required inputs.

Thus, appropriate trajectories can be planned in this space. In particular, for hovering, $\mathbf{r}_T(t) = \mathbf{r}_0$ and $\psi_T(t) = \psi_0$.

The command accelerations, $\ddot{\mathbf{r}}_i^{\text{des}}$, are calculated from a proportional plus derivative (PD) controller. Define the position error in terms of components using the standard reference triad \mathbf{a}_i by

$$e_p = (r_T - r).$$

Similarly, define the velocity error by

$$e_v = \dot{r}_T - \dot{r}.$$

In order to guarantee that this error goes exponentially to zero, it is required that

$$(\ddot{r}_{i,T} - \ddot{r}_i^{\text{des}}) + k_{d,i}(\dot{r}_{i,T} - \dot{r}_i) + k_{p,i}(r_{i,T} - r_i) = 0, \quad (16.28)$$

where $\dot{r}_{i,T} = \ddot{r}_{i,T} = 0$ for hover.

Equation (16.26) leads to the relationship between the desired accelerations and roll and pitch angles. Given that $\Delta\theta = \theta - \theta_0 = \theta$ and $\Delta\phi = \phi - \phi_0 = \phi$,

$$\ddot{r}_1^{\text{des}} = g(\theta^{\text{des}} \cos \psi_T + \phi^{\text{des}} \sin \psi_T) \quad (16.29a)$$

$$\ddot{r}_2^{\text{des}} = g(\theta^{\text{des}} \sin \psi_T - \phi^{\text{des}} \cos \psi_T) \quad (16.29b)$$

$$\ddot{r}_3^{\text{des}} = \frac{1}{m}u_1 - g. \quad (16.29c)$$

For hover, (16.29c) yields

$$u_1 = mg + m\ddot{r}_3^{\text{des}} = mg - m(k_{d,3}\dot{r}_3 + k_{p,3}(r_3 - r_{3,0})). \quad (16.30)$$

Equations (16.29a) and (16.29b) can be used to compute the desired roll and pitch angles for the attitude controller:

$$\phi^{\text{des}} = \frac{1}{g}(\ddot{r}_1^{\text{des}} \sin \psi_T - \ddot{r}_2^{\text{des}} \cos \psi_T) \quad (16.31a)$$

$$\theta^{\text{des}} = \frac{1}{g}(\ddot{r}_1^{\text{des}} \cos \psi_T + \ddot{r}_2^{\text{des}} \sin \psi_T). \quad (16.31b)$$

The desired roll and pitch velocities are taken to be zero.

$$p^{\text{des}} = 0 \quad (16.32a)$$

$$q^{\text{des}} = 0. \quad (16.32b)$$

Since the yaw, $\psi_T(t)$, is prescribed independently by the trajectory generator, the controller uses

$$\psi^{\text{des}} = \psi_T(t) \quad (16.33a)$$

$$\dot{\psi}^{\text{des}} = \dot{\psi}_T(t). \quad (16.33b)$$

These equations provide the setpoints for the attitude controller in (16.27).

Note that the attitude controller must run an order of magnitude faster than the position control loop in order for this to work. In practice as discussed in Michael et al. (2010), the position controller runs at 100 Hz, while the inner attitude control loop runs at 1 kHz.

An alternate error metric can be used for more aggressive trajectories which only does not consider error in the tangent direction. Let the unit tangent vector of the trajectory (unit vector along $\dot{\mathbf{r}}_T$) be $\hat{\mathbf{t}}$. The unit normal to the trajectory, $\hat{\mathbf{n}}$, is derived by differentiating the tangent vector with respect to time or arc length, and finally, the unit binormal vector is the cross product $\hat{\mathbf{b}} = \hat{\mathbf{t}} \times \hat{\mathbf{n}}$. The position and velocity errors are defined according to the following equations:

$$\mathbf{e}_p = ((\mathbf{r}_T - \mathbf{r}) \cdot \hat{\mathbf{n}})\hat{\mathbf{n}} + ((\mathbf{r}_T - \mathbf{r}) \cdot \hat{\mathbf{b}})\hat{\mathbf{b}}$$

and

$$\mathbf{e}_v = \dot{\mathbf{r}}_T - \dot{\mathbf{r}}.$$

Note that here the position error in the tangent direction is ignored, only considering position error in the plane that is normal to the curve at the closest point. Once again the commanded acceleration, $\ddot{\mathbf{r}}_i^{\text{des}}$, is calculated from the PD feedback as shown in (16.28). In vector notation, this is

$$(\ddot{\mathbf{r}}_T - \ddot{\mathbf{r}}^{\text{des}}) + \mathbf{k}_d \mathbf{e}_v + \mathbf{k}_p \mathbf{e}_p = 0. \quad (16.34)$$

Finally, (16.31)–(16.33) is used to compute the desired roll and pitch angles. Again the reader is referred to Michael et al. (2010) for more details including experimental results obtained from these controllers.

16.3.1.4 Linear Quadratic Regulators

The gains used in a controller have a critical effect on its performance and stability. Since the model is linearized, the controller can be framed as a linear quadratic regulator. This allows the problem of choosing gains to be formatted as an optimization problem. A quadratic functional can be used for the cost:

$$J = \int_0^\infty (\mathbf{x} - \mathbf{x}_0)^T \mathbf{Q} (\mathbf{x} - \mathbf{x}_0) + (\mathbf{u} - \mathbf{u}_0)^T \mathbf{R} (\mathbf{u} - \mathbf{u}_0) dt \quad (16.35)$$

which is subject to the dynamic constraints that $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$. \mathbf{Q} and \mathbf{R} are chosen to weight the position errors and control efforts depending on the task at hand.

The analytic solution can be found using calculus of variations, which leads to a controller of the form

$$(\mathbf{u} - \mathbf{u}_0) = -\mathbf{K}(\mathbf{x} - \mathbf{x}_0). \quad (16.36)$$

K can be solved for using the Riccati equation, which can be found in many texts on optimal control, such as Kirk (2004).

16.3.2 Nonlinear Control

In order to control the quadrotor along trajectories that require large rotations, a different control law is needed. A nonlinear controller can track trajectories in the differentially flat output space defined by $\sigma(t) = [\mathbf{r}_{\text{des}}(t)^T, \psi_{\text{des}}(t)^T]^T$. The error metrics on position and velocity are defined as

$$\mathbf{e}_p = \mathbf{r} - \mathbf{r}_{\text{des}}, \mathbf{e}_v = \dot{\mathbf{r}} - \dot{\mathbf{r}}_{\text{des}}. \quad (16.37)$$

The vector describing the total force to apply to the quadrotor is computed using

$$\mathbf{F}_{\text{des}} = -K_p \mathbf{e}_p - K_v \mathbf{e}_v - m\mathbf{g}\mathbf{a}_3 + m\ddot{\mathbf{r}}_{\text{des}}. \quad (16.38)$$

With K_p and K_v being positive definite matrices of gains. The first input is chosen to be the desired force vector projected onto the body frame z axis of the quadrotor as such:

$$u_1 = -\mathbf{F}_{\text{des}} \cdot \mathbf{b}_3. \quad (16.39)$$

For the attitude control, the z axis of the quadrotor body frame should align with the desired force vector, as the quadrotor can only produce force along this axis. Using this fact and the specified differentially flat outputs, the desired rotation matrix R_{des} can be defined. Next, the error metric for rotation is defined as

$$\mathbf{e}_R = \frac{1}{2}(R_{\text{des}}^T R - R^T R_{\text{des}})^\vee \quad (16.40)$$

where \vee represents the “unhat” operator which transforms a skew-symmetric matrix into a vector. The vector is arranged such that $Ab = A^\vee \times b$ for any skew-symmetric matrix A and vector b . The derivative error metric for attitude control will be

$$\mathbf{e}_\omega = {}^A\omega^B - {}^A\omega_{\text{des}}^B. \quad (16.41)$$

${}^A\omega_{\text{des}}^B$ can be found from the differential flatness derivation. So the attitude controller will simply be a PD controller using these two error metrics with some gains:

$$\mathbf{u}_2 = \mathcal{I}(-K_R \mathbf{e}_R - K_\omega \mathbf{e}_\omega) + {}^A\omega^B \times \mathcal{I}({}^A\omega^B) - \mathcal{I}(\hat{\omega} R^T R_{\text{des}} \omega_{\text{des}} - R^T R_{\text{des}} \dot{\omega}_{\text{des}}). \quad (16.42)$$

An advantage to using this controller design is that under a few assumptions, statements can be made about the stability of the controller. According to Lee et al. (2010), if actuator saturation is ignored and K_R and K_ω are chosen to be positive, the attitude error dynamics are exponentially stable provided the initial configuration of the quadrotor satisfies the following:

$$\text{tr}(I - R_{\text{des}}^T(0)R(0)) < 2 \quad (16.43)$$

$$\|e_\omega(0)\|^2 < \frac{2}{\lambda_{\max}(\mathcal{I})} k_R (2 - \frac{1}{2} \text{tr}(I - R_{\text{des}}^T(0)R(0))). \quad (16.44)$$

If the initial conditions of the vehicle are in a smaller sublevel set satisfying

$$\text{tr}(I - R_{\text{des}}^T(0)R(0)) < 1 \quad (16.45)$$

then the complete dynamics are exponentially stable. Both of these propositions are proved in Lee et al. (2010). This controller has the advantage that it functions directly on $SE(3)$, and avoids the singularities and complications associated with Euler angles or quaternion representations.

Another property of note is that the basin of attraction of the attitude control subsystem of this controller increases as the vehicle scale decreases, which can be seen from the condition on the angular rate, since the maximum angular velocity error permissible is proportional to the inverse of the maximum eigenvalue of the inertia. Thus, smaller inertia tensors lead to stabilization starting with higher angular velocities. This is further explained in Kumar and Michael (2011).

In practice, it is possible to neglect the nonlinear terms (${}^A\omega^B \times \mathcal{I}^A\omega^B$ and $\mathcal{I}(\hat{\omega} R^T R_{\text{des}} \omega_{\text{des}} - R^T R_{\text{des}} \dot{\omega}_{\text{des}})$) and still achieve good results (Mellinger and Kumar 2011). This neglect can be justified by inspecting the individual terms of the attitude controller. The first two terms, $-\mathcal{I}K_R \mathbf{e}_R$ and $-\mathcal{I}K_\omega \mathbf{e}_\omega$, are on the order of $I_{zz}\omega_z$ for both the Nano Quadrotor and the Hummingbird. The nonlinear terms are both on the order of $I_{zz}\omega_z^2$. Since ω_z is usually much smaller than 1, this means that the nonlinear terms are much smaller than the linear terms.

16.4 Experimental Results

This section presents experimental results for the linearized control of the Nano Quadrotor platform. The reader is referred to Mellinger and Kumar (2011) for results for the Hummingbird platform. A diagram of the system architecture used with the Nano Quadrotor is presented in Fig. 16.5. The system consists of the Vicon motion capture system (Vicon MX Systems 2012) for perception, which tracks the position and orientation of the quadrotor using an array of cameras and reflective markers. The Vicon system sends data to a desktop computer where the high-level decisions and position control are performed. The desktop communicates via wireless module to the Nano Quadrotor, which perform attitude control onboard.

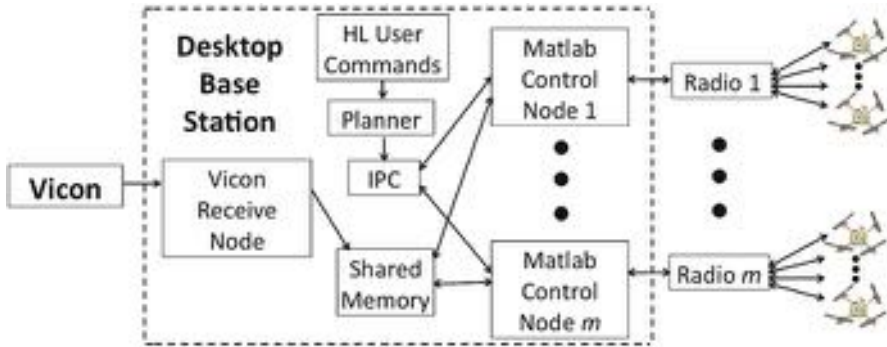

Fig. 16.5 System architecture for Nano Quadrotor. There are three software modules: (a) the Vicon interface; (b) the user commands or trajectory planner; and (c) the control software for each vehicle

The diagram shows how several control nodes may be used to control a swarm of Nano Quadrotors. A similar architecture is used for the Hummingbirds. Each component of the system is described below.

16.4.1 Vicon Motion Capture System

The Vicon motion capture system provides a state estimate for the quadrotor, which is nearly ground truth. The Vicon system offers three important features. First, *it is fast*: the system can be run at or below 375 Hz. Second, *it is precise*: experimental tests show that the deviations of position estimates for single static markers are on the order of $50\text{ }\mu\text{m}$ which is well beyond the requirements for flight. Lastly, *it is robust*: the Vicon *Tracker* software assumes that markers in models are rigidly attached which enables the system to maintain tracking even if all but one camera are occluded. Using this software, tracking of quadrotors is rarely lost, even during extreme situations such as fast maneuvers (speeds of $3.5\text{ }\frac{\text{m}}{\text{s}}$, accelerations of $15\text{ }\frac{\text{m}}{\text{s}^2}$, and angular speeds of $1,000\text{ }\frac{\circ}{\text{s}}$).

16.4.2 Software and Integration

The control software for the quadrotors is integrated with the motion capture using a custom interprocess communication (IPC) framework as shown in Fig. 16.5. The high-level control such as trajectory generation and position control as in Sect. 16.3.1.3 is done using MATLAB (2011), which then sends commands to the robot via XBee radios using the ZigBee communication protocol at 100 Hz. Low-level processing such as attitude and motor control (16.27) is performed onboard.

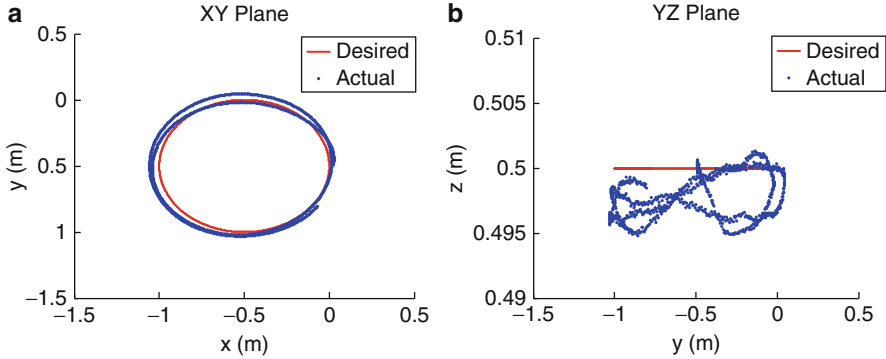

Fig. 16.6 The desired circular trajectory and the actual trajectory, run at $1.2 \frac{\text{rad}}{\text{s}}$, projected along the x - y horizontal plane and a vertical y - z plane. Note the small scale on the z axis

16.4.3 Results

As discussed above in Sects. 16.2.6 and 16.3, trajectories for the quadrotor can be defined by $r(t)$ and $\psi(t)$. This subsection presents results for the linearized controller running on the Nano platform for two different trajectories.

First, Figs. 16.6 and 16.7 show the trajectory and the errors for a Nano Quadrotor commanded to fly in a circular trajectory of radius 0.5 m. The maximum accelerations encountered are on the order of $0.008 \frac{\text{m}}{\text{s}^2}$. The errors are on the order of 10 cm in the horizontal plane and less than 1 cm in the vertical plane. While the errors in the horizontal plane are significantly higher than the errors in the vertical direction, the errors never exceed 22 cm.

Similarly, Figs. 16.8 and 16.9 present the trajectory and errors for a Nano Quadrotor flying in a helical trajectory of radius 0.35 m and pitch $0.05 \frac{\text{m}}{\text{rad}}$. The errors are on the order of 10 cm in the horizontal plane and less than 1 cm in the vertical plane. Although there is a vertical motion in this experiment, the horizontal errors remain significantly larger than the vertical errors. The errors in this experiment never exceed 26 cm.

These are two representative experiments. The maximum roll angles for the circle and helix trajectories were 0.11 and 0.27 rad, respectively. Similarly, the maximum pitch angles for the circle and helix trajectories were 0.19 and 0.51 rad. As the requested speed of the quadrotor around the circle increases, so does the required excursion from hover. For a circle trajectory run at $2 \frac{\text{rad}}{\text{s}}$, the maximum roll and pitch angles were 0.82 and 0.41 rad, much larger than the circle run at $1.2 \frac{\text{rad}}{\text{s}}$. In general, as the commanded trajectory becomes more aggressive in terms of changes in speed and centripetal acceleration, the roll and pitch angles required increase, and the errors in trajectory following increase. In this work the experiments were conducted far away from walls and ceilings. As shown in Powers et al. (2012), ground and ceiling effects can cause significant disturbances which are not easily characterized using the models in this chapter.

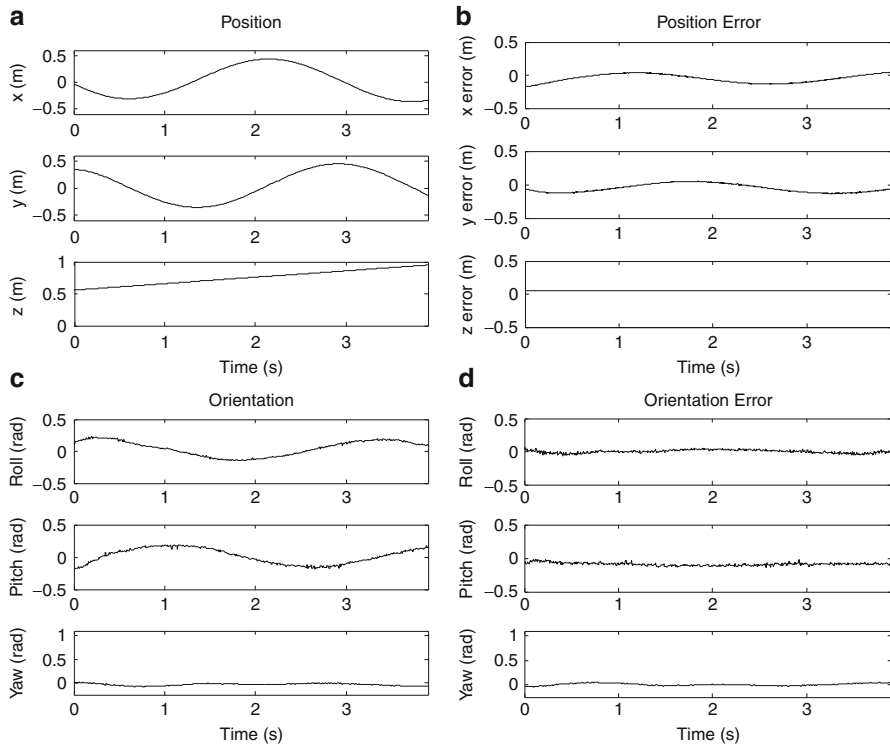

Fig. 16.9 The position and orientation history and the errors in trajectory control for the experiment with the helical trajectory

16.5 Conclusion

This chapter presents a model of the rigid body dynamics for a quadrotor. The quadrotor is underactuated with a 12-dimensional state space and four actuators. The system is shown to be differentially flat. Two controllers are discussed. The first is a linear controller based on a linearized model of the dynamics. The second is a nonlinear controller that is effective for operation in conditions where the roll and pitch angles are larger. Finally, experimental results with quadrotors are shown to illustrate the basic approach to modeling and control.

Abstract

The methods presented in this chapter are for use with hover-capable flapping wing vehicles in the conceptual design phase. The class of flapping wing vehicles considered are those that maneuver by making changes to the motion of flapping wings, rather than making use of conventional aerodynamic surfaces.

Methods are presented that allow one to iterate between vehicle design, trim, and controllability analysis until closure is achieved. The motion of the flapping wings is characterized by seven wing motion parameters: wing stroke amplitude, symmetric and asymmetric frequency, bias, upstroke and downstroke angle-of-attack limits, and wing stroke plane inclination. This chapter presents a table of cycle-averaged control derivatives that can be used with the multivariable chain rule to produce control derivative estimates for a diverse set of wing beat generation and control mechanisms that might be encountered in flapping wing vehicle designs. A method is presented that will enable the designer to estimate how the seven wing motion parameters change in response to changes in the control mechanism position; a step that is necessary to make use of the chain rule. A method for estimating the combined effect of fuselage motion and flapping wing motion is presented as well. Control design considerations and simulation methods are also discussed.

17.1 Introduction

The flight dynamics and control of flapping wing micro air vehicles (MAVs) are significantly more complex than those of fixed wing and even rotary-winged aircraft. The class of MAVs considered in this chapter make use of variations in the motion of flapping wings to affect changes to the aircraft trajectory. This class of aircraft does not make use of conventional steady aerodynamic surfaces such as elevators, rudders, and ailerons for control. Part of the complexity associated with such aircraft arises because the forces and moments produced by flapping wings are periodic in nature. Additionally, for flight control and simulation purposes, these forces are transformed into a body-fixed reference frame that results in the signs of these forces becoming functions of the wing position and attitude relative to the vehicle center-of-mass. It is well recognized that unsteady aerodynamic effects (Sane and Dickinson 2001), fluid-structure interactions (Stanford and Beran 2010), and wing-load interactions with drive mechanisms (Doman et al. 2011) play a role in the instantaneous behavior of the forces and moments. Nevertheless, a number of researchers have reported (Anderson 2011; Ol and Granlund 2012; Doman et al. 2010a; Deng et al. 2006a, b) that adequate controllers for such vehicles can be designed by making use of cycle-averaged models of the aerodynamic forces and moments. The success of this idea is due in large part to the differences between the frequency of the wingbeats and the time constants associated with the motion of the fuselage. These models map changes in the generalized aerodynamic forces to wing kinematic properties that vary slowly when compared to the frequency of the flapping wings. When the control problem is viewed from the cycle-averaged perspective, conventional control approaches have been shown to provide adequate tracking performance when applied to simulations of vehicles that model periodic and unsteady aerodynamic forces and moments.

This book chapter provides a synopsis of analytical results that facilitate vehicle simulation, design for trim, and the computation of cycle-averaged aerodynamic

stability and control derivatives for flapping winged aircraft about a quasi-equilibrium hover condition. Vehicle design parameters appear in the analytical expressions and provide the designer with a tool that connects vehicle design to controllability. The results presented in this chapter were derived using blade element theory and the assumption that the wing stroke position can be characterized as piecewise cosinusoidal. Seven variations in wing motion are considered, namely, symmetric and asymmetric wingbeat frequency, wing stroke amplitude and bias, upstroke and downstroke angle-of-attack limits, and wing stroke plane inclination. Control mechanisms on flapping wing aircraft influence one or more of these seven parameters and the control derivatives associated with a specific mechanism. One can compute the changes in the wingbeat kinematic parameters with respect to changes in the position of the control mechanism available on a specific aircraft design. Using the multivariable chain rule, this result can then be combined with cycle-averaged aerodynamic control derivatives to provide estimates of the cycle-averaged control derivatives for a wide range of flapping wing vehicle control mechanisms. It is important to remember that these estimates will not include the effects of unsteady aerodynamics, fluid-structure interactions, wing inertial effects, or wing-load interactions with the drive mechanism. However, these estimates do provide a point of departure for a control synthesis problem for a very complex system that may provide adequate performance when applied to the vehicle itself or high-fidelity simulation models and can, if necessary, be subsequently tuned to account for more complex phenomena.

17.2 Idealized Wing Motion

Seven parameters are considered that, when taken together, can approximate a wide range of wing movements. Figure 17.1 illustrates a generic hover-capable MAV or animal that has the ability to change these seven parameters. The illustrations show the body-axes coordinate system (x_B, y_B, z_B) , the wing root coordinate system, (x_r, y_r, z_r) , and the geometry of the wing. The center-of-gravity of the vehicle is offset from the wing root hinge point in the x_B, z_B plane by $\Delta x, \Delta z$, while the distance between the wing root hinge points is defined as w . The wing root y-axis, y_r , is fixed, while the wing planform axis, y_{wp} moves with the wing. The y_B axis points in the direction of the right wing when it passes through its neutral position. The center-of-pressure of the wing is defined by the location x_{cp}, y_{cp} , written in a wing-carried planform frame (x_{wp}, y_{wp}) .

The mathematical model that is used to describe the motion of the wing root or spar is given by

$$\phi_U(t) = A \cos [(\omega - \delta)t] + \eta, \quad 0 \leq t < \frac{\pi}{(\omega - \delta)} \quad (17.1)$$

$$\phi_D(t) = A \cos [(\omega + \sigma)t + \xi] + \eta, \quad \frac{\pi}{(\omega - \delta)} \leq t < \frac{2\pi}{\omega} \quad (17.2)$$

where $\phi_U(t)$ and $\phi_D(t)$ denote the angular position associated with a wing on the upstroke and downstroke, respectively, A denotes the stroke amplitude, η defines the wing bias or the wing oscillation offset from the zero position, ω denotes the symmetric frequency, δ is the asymmetric frequency that allows the upstroke and downstroke velocity profiles to differ,

$$\sigma \triangleq \frac{\delta\omega}{\omega - 2\delta} \quad (17.3)$$

and the phase shift, which enforces a matching condition at stroke reversal, is given by

$$\xi \triangleq \frac{-2\pi\delta}{\omega - 2\delta} \quad (17.4)$$

The bottom four diagrams in Fig. 17.1 show the effects of control variables on the wingbeat motion. Shown in the first subplot in the second row of Fig. 17.1 are the effects of a positive asymmetric frequency, δ , and a positive bias, η . When $\delta > 0$, the term $(\omega - \delta)$ in Eq. 17.1 is decreased, resulting in a smaller frequency, as shown by more lines in the strobed animation. In turn, for $\delta > 0$, the term $(\omega + \sigma)$ is increased, resulting in a larger frequency and fewer lines in the strobed animation. The bias simply shifts all points in the wingbeat profile fore or aft of the nominal neutral position of the wing spar, as can be seen with the right wing in the first subplot of the second row of Fig. 17.1. The remaining subplots show the effects of upstroke and downstroke angle-of-attack and stroke plane variation.

The subsequent information presented allows for the independent actuation of wings. In other words, the right and left wings are taken to be driven by independent motion sources; however, the results are also applicable to designs where the left and right wings are coupled. Figure 17.2 graphically illustrates the effects of differences in asymmetric frequency, bias, and amplitude. The top two plots show the effect of asymmetric frequency for both positive and negative values of δ . The bottom figures shows the wing bias, η , and the amplitude adjustment, A .

The wingbeat cycle is split into two parts, the first part is the upstroke, while the second part is the downstroke. Considering Fig. 17.2, the upstroke is defined as moving from a wing position of 1 rad to a wing position of -1 rad, while the downstroke moves from a wing position of -1 rad to a wing position of 1 rad. A positive asymmetric frequency, δ , impedes or slows down the upstroke while the downstroke advances or speeds up, as shown in the upper left plot in Fig. 17.2. A negative asymmetric frequency has the opposite effect in that the upstroke is advanced, while the downstroke is impeded. The wing bias shifts the midstroke wingbeat angular position fore or aft by the bias amount, while the amplitude adjusts the limits of wing stroke.

Both the bias and amplitude variation, as presented in Fig. 17.2, yield discontinuous wingbeat positions. The physical mechanism used to produce the wingbeat motion would not allow such discontinuities and would smooth the discontinuous functions but would result in an actual wingbeat motion that is different from that which was commanded. To avoid this issue, techniques exist that modify the

Fig. 17.1 Strobed illustration of effect of variations in wing kinematics and definition of parameters

wingbeat forcing functions to yield continuous functions (Doman et al. 2010b; Oppenheimer et al. 2011a) even when the bias and/or amplitude change from one wingbeat cycle to another.

The aerodynamic model employed to generate the results in this work is applicable to vehicle designs that employ passive angle-of-attack regulation in the form of limiters (Wood 2008; Doman and Regisford 2010). The subsequent results assume that the wing angle-of-attack changes instantaneously at the end of an upstroke or downstroke and remains on a limit, α_u or α_d , over the course of an upstroke or downstroke, respectively. Finally, the model allows for the variation in stroke plane inclination, ζ , which allows the resultant aerodynamic force vector to be inclined with respect to the MAV fuselage.

Fig. 17.2 Examples of split cycle, bias, and amplitude wingbeat variations

17.3 Instantaneous Aerodynamic Forces and Moments

The seven parameters used to describe the motion of the wings can be used to approximate a wide range of wing motions; however, in practice, the actual motion is produced by drive elements and mechanisms and will therefore vary from the idealized model of wingbeat motion presented in Fig. 17.2. Nonlinear linkage-based mechanisms, load interactions with drive elements, and wing flexibility are just a few phenomena that can cause such departures from the idealized model of wing motion. The equations below provide a blade element-based estimate of the instantaneous forces and moments that act on a flapping wing vehicle. The equations are useful for simulations that are used to test the performance and robustness of model-based control laws designed using cycle-averaged models of such aircraft. They are also useful for conceptual design studies and computing quasi-equilibrium trim conditions for such vehicles. Note that the angular displacement of the wing in the stroke plane, $\phi(t)$; the wing angle-of-attack, $\alpha(t)$; and the stroke plane

Table 17.1 Aerodynamic forces expressed in body frame

| Phase | Body frame force vector |
|---------------|--|
| RW upstroke | $\mathbf{F}_{\text{RWU}}^B(t) = \begin{bmatrix} L(t) \cos \zeta(t) + D(t) \cos \phi(t) \sin \zeta(t) \\ -D(t) \sin \phi(t) \\ -L(t) \sin \zeta(t) + D(t) \cos \phi(t) \cos \zeta(t) \end{bmatrix}$ |
| RW downstroke | $\mathbf{F}_{\text{RWD}}^B(t) = \begin{bmatrix} L(t) \cos \zeta(t) - D(t) \cos \phi(t) \sin \zeta(t) \\ D(t) \sin \phi(t) \\ -L(t) \sin \zeta(t) - D(t) \cos \phi(t) \cos \zeta(t) \end{bmatrix}$ |
| LW upstroke | $\mathbf{F}_{\text{LWU}}^B(t) = \begin{bmatrix} L(t) \cos \zeta(t) + D(t) \cos \phi(t) \sin \zeta(t) \\ D(t) \sin \phi(t) \\ -L(t) \sin \zeta(t) + D(t) \cos \phi(t) \cos \zeta(t) \end{bmatrix}$ |
| LW downstroke | $\mathbf{F}_{\text{LWD}}^B(t) = \begin{bmatrix} L(t) \cos \zeta(t) - D(t) \cos \phi(t) \sin \zeta(t) \\ -D(t) \sin \phi(t) \\ -L(t) \sin \zeta(t) - D(t) \cos \phi(t) \cos \zeta(t) \end{bmatrix}$ |

inclination, $\zeta(t)$, are written as general functions of time in the instantaneous model, in order to apply to a wide class of vehicles. Table 17.1 provides expressions for the instantaneous aerodynamic force vectors.

F_{RWU}^B and F_{RWD}^B denote forces associated with the right wing on the upstroke and downstroke written in the body-axes coordinate frame, respectively. F_{LWU}^B and F_{LWD}^B denote the same for the left wing. The lift, $L(t)$, and drag, $D(t)$, are expressed in wing-carried frames and are given by

$$L(t) = k_L \dot{\phi}(t)^2 \quad (17.5)$$

$$D(t) = k_D \dot{\phi}(t)^2 \quad (17.6)$$

where,

$$k_L = \frac{\rho}{2} I_A C_L(\alpha) \quad (17.7)$$

$$k_D = \frac{\rho}{2} I_A C_D(\alpha) \quad (17.8)$$

and I_A is the wing planform area moment of inertia about the spar root hinge point that defines the stroke plane. The lift and drag coefficients are given by the empirical formulae (Sane and Dickinson 2001)

$$C_L(\alpha) = 0.225 + 1.58 \sin(2.13\alpha - 7.2) \quad (17.9)$$

$$C_D(\alpha) = 1.92 - 1.55 \cos(2.04\alpha - 9.82) \quad (17.10)$$

where α is expressed in degrees. The center-of-pressure of each planform must be obtained in order to compute moments on the fuselage. The center-of-pressure location for each wing can be computed as

$$x_{cp} = \frac{\int_0^R y_{wp}^2 \frac{1}{2} c(y_{wp})^2 dy_{wp}}{\int_0^R y_{wp}^2 c(y_{wp}) dy_{wp}} \quad (17.11)$$

$$y_{cp} = \frac{\int_0^R y_{wp}^3 c(y_{wp}) dy_{wp}}{\int_0^R y_{wp}^2 c(y_{wp}) dy_{wp}} \quad (17.12)$$

where the subscript wp indicates a coordinate axis within a planform frame and $c(y_{wp})$ is the wing chord as a function of span. Let $\Delta \mathbf{r}_R^B$ and $\Delta \mathbf{r}_L^B$ denote the position vector from the vehicle center-of-gravity to the right and left wing root hinge points, i.e.,

$$\Delta \mathbf{r}_R^B \triangleq [\Delta x \ w/2 \ \Delta z]^T \quad (17.13)$$

$$\Delta \mathbf{r}_L^B \triangleq [\Delta x \ -w/2 \ \Delta z]^T \quad (17.14)$$

where $\Delta x, w, \Delta z$ are defined in Fig. 17.1. It is assumed that the vehicle center-of-gravity is fixed due to the wing mass being much lower than the mass of the fuselage and drive mechanisms. The centers of pressure associated with each wing and stroke, expressed in the body frame, are summarized in Table 17.2.

The expressions for the aerodynamic moments associated with each wing and stroke are given by

$$\begin{aligned} \mathbf{M}_{RWU}^B &= \mathbf{r}_{cpRWU}^B \times \mathbf{F}_{RWU}^B \\ \mathbf{M}_{RWD}^B &= \mathbf{r}_{cpRWD}^B \times \mathbf{F}_{RWD}^B \\ \mathbf{M}_{LWU}^B &= \mathbf{r}_{cpLWU}^B \times \mathbf{F}_{LWU}^B \\ \mathbf{M}_{LWD}^B &= \mathbf{r}_{cpLWD}^B \times \mathbf{F}_{LWD}^B \end{aligned} \quad (17.15)$$

Table 17.2 Centers of pressure for each wing expressed in the body frame

| CP location | Body frame expression |
|---------------|--|
| RW upstroke | $\mathbf{r}_{cpRWU}^B(t) = \begin{bmatrix} x_{cp} \sin \alpha(t) \cos \zeta(t) + \sin \zeta(t)(-x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta x \\ x_{cp} \sin \phi(t) \cos \alpha(t) + y_{cp} \cos \phi(t) + \frac{w}{2} \\ -x_{cp} \sin \alpha(t) \sin \zeta(t) + \cos \zeta(t)(-x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta z \end{bmatrix}$ |
| RW downstroke | $\mathbf{r}_{cpRWD}^B(t) = \begin{bmatrix} x_{cp} \sin \alpha(t) \cos \zeta(t) + \sin \zeta(t)(x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta x \\ -x_{cp} \sin \phi(t) \cos \alpha(t) + y_{cp} \cos \phi(t) + \frac{w}{2} \\ -x_{cp} \sin \alpha(t) \sin \zeta(t) + \cos \zeta(t)(x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta z \end{bmatrix}$ |
| LW upstroke | $\mathbf{r}_{cpLWU}^B(t) = \begin{bmatrix} x_{cp} \sin \alpha(t) \cos \zeta(t) + \sin \zeta(t)(-x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta x \\ -x_{cp} \sin \phi(t) \cos \alpha(t) - y_{cp} \cos \phi(t) - \frac{w}{2} \\ -x_{cp} \sin \alpha(t) \sin \zeta(t) + \cos \zeta(t)(-x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta z \end{bmatrix}$ |
| LW downstroke | $\mathbf{r}_{cpLWD}^B(t) = \begin{bmatrix} x_{cp} \sin \alpha(t) \cos \zeta(t) + \sin \zeta(t)(x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta x \\ x_{cp} \sin \phi(t) \cos \alpha(t) - y_{cp} \cos \phi(t) - \frac{w}{2} \\ -x_{cp} \sin \alpha(t) \sin \zeta(t) + \cos \zeta(t)(x_{cp} \cos \phi(t) \cos \alpha(t) + y_{cp} \sin \phi(t)) + \Delta z \end{bmatrix}$ |

17.4 Quasi-equilibrium Hover and Vehicle Design

For insight into how to design a tailless flapping wing aircraft that can be trimmed, it is useful to consider the expression for a cycle-averaged generalized force:

$$\bar{G} = \frac{\omega}{2\pi} \int_0^{\frac{2\pi}{\omega}} G(\phi(t)) dt \quad (17.16)$$

The necessary conditions for a flapping wing aircraft to achieve a quasi-equilibrium hover condition are that the cycle-averaged x-body force must be equal to the weight, W , of the aircraft and the cycle-averaged y- and z-body forces and body moment vector must be equal to zero, namely,

$$\bar{X}^B \triangleq \bar{X}_{LW}^B + \bar{X}_{RW}^B = W \quad (17.17)$$

$$\bar{Y}^B \triangleq \bar{Y}_{LW}^B + \bar{Y}_{RW}^B = 0 \quad (17.18)$$

$$\bar{Z}^B \triangleq \bar{Z}_{LW}^B + \bar{Z}_{RW}^B = 0 \quad (17.19)$$

$$\bar{M}_x^B \triangleq \bar{M}_{xLW}^B + \bar{M}_{xRW}^B = 0 \quad (17.20)$$

$$\bar{M}_y^B \triangleq \bar{M}_{yLW}^B + \bar{M}_{yRW}^B = 0 \quad (17.21)$$

$$\bar{M}_z^B \triangleq \bar{M}_{zLW}^B + \bar{M}_{zRW}^B = 0 \quad (17.22)$$

These conditions are necessary for a flapping wing aircraft to orbit a fixed point in space. These conditions are not sufficient for conventional steady equilibrium because of the periodic forces and moments produced by flapping wings. The periodicity of the forces causes limit-cycle oscillations to occur about a point, thus the use of the term quasi-equilibrium hover or trim condition. Furthermore, certain initial conditions must be met in order to avoid drifting away from the quasi-equilibrium point (Oppenheimer et al. 2010a). By making use of the instantaneous equations for the forces and moments from the previous section and computing cycle-averages from Eq. 17.16, one can solve for values of the seven wing motion parameters and center-of-gravity locations that satisfy the necessary conditions. In general, this calculation will have to be performed numerically. A typical method (Doman and Regisford 2010) for solving the trim problem follows:

1. Determine the stroke plane inclination, ζ , or upstroke and downstroke angle-of-attack combination, α_U , α_D , that causes $\bar{Z}^B = 0$ for a given drive mechanism that produces wing spar motion $\phi(t)$.
2. Adjust the symmetric frequency ω and/or amplitude A such that $\bar{X}^B = W$.
3. Determine the center-of-gravity location, Δx and Δz , and/or wing bias, η , such that $\bar{M}_y^B = 0$.
4. If the left and right wings are synchronized, then $\bar{Y}^B = \bar{M}_x^B = \bar{M}_z^B = 0$.

17.5 Flapping Wing Aerodynamic Control Derivatives

Cycle-averaged control derivatives can be physically interpreted as the sensitivities of the cycle-averaged aerodynamic forces and moments to changes in the parameters that characterize the flapping motion of the wings. The method by which such control derivatives can be obtained is outlined below. Let $G(t)$ denote a generalized periodic aerodynamic force of period $2\pi/\omega$ that is produced by a flapping wing. The generalized forces are written in body-axis coordinates where the origin of the coordinate frame is fixed to the fuselage center-of-gravity. A cycle-averaged generalized aerodynamic force is given by

$$\bar{G} = \frac{\omega}{2\pi} \left[\int_0^{\frac{\pi}{\omega-\delta}} G(t)dt + \int_{\frac{\pi}{\omega-\delta}}^{\frac{2\pi}{\omega}} G(t)dt \right] \quad (17.23)$$

The cycle-averaged control derivatives for a given generalized force are given by

$$\left[\partial \bar{G} / \partial \omega \quad \partial \bar{G} / \partial \delta \quad \partial \bar{G} / \partial A \quad \partial \bar{G} / \partial \eta \quad \partial \bar{G} / \partial \zeta \quad \partial \bar{G} / \partial \alpha_u \quad \partial \bar{G} / \partial \alpha_d \right] \Big|_{\text{hover}} \quad (17.24)$$

Table 17.3 was created using the procedure described above, and it presents all nonzero control derivatives associated with the seven wingbeat kinematic parameters for the specific case where $\zeta = \delta = \eta = 0$ at hover. More general expressions for the control derivatives may be found in Oppenheimer et al. (2010b, 2011b). In Table 17.3, $J_1(A)$ is a Bessel function of the first kind. Similarly $J_0(A)$ and $J_2(A)$ are Bessel functions of the zeroth and second kind. Finally the derivatives of k_L and k_D with respect to angle of attack are denoted by $d_L = \partial k_L / \partial \alpha$ and $d_D = \partial k_D / \partial \alpha$, respectively.

17.6 Influence of Control Mechanisms on Wing Motion and Cycle-Averaged Generalized Forces

Wing drive mechanisms for flapping wing aircraft must produce periodic wingbeat motion. Control mechanisms will cause variations in one or more of the seven parameters described above. A general procedure for estimating the influence of changes in the position of control mechanisms on flapping wing motion is to first compute the wing spar position, $\phi(t)$, over one complete wingbeat cycle at the quasi-equilibrium hover condition and then adjust the parameters of Eqs. 17.1 and 17.2 to fit the actual wing motion profile. By adjusting the state of the control mechanism, such that one or more of the seven parameters is altered, and recomputing the fit parameters, an approximation for the partial derivatives of the seven parameters with respect to changes in the control mechanism can be estimated. A simple fitting procedure for the periodic wing root position follows:

1. Determine the period, T , of the wingbeat and compute the symmetric frequency:

Table 17.3 Nonzero cycle-averaged control derivatives evaluated at quasi-equilibrium hover

| Sensitivity | Left wing | Right wing |
|---|--|--|
| $\partial \overline{F_x^B} / \partial \omega$ | $A^2 \omega k_L$ | $A^2 \omega k_L$ |
| $\partial \overline{F_x^B} / \partial A$ | $A \omega^2 k_L$ | $A \omega^2 k_L$ |
| $\partial \overline{F_x^B} / \partial \alpha_u$ | $1/4 A^2 \omega^2 d_L$ | $1/4 A^2 \omega^2 d_L$ |
| $\partial \overline{F_x^B} / \partial \alpha_d$ | $1/4 A^2 \omega^2 d_L$ | $1/4 A^2 \omega^2 d_L$ |
| $\partial \overline{F_z^B} / \partial \delta$ | $-A \omega k_D J_1(A)$ | $-A \omega k_D J_1(A)$ |

| $\partial \overline{M_x^B} / \partial \alpha_d$ | $-1/4 A \omega^2 d_D (A y_{cp} + J_1(A) w)$ | $1/4 A \omega^2 d_D (A y_{cp} + J_1(A) w)$ |
| $\partial \overline{M_x^B} / \partial \zeta$ | $A \omega^2 k_L (J_1(A) y_{cp} + A w/4)$ | $-A \omega^2 k_L (J_1(A) y_{cp} + A w/4)$ |
| $\partial \overline{M_y^B} / \partial \delta$ | $A \omega J_1(A) (k_D (\Delta x_R^B - x_{cp} \sin(\alpha)) - k_L x_{cp} \cos(\alpha))$ | $A \omega J_1(A) (k_D (\Delta x_R^B - x_{cp} \sin(\alpha)) - k_L x_{cp} \cos(\alpha))$ |
| $\partial \overline{M_y^B} / \partial \eta$ | $A \omega^2 J_1(A) y_{cp} k_L$ | $A \omega^2 J_1(A) y_{cp} k_L$ |
| $\partial \overline{M_y^B} / \partial \alpha_u$ | $-A \omega^2 J_1(A) (\Delta x_R^B d_D + x_{cp} ((d_L + k_D) \cos(\alpha) + (d_D - k_L) \sin(\alpha)))$ | $-A \omega^2 J_1(A) (\Delta x_R^B d_D + x_{cp} ((d_L + k_D) \cos(\alpha) + (d_D - k_L) \sin(\alpha)))$ |
| $\partial \overline{M_y^B} / \partial \alpha_d$ | $A \omega^2 J_1(A) (\Delta x_R^B d_D + x_{cp} ((d_L + k_D) \cos(\alpha) + (d_D - k_L) \sin(\alpha)))$ | $A \omega^2 J_1(A) (\Delta x_R^B d_D + x_{cp} ((d_L + k_D) \cos(\alpha) + (d_D - k_L) \sin(\alpha)))$ |
| $\partial \overline{M_y^B} / \partial \zeta$ | $1/2 A^2 \omega^2 \Delta x_R^B k_L$ | $1/2 A^2 \omega^2 \Delta x_R^B k_L$ |
| $\partial \overline{M_z^B} / \partial \omega$ | $2 A \omega k_L (J_1(A) y_{cp} + A w/4)$ | $-2 A \omega k_L (J_1(A) y_{cp} + A w/4)$ |
| $\partial \overline{M_z^B} / \partial A$ | $A \omega^2 k_L ((J_1(A)/A + (J_0(A) - J_2(A))/2) y_{cp} + w/2)$ | $-A \omega^2 k_L ((J_1(A)/A + (J_0(A) - J_2(A))/2) y_{cp} + w/2)$ |
| $\partial \overline{M_z^B} / \partial \alpha_u$ | $-1/2 A \omega^2 d_L (J_1(A) y_{cp} + A w/4)$ | $1/2 A \omega^2 d_L (J_1(A) y_{cp} + A w/4)$ |
| $\partial \overline{M_z^B} / \partial \alpha_d$ | $-1/2 A \omega^2 d_L (J_1(A) y_{cp} + A w/4)$ | $1/2 A \omega^2 d_L (J_1(A) y_{cp} + A w/4)$ |

$$\omega = \frac{2\pi}{T} \quad (17.25)$$

2. Determine the time at which wing stroke reversal occurs, T_R , and compute the asymmetric frequency:

$$\delta = \omega - \frac{\pi}{T_R} \quad (17.26)$$

3. Compute the stroke amplitude:

$$A = \frac{1}{2} [\phi_{\max} - \phi_{\min}] \quad (17.27)$$

4. Compute the wing stroke bias:

$$\eta = \phi_{\max} - A \quad (17.28)$$

5. Compute the best fit stroke plane angle:

$$\hat{\zeta} = \arg \min_z \int_0^{\frac{2\pi}{\omega}} (\zeta(t) - z)^2 dt \quad (17.29)$$

Note that this computation is trivial if the control mechanism simply tilts the stroke plane at a constant angle.

6. Compute the best fit upstroke angle-of-attack

$$\hat{\alpha}_u = \arg \min_{a_u} \int_0^{\frac{\pi}{\omega-\delta}} (\alpha(t) - a_u)^2 dt \quad (17.30)$$

7. Compute the best fit downstroke angle-of-attack

$$\hat{\alpha}_d = \arg \min_{a_d} \int_{\frac{\pi}{\omega-\delta}}^{\frac{2\pi}{\omega}} (\alpha(t) - a_d)^2 dt \quad (17.31)$$

Approximations to the partial derivatives of the seven parameters with respect to the control inputs can be obtained by finite difference methods. These partial derivatives can be used in conjunction with the cycle-averaged aerodynamic control derivatives presented in Table 17.3 to compute estimates of a control effectiveness matrix for a wide range of control inputs that might be found on flapping wing aircraft. The multivariable chain rule can be used to compute the sensitivities of a cycle-averaged generalized force to changes in a general control input u . Application of the multivariable chain rule yields

$$\frac{\partial \bar{G}}{\partial u} = \frac{\partial \bar{G}}{\partial \omega} \frac{\partial \omega}{\partial u} + \frac{\partial \bar{G}}{\partial \delta} \frac{\partial \delta}{\partial u} + \frac{\partial \bar{G}}{\partial A} \frac{\partial A}{\partial u} + \frac{\partial \bar{G}}{\partial \eta} \frac{\partial \eta}{\partial u} + \frac{\partial \bar{G}}{\partial \zeta} \frac{\partial \zeta}{\partial u} + \frac{\partial \bar{G}}{\partial \alpha_u} \frac{\partial \alpha_u}{\partial u} + \frac{\partial \bar{G}}{\partial \alpha_d} \frac{\partial \alpha_d}{\partial u} \quad (17.32)$$

Equation 17.32 serves as a basis for generating the linear control effectiveness matrix, \mathbf{B} , for a suite of control effectors that change the cycle-averaged forces and moments acting on a vehicle through changes in the wingbeat kinematics. The control effectiveness matrix is

$$\mathbf{B} \triangleq \begin{bmatrix} \partial \bar{F}_x^B / \partial u_1 & \partial \bar{F}_x^B / \partial u_2 & \dots & \partial \bar{F}_x^B / \partial u_m \\ \partial \bar{F}_y^B / \partial u_1 & \partial \bar{F}_y^B / \partial u_2 & \dots & \partial \bar{F}_y^B / \partial u_m \\ \partial \bar{F}_z^B / \partial u_1 & \partial \bar{F}_z^B / \partial u_2 & \dots & \partial \bar{F}_z^B / \partial u_m \\ \partial \bar{M}_x^B / \partial u_1 & \partial \bar{M}_x^B / \partial u_2 & \dots & \partial \bar{M}_x^B / \partial u_m \\ \partial \bar{M}_y^B / \partial u_1 & \partial \bar{M}_y^B / \partial u_2 & \dots & \partial \bar{M}_y^B / \partial u_m \\ \partial \bar{M}_z^B / \partial u_1 & \partial \bar{M}_z^B / \partial u_2 & \dots & \partial \bar{M}_z^B / \partial u_m \end{bmatrix} \quad (17.33)$$

Given a desired cycle-averaged force and moment vector, $[\bar{F}_{x_{des}} \ \bar{F}_{y_{des}} \ \bar{F}_{z_{des}} \ \bar{M}_{x_{des}} \ \bar{M}_{y_{des}} \ \bar{M}_{z_{des}}]^T$, the objective is to find the control vector, $[u_1 \ u_2 \ \dots \ u_m]^T$, such that

$$\begin{bmatrix} \bar{F}_{x_{des}} \\ \bar{F}_{y_{des}} \\ \bar{F}_{z_{des}} \\ \bar{M}_{x_{des}} \\ \bar{M}_{y_{des}} \\ \bar{M}_{z_{des}} \end{bmatrix} = \mathbf{B} \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_m \end{bmatrix} \quad (17.34)$$

Control allocation methods (Oppenheimer et al. 2010c) can be used to solve Eq. 17.34. These methods blend the available effectors to provide the cycle-averaged forces and moments commanded by a standard control law. The control designer must bear in mind that the dynamics of the fuselage must evolve on a much slower timescale than the wingbeats and that one can only influence the cycle-averaged forces and moments rather than the instantaneous periodic forces and moments. Thus, special provisions must be made to ensure that the controller and control allocator do not attempt to compensate for fuselage motion errors occurring within the timescale of the wingbeat. A simple method of addressing this problem is to implement a “cycle zero-order hold” that only allows new control input commands to be passed to the control effectors once per wingbeat cycle (Doman et al. 2010a). The advantage of this method is that it allows one to use any standard method to control a flapping wing aircraft that operates under the influence of periodic rather than steady forces and moments. The steady force and moment commands generated by the control law are interpreted as cycle-averaged force and moment commands, and the control allocation algorithm effectively finds the inverse mapping between those commands and a set of control effector positions that are required to produce them.

17.7 Flapping Wing Aerodynamic Stability Derivatives

Extracting stability derivatives requires that the effects of the fuselage velocity be added to the force and moment computations. Previous works have extended the quasi-steady model presented here to include such effects without great computational cost (Sigthorsson et al. 2012a; Faruque and Humbert 2010). There, the expression for the velocity field, used to compute the dynamic pressure over the surfaces of the wings, includes the rigid body velocities. The instantaneous forces and moments for a particular vehicle configuration can be computed by gridding the surfaces of the wings and applying numerical integration over the surface. The cycle-averaged forces and moments are obtained by numerical integration with respect to time over a full wingbeat cycle. Numerical estimation of partial derivatives with respect to fuselage velocity changes over the wingbeat cycle can then be computed to obtain cycle-averaged stability derivatives, which can be used to form the elements of a system matrix (Sigthorsson et al. 2012b).

In order to account for the vehicle velocity in the aerodynamic force expressions, the computation of the dynamic pressure on the wing and the angle-of-attack is required. These terms are functions of the total velocity of the wing with respect to quiescent air. The total velocity of the wing at a point

$$\mathbf{r}^{wp} \triangleq [-x_{wp} \ y_{wp} \ 0]^T \quad (17.35)$$

on the wing planform is composed of the velocity due to the wing flapping, \mathbf{v}_f ; fuselage translational velocity, \mathbf{v}_b ; and the fuselage rotational velocity, Ω

$$\mathbf{v}^B(\mathbf{r}) = \begin{bmatrix} v_x^B(\mathbf{r}) & v_y^B(\mathbf{r}) & v_z^B(\mathbf{r}) \end{bmatrix}^T \triangleq \mathbf{v}_f^B(\mathbf{r}) + \mathbf{v}_b^B + (\Omega^B \times \mathbf{r}^B) \quad (17.36)$$

Furthermore, the small angle between the local freestream velocity due to flapping and fuselage motion at a point on the wing planform is found to be Sigthorsson et al. (2012a)

$$\alpha_v(\mathbf{r}) = \text{atan} \left(v_z^{wp}(\mathbf{r}), \sqrt{(v_x^{wp}(\mathbf{r}))^2 + (v_y^{wp}(\mathbf{r}))^2} \right) \quad (17.37)$$

The local angle-of-attack, defined as $\alpha(\mathbf{r}) \triangleq |\alpha_v(\mathbf{r})|$, is used to compute the lift and drag coefficients. By definition, the drag is along the local freestream velocity vector and the lift is perpendicular to the drag. Define a frame V with its origin at \mathbf{r} , the drag is along the positive x -axis, the lift lies on the z -axis, and the y -axis lies in the wing planform plane. The infinitesimal aerodynamic force is expressed as

$$d\mathbf{F}^V = \begin{bmatrix} dD \\ 0 \\ \text{sgn}(\alpha_v(\mathbf{r}))dL \end{bmatrix} \quad (17.38)$$

where the infinitesimal lift and drag forces are, respectively,

$$dL = \frac{\rho}{2} \|\mathbf{v}(\mathbf{r})\|^2 C_L(\alpha(\mathbf{r})) dx_{wp} dy_{wp} \quad (17.39)$$

$$dD = \frac{\rho}{2} \|\mathbf{v}(\mathbf{r})\|^2 C_D(\alpha(\mathbf{r})) dx_{wp} dy_{wp} \quad (17.40)$$

and the infinitesimal aerodynamic moment is

$$d\mathbf{M}^B = \mathbf{r}^B \times d\mathbf{F}^B \quad (17.41)$$

where the moment arm associated with a point on the planform, \mathbf{r}^B , can be obtained directly from Table 17.2 by substituting the subscripts cp with wp . Many flapping wing aircraft make use of passive angle-of-attack regulation, where dynamic pressure acting on the wing causes it to rotate to a wing stop, or twist due

to the load. When flapping in still air at hover, the wing rotation is well defined as it takes place at stroke reversal. As the fuselage velocity increases, the wing rotation points become more difficult to compute. To illustrate the difficulty, consider an extreme but impractical case where the fuselage forward velocity is equal to the maximum blade tip velocity of the wing, measured relative to the fuselage. In this case, the dynamic pressure at the blade tip would be zero on the upstroke; thus, the wing would experience little to no passive rotation at midstroke. It is therefore intractable to write a general expression for the total aerodynamic force and center-of-pressure location using a fixed wing rotation stop over each upstroke and downstroke. However, at small velocities the wing rotation can be approximated as constant over the upstroke, α_u , and downstroke, α_d . Using this approximation and, for brevity, dropping the explicit notation of which variables depend on \mathbf{r} and t , the infinitesimal aerodynamic force for the right wing on the upstroke and downstroke, respectively, is expressed as follows:

$$d\mathbf{F}_{\text{RWU}}^B = \frac{\rho \|\mathbf{v}\|}{2} \begin{bmatrix} \cos(\zeta) \sin(\alpha_u) - \cos(\alpha_u) \cos(\phi) \sin(\zeta) & \sin(\zeta) \sin(\phi) & \cos(\alpha_u) \cos(\zeta) + \cos(\phi) \sin(\alpha_u) \sin(\zeta) \\ \cos(\alpha_u) \sin(\phi) & \cos(\phi) & -\sin(\alpha_u) \sin(\phi) \\ -\cos(\alpha_u) \cos(\zeta) \cos(\phi) - \sin(\alpha_u) \sin(\zeta) & \cos(\zeta) \sin(\phi) & \cos(\zeta) \cos(\phi) \sin(\alpha_u) - \cos(\alpha_u) \sin(\zeta) \end{bmatrix} \\ * \left(\mathbf{v}^{wp} C_D(\alpha) + \begin{bmatrix} -v_x^{wp} v_z^{wp} / \sqrt{(v_x^{wp})^2 + (v_y^{wp})^2} \\ -v_y^{wp} v_z^{wp} / \sqrt{(v_x^{wp})^2 + (v_y^{wp})^2} \\ \sqrt{(v_x^{wp})^2 + (v_y^{wp})^2} \end{bmatrix} \text{sgn}(v_z^{wp}) C_L(\alpha) \right) dx_{wp} dy_{wp} \quad (17.42)$$

$$d\mathbf{F}_{\text{RWD}}^B = \frac{\rho \|\mathbf{v}\|}{2} \begin{bmatrix} \cos(\zeta) \sin(\alpha_d) + \cos(\alpha_d) \cos(\phi) \sin(\zeta) & \sin(\zeta) \sin(\phi) & -\cos(\alpha_d) \cos(\zeta) + \cos(\phi) \sin(\alpha_d) \sin(\zeta) \\ -\cos(\alpha_d) \sin(\phi) & \cos(\phi) & -\sin(\alpha_d) \sin(\phi) \\ \cos(\alpha_d) \cos(\zeta) \cos(\phi) - \sin(\alpha_d) \sin(\zeta) & \cos(\zeta) \sin(\phi) & \cos(\zeta) \cos(\phi) \sin(\alpha_d) + \cos(\alpha_d) \sin(\zeta) \end{bmatrix} \\ * \left(\mathbf{v}^{wp} C_D(\alpha) + \begin{bmatrix} -v_x^{wp} v_z^{wp} / \sqrt{(v_x^{wp})^2 + (v_y^{wp})^2} \\ -v_y^{wp} v_z^{wp} / \sqrt{(v_x^{wp})^2 + (v_y^{wp})^2} \\ \sqrt{(v_x^{wp})^2 + (v_y^{wp})^2} \end{bmatrix} \text{sgn}(v_z^{wp}) C_L(\alpha) \right) dx_{wp} dy_{wp} \quad (17.43)$$

The force for the left wing is the same for a symmetric stroke but with a sign change on the second component of the force vector.

After gridding the wing planforms, the instantaneous aerodynamic forces and moments can be computed by numerically integrating the differential forces and moments over the planform area. In order to compute the cycle-averaged forces and moments, the total instantaneous forces and moments can be numerically integrated with respect to time over the period of the wingbeat. Cycle-averaged stability derivatives can be estimated through numerical difference computations applied to the vehicle linear and angular velocities.

17.8 Simulation Methods

Rigid body equations of motion for aircraft can be used as a point of departure for simulation analysis, provided that the mass of the wings is small when compared to the mass of the fuselage (Doman et al. 2010a). The reader is referred to the multibody equations of motion for flapping wing aircraft for cases where this condition is violated (Bolender 2009). It is important to note that the forces and moments that drive these equations are periodic functions of time. The equations of motion for a rigid body aircraft are

$$\begin{bmatrix} \dot{p} \\ \dot{q} \\ \dot{r} \end{bmatrix} = \mathbf{I}^{-1} (\mathbf{M}^B(\mathbf{t}) - \boldsymbol{\Omega} \times \mathbf{I} \boldsymbol{\Omega}) \quad (17.44)$$

$$\begin{bmatrix} \dot{u} \\ \dot{v} \\ \dot{w} \end{bmatrix} = \begin{bmatrix} qw - rv \\ ru - pw \\ pv - qu \end{bmatrix} + \frac{1}{m} [\mathbf{F}^B(t)] - \mathbf{R}_I^B \begin{bmatrix} 0 \\ 0 \\ -g \end{bmatrix} \quad (17.45)$$

$$\begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{z} \end{bmatrix} = \mathbf{R}_B^I \begin{bmatrix} u \\ v \\ w \end{bmatrix} \quad (17.46)$$

$$\begin{bmatrix} \dot{q}_0 \\ \dot{q}_1 \\ \dot{q}_2 \\ \dot{q}_3 \end{bmatrix} = \begin{bmatrix} 0 & -p & -q & -r \\ p & 0 & r & -q \\ q & -r & 0 & p \\ r & q & -p & 0 \end{bmatrix} \begin{bmatrix} q_0 \\ q_1 \\ q_2 \\ q_3 \end{bmatrix} \quad (17.47)$$

where \mathbf{I} is the mass moment of inertia matrix; $\boldsymbol{\Omega} = [p \ q \ r]^T$ is the body-axis angular rate vector; $\mathbf{M}^B(t)$ is the sum of the left and right wing instantaneous aerodynamic body-axis moment vectors consisting of the rolling, pitching, and yawing moments; u, v, w are the body-axis translational velocities; $\mathbf{F}^B(t)$ is sum of the left and right wing instantaneous aerodynamic body-axis force vectors; m is the vehicle mass; g is the acceleration due to gravity; x, y, z are the vehicle positions with respect to an inertial frame; and $\mathbf{q} = q_0 + q_1\hat{i} + q_2\hat{j} + q_3\hat{k}$ is a quaternion used to perform the 3-2-1 standard Euler transformation. Also, $\mathbf{R}_B^I = \mathbf{R}_I^{B^T}$ are rotation matrices that transform from body to inertial axes and back.

A simple blade element-based simulation can be constructed using the instantaneous forces and moments that can be computed from Tables 17.1 and 17.2 and Eq. 17.15. Such models account for periodic forces and moments due to fluctuations in dynamic pressure; however, they do not account for unsteady aerodynamic effects. Such simulations can be used to assess the efficacy of a cycle-averaged model-based control law when applied to a vehicle model that includes time periodic variations in the forces and moments due to the flapping wings without unsteady aerodynamic or structural flexibility effects. Directly modeling such effects can consume significant computational resources, which can produce a simulation that

is impractical for the study of the behavior of control systems for flapping wing aircraft. It is recommended that such effects be captured in tabular form based upon the results of either high-fidelity computational methods or experiments, e.g., the low Reynolds number experiments of Sane and Dickinson (2001). Such results can be used to produce instantaneous lift and drag coefficients as a function of stroke angle, angle-of-attack, amplitude, frequency, and asymmetric frequency. This more complete representation may include translational and rotational aerodynamic contributions, unsteady aerodynamic effects, and fluid structure interactions. For each set of parameters considered in a table, the lift and drag coefficients should be estimated for a given stroke angle and angle-of-attack. Instantaneous estimates of the aerodynamic forces produced in this way should be representative of the steady-state periodic forces produced by the wings. In other words, transients due to changes in parameters other than stroke angle and angle-of-attack would not appear in such a model. Whether a simple blade element model or a higher-fidelity table-lookup is used, both simulations will provide the designer with a model that can be used to assess the performance of cycle-averaged model-based control laws on aircraft models that are driven by periodic forces and moments.

17.9 Conclusion

The methods presented in this chapter are intended for use with hover-capable flapping wing vehicles in the conceptual design phase. The methods allow engineers to iterate between vehicle design, trim, and controllability analysis until closure is achieved. Prototype model-based controllers can be designed by using the control derivative tables, the multivariable chain rule, and conventional control design methods. The resulting control laws provide a point of departure design that can be tested on the prototype aircraft or in higher-fidelity simulations. Tuning and optimization of the control law will likely be required to compensate for the effects of unmodeled unsteady aerodynamic effects, fluid-structure interactions, as well as interactions between wing loads, drive mechanism loads, and prime movers.

Abstract

Two complete system architectures for a guidance, navigation, and control solution of small UAVs are presented. These systems (developed at the University of California Santa Cruz and the University of Minnesota) are easily reconfigurable and are intended to support test beds used in navigation, guidance, and control research. The systems described both integrate a low-cost inertial measurement unit, a GPS receiver, and a triad of magnetometers to generate a navigation solution (position, velocity, and attitude estimation) which, in turn, is used in the guidance and control algorithms. The navigation solution described is a 15-state extended Kalman filter which integrates the inertial sensor and GPS measurement to generate a high-bandwidth estimate of a UAV's state. Guidance algorithms for generating a flight trajectory based on waypoint definitions are also described. A PID controller which uses the navigation filter estimate and guidance algorithm to track a flight trajectory is detailed. The full system architecture – the hardware, software, and algorithms – is included for completeness. Hardware in the loop simulation and flight test results documenting the performance of these two systems is given.

18.1 Introduction

In current usage, the term uninhabited aerial vehicles or UAVs refers to aircraft which fly without a human operator onboard. They span a wide range in size and complexity. The largest UAVs such as Predator or Global Hawk can weigh several thousand pounds and have wingspans on the order of 10 to 100 ft. At the other end of the size spectrum are UAVs whose maximum dimensions and mass are on the order of centimeters and grams, respectively. In general, these vehicles are being used or envisioned for use in operations where they serve primarily as a platform for a sensor payload. The sensor payload can be as simple as an electro-optical camera or as complex as synthetic aperture radar used for remote sensing.

Regardless of their size and mission, all UAVs share the need for sensor or sensor systems which provide an estimate of the vehicle's full state vector. The state vector normally consists of three position coordinates, three components of the velocity vector, and anywhere between three and nine parameters which describe the vehicle's attitude. In addition to state sensing and estimation, UAVs (especially one that operates autonomously) need control and guidance systems which allow them to maneuver in a way consistent with their mission. In simple terms, the guidance system generates instruction on what state trajectory the UAV should follow in accomplishing its mission. The control system in turn operates the aircraft controls (aileron, elevators, thrust, etc.) to follow the trajectory generated by the guidance systems. A high-level depiction of a GNC system is shown in Fig. 18.1 and consists of both airborne and ground components.

Off-the-shelf guidance, navigation, and control (GNC) solutions for small UAVs (i.e., UAVs which fall in the so-called "Class I" category of vehicles as defined in UAS CoE 2010) exist. Some of these off-the-shelf solutions consist of the

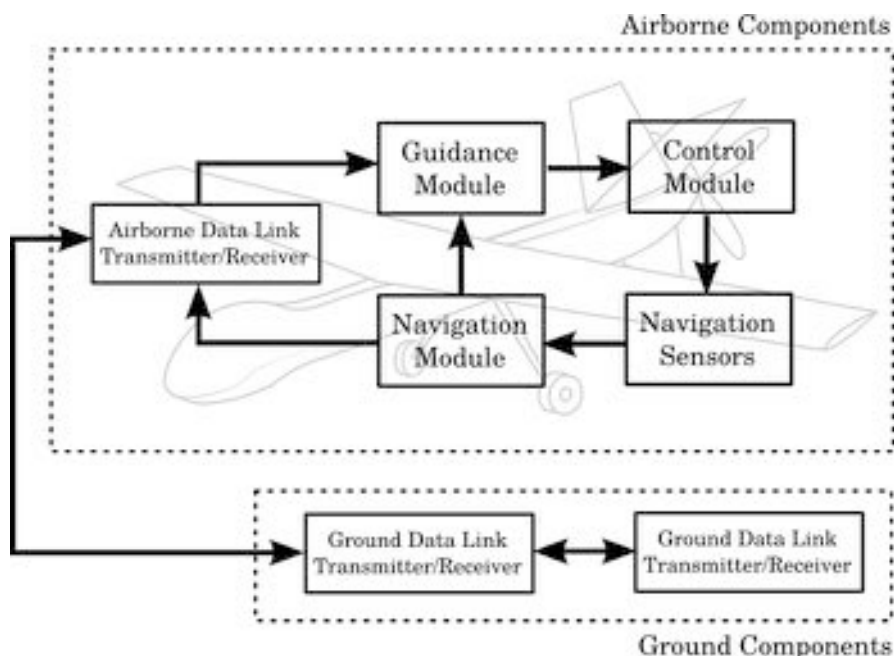

Fig. 18.1 Unmanned aerial system (UAS) concept of operation

vehicle itself, avionics, and associated ground support systems. While most of these “turnkey” solutions allow some level of customization by the user, they can be very restrictive for use in research environments. For example, in research on the robust control problem, the effect of uncertainties and potential fault modes in the guidance and navigation algorithms must be known. Very few off-the-shelf solutions allow access to the internals of the GNC solution. Thus, a GNC solution that is inexpensive and easily reconfigurable is desirable for the research community.

This chapter describes two such GNC solutions for small UAVs. This chapter discusses the implementation aspect of the GNC modules on University of California Santa Cruz’s (UCSC) and University of Minnesota’s (UMN) UAVs. The UAV laboratory at UMN is equipped with two fixed-wing aircraft models: Ultrastick 25e and Ultrastick 120. Shown in, Fig. 18.2 is the Ultrastick 120, also known as FASER (Free-flying for Subscale Experimental Research). FASER is equipped with conventional flight control surfaces and a pair of wingtip vanes on each side of the aircraft to measure aerodynamic angles (angle-of-attack and sideslip angle). Prior to joining the UAV Laboratory, FASER’s airframe was formerly used by NASA for their research program (Owens et al. 2006). Extensive wind tunnel testing during its time at NASAs has been used to develop a comprehensive aerodynamic model of the aircraft. At University of Minnesota, FASER is the workhorse for the multi-sensor navigation research such as GPS attitude and heading determination system, synthetic airdata estimator (Lie and Gebre-Egziabher 2012), and vision-aided navigation (Chu et al. 2011). Thor, an Ultrastick 25e, is an approximately

Fig. 18.2 Free-flying for Subscale Experimental Research (FASER) UAV (a modified Ultra-stick 120)

Fig. 18.3 The UCSC SLUGS autopilot (a) and Multex Mentor UAV (b)

65 % scaled model of FASER with the same basic configuration. As an addition to the system identification work (Dorobantu et al. 2011), this UAV is used for fault-tolerant control research at the University. The UAV Laboratory Web site (Murch 2012b) provides a detailed information on the airframe, avionics, and software architecture. The flight software is available as an open source software package available upon request.

The UCSC autopilot, Santa Cruz Low-Cost UAV GNC Subsystem (SLUGS), has been developed over the past 5 years in order to implement a rapidly reconfigurable autopilot for UAV guidance, navigation, and control research. The SLUGS, pictured in Fig. 18.3a, consists of two fast dsPIC33 microcontrollers (DSC's) and a suite of sensors; the SLUGS-based electric UAV is pictured in Fig. 18.3b. Details of the design, development, and deployment of the SLUGS can be found in Lizarraga (2009) and Lizarraga et al. (2011a,b, 2009a,b).

Section 18.2 describes the UMN's navigation module for attitude and position estimation. Sections 18.3 and 18.4 describe the inner loop control and guidance algorithm implemented on the UCSC SLUGS platform, respectively, including simulation and experimental results.

18.2 Attitude and Position Estimation

In order to be able to guide and control the UAV, the state of the UAV must be available to the controller at high fidelity and high bandwidth. Accurate position is required to perform automatic control for precision applications (e.g., landing). The navigation module in the GNC system implements aircraft state estimation. The advent of powerful computers made available at relatively low cost has allowed sensor fusion for navigation; sensor fusion is a technique of optimally blending information from multiple different (flawed) sensors. Multi-sensor navigation framework aims to obtain the most information about the aircraft states by using minimum combination of sensors. This is key to UAV operations where size, weight, and power are all critical. This section will describe the navigation module implemented on University of Minnesota's UAV.

The complete state of the UAV comprises its position, velocity, attitude, airspeed, angle-of-attack, sideslip angle, and rotation (pitch, roll, and yaw) rates. Position, velocity, and attitude are also known as the navigation state (Gleason and Gebre-Egziabher 2009). The sensors used to measure these quantities are called navigation sensors: an inertial measurement unit (IMU) and global positioning system (GPS) receiver. Figure 18.4a shows the Analog Devices IMU ADIS16405 installed on the UAVs at University of Minnesota. It is a 6 degree-of-freedom temperature calibrated inertial measurement unit with 3-axis accelerometers, 3-axis gyros, and 3-axis magnetometer. With a flight computer that computes the navigation state only from IMU measurements, it is known as an inertial navigation system (INS). Figure 18.4b shows Crescent, an OEM GPS receiver from Hemisphere GPS. In addition to the differentially corrected position and velocity estimates, Crescent also outputs raw pseudorange and carrier phase measurement. These features enable a great deal of navigation research at the UMN UAV Laboratory. Crescent's small form-factor and low power consumption also makes it a very suitable choice for UAV applications.

Fig. 18.4 Navigation sensor of UMN UAV: ADIS16405 (a) and Hemisphere Crescent OEM GPS receiver (b)

Fig. 18.5 UMN's Thor instrumented with five-hole pitot tube from Goodrich to measure airspeed, α , and β

Airspeed, angle-of-attack (α), and sideslip angle (β) are known as the airdata quantities, which are traditionally measured using airdata sensors such as pitot tube and wind vane. Another alternative for measuring these angles is to use a multiple hole pitot tube such as the 5-hole pitot tube as shown in Fig. 18.5. Recent work (Lie and Gebre-Egziabher 2012) has shown that this airdata can also be estimated by using sensor fusion from the IMU and GPS.

The navigation state is of particular interest. INS/GPS integration has been studied extensively in the past decades to estimate aircraft's navigation state. This section will focus on the implementation aspects of an integrated navigation systems using inertial sensors and GPS (INS/GPS system). A brief description of INS/GPS is provided; a more in-depth discussion can be found in Gleason and Gebre-Egziabher (2009), Groves (2008), Farrell and Barth (1999), and Titterton and Weston (2004). System architecture and implementation challenges are discussed next. Following these descriptions, FASER's flight test result is presented.

18.2.1 INS/GPS Integrated Navigation System

An inertial navigation system (INS) uses the output of inertial sensors to estimate the vehicle's position, velocity, and attitude. A complete six degree-of-freedom inertial sensor consists of 3-axis accelerometers and 3-axis gyros. The accelerometer measures the specific force acting on the platform and the gyros measures its rotation. Inertial sensors can be categorized according to its resulting navigational accuracy (Gleason and Gebre-Egziabher 2009; Gebre-Egziabher 2001). Automotive-grade micro electro-mechanical system (MEMS) inertial sensors are most suitable for low-cost UAV applications; however, when operating as a stand-alone navigator, these sensors produce positioning errors on the order of several hundreds of meter per minute. These large errors in the position, velocity, and attitude estimates are mainly due to sensor bias and noise that corrupt the measurements. They are also a

function of the initial error on the state estimates. The position error grows linearly with the initial velocity error estimate, quadratically with uncorrected bias, and at a cubic rate with attitude error (Titterton and Weston 2004). Despite the unbounded growth of the error with time, one of the important advantages of inertial navigators is that they are self-contained; that is, they require no external signal to provide a navigation solution. In terms of the data rate, the navigation states can be computed at a rate limited only by the processing power of the flight computer.

Contrast GPS to the advantages and disadvantages of an inertial navigator: GPS requires an external signal to operate, and although the navigation solution accuracy depends on the signal quality and the geometry of the satellite in view, this error is not a function of time (Misra and Enge 2001). Although there are specialized GPS receivers that can generate data up to 100 Hz, most low-cost GPS receivers provide output data at 1–10 Hz. In other words, although GPS navigation solution has long-term stability, the bandwidth of the solution is much lower than that of an inertial navigator.

Integration of INS with GPS allows a navigation solution that has the high bandwidth of the inertial sensors and the drift-free long-term stability of the GPS solution. Attitude determination is an integral part of strapdown INS. This is because the specific force measured by the accelerometer needs to be transformed into the navigation frame in which the position and velocity are calculated. This transformation calls for the knowledge of the orientation of the platform (defined as the attitude).

Attitude can be equivalently described by a set of three angles known as the Euler angle sequence or the four-parameter attitude quaternion. An Euler angle sequence consists of the yaw (ψ), pitch (θ), and roll (ϕ) angles that describe three successive rotations about the body z , y , and x axes, respectively. Although this representation carries physical interpretation, it is singular at $\theta = \pm 90^\circ$. The attitude quaternion is a set of four numbers that can be related to the roll, pitch, and yaw angles using the following relationship:

$$\begin{aligned}\phi &= \arctan\left(\frac{2q_2q_3 + 2q_0q_1}{2q_0^2 + 2q_3^2 - 1}\right) \\ \theta &= \arcsin(-2q_1q_3 + 2q_0q_2) \\ \psi &= \arctan\left(\frac{2q_2q_3 + 2q_0q_1}{2q_0^2 + 2q_3^2 - 1}\right).\end{aligned}\tag{18.1}$$

The quaternion $\mathbf{q} = [q_0 \ q_1 \ q_2 \ q_3]$ represents the transformation from the local North-East-Down coordinate to the body-fixed frame. Although it has no singularity, directly visualizing the aircraft's orientation can be challenging. Hence, for remote pilot display purposes and most control algorithms, the quaternion attitude needs to be transformed into its corresponding roll, pitch, and yaw angles. For applications where only benign maneuvers are expected, the Euler angle representation can instead be used.

Attitude determination using gyro's output calls for integrating the angular velocity to propagate the attitude forward in time. Since gyros measure inertial rotation, they must be compensated to account for both the earth's rotation rate and the transport rate (Groves 2008) due to the Earth's curvature. For most low-cost UAV applications, these terms are small ($\sim 10^{-5}$ rad/sec) compared to the noise level in the sensors. Hence, they can be neglected for all practical purposes. When calculating attitude at the IMU sample rate, the following equations can be used: for an Euler angle attitude representation:

$$\begin{bmatrix} \phi[k+1] \\ \theta[k+1] \\ \psi[k+1] \end{bmatrix} = \begin{bmatrix} 1 & \sin(\phi[k]) \tan(\theta[k]) & \cos(\phi[k]) \tan(\theta[k]) \\ 0 & \cos(\phi[k]) & -\sin(\phi[k]) \\ 0 & \sin(\phi[k]) \sec(\theta[k]) & \cos(\phi[k]) \sec(\theta[k]) \end{bmatrix} \begin{bmatrix} \omega_x^B[k] \Delta t \\ \omega_y^B[k] \Delta t \\ \omega_z^B[k] \Delta t \end{bmatrix} \quad (18.2)$$

and for a quaternion attitude representation:

$$\mathbf{q}[k+1] = \mathbf{q}[k] \otimes \left[1 \quad \frac{1}{2} \omega_x[k]^B \Delta t \quad \frac{1}{2} \omega_y[k]^B \Delta t \quad \frac{1}{2} \omega_z[k]^B \Delta t \right] \quad (18.3)$$

where \otimes operator is the quaternion multiplication operator. Details on quaternion algebra can be found on Lefferts et al. (1982).

In order to improve the navigation solution between subsequent GPS solutions, the filter makes frequent corrections to compensate for the inertial sensor errors. Although more sophisticated sensor error models exist, a simplified model presented in Gebre-Egziabher (2001) is used in this implementation. In this model, the sensor output (e.g., gyro) as a function of time can be written as

$$\omega(t) = \tilde{\omega}(t) + b_{gs} + b_{gd}(t) + w_g \quad (18.4)$$

where $\tilde{\omega}(t)$ represents the true angular velocity, b_{gs} is the turn-on bias, $b_{gd}(t)$ is a time-varying bias, and w_g is measurement noise that can be regarded as white noise. $b_{gd}(t)$ is modeled as first-order Gauss-Markov process, written as

$$\dot{b}_{gd}(t) = -\frac{1}{\tau} b_{gd}(t) + w_b. \quad (18.5)$$

This model is robust to parameters that are unobservable when the UAV is not accelerating (Gleason and Gebre-Egziabher 2009). Using this model, the estimated sensor bias is not simply the true bias corrupting the measurement; it also accounts for all unmodeled errors that corrupt the sensor measurement.

The architecture of the INS/GPS filter using an extended Kalman filter (EKF) (Simon 2006) is shown on Fig. 18.6. Included in the state vector (Euler angle representation) are:

$$\mathbf{x} = \left[\underbrace{L \ \Lambda \ h}_{\text{Position}} \quad \underbrace{V_{\text{North}} \ V_{\text{East}} \ V_{\text{Down}}}_{\text{Groundspeed}} \quad \underbrace{\phi \ \theta \ \psi}_{\text{Attitude}} \quad \underbrace{b_{ax} \ b_{ay} \ b_{az}}_{\text{AccelBias}} \quad \underbrace{b_{gx} \ b_{gy} \ b_{gz}}_{\text{GyroBias}} \right]. \quad (18.6)$$

Fig. 18.6 Block diagram of INS/GPS integration

The time update process, executed at the internal IMU sample rate, is:

$$[\phi[k+1] \ \theta[k+1] \ \psi[k+1]]^T = f(\phi[k], \theta[k], \psi[k]) \cdot \omega^B[k-1] \cdot \Delta t \quad (18.7)$$

$$\mathbf{V}^N[k+1] = \mathbf{V}^N[k] + C_B^N[k] \mathbf{f}^B[k] \cdot \Delta t \quad (18.8)$$

$$h[k+1] = h[k] - V_{\text{Down}[k]} \cdot \Delta t$$

$$\Lambda[k+1] = \Lambda[k] + \frac{V_{\text{East}[k]}}{R_E + h[k]} \cdot \Delta t \quad (18.9)$$

$$L[k+1] = L[k] + \frac{V_{\text{North}[k]}}{R_E + h[k]} \cdot \Delta t$$

The covariance is updated according to

$$\mathbf{P}^{(-)}[k+1] = \Phi[k] \mathbf{P}^{(+)}[k] \Phi[k]^T + \mathbf{Q}[k]. \quad (18.10)$$

The state transition matrix can be approximated as $\Phi[k] = \mathbf{I} + \mathbf{F}[k] \cdot \Delta t$. \mathbf{F} is the Jacobian of the time-update equations and \mathbf{Q} is the process noise covariance matrix. Details on the elements of \mathbf{F} and \mathbf{Q} can be found in Gleason and Gebre-Egziabher (2009).

When GPS position and velocity becomes available at time-step k , the measurement update process is outlined as follows. The measurement, \mathbf{y} , is defined as follows:

$$\mathbf{y}|_{\text{GPS}} = [p_N \ p_E \ p_D \ V_{\text{North}} \ V_{\text{East}} \ V_{\text{Down}}]|_{\text{GPS}} \quad (18.11)$$

where p_N , p_E , and p_D are the reported North-East-Down position with respect to a specific location, e.g., the initial position.

Define the state error as:

$$\delta \mathbf{y} = \mathbf{y}|_{\text{GPS}} - [p_N \ p_E \ p_D \ V_{\text{North}} \ V_{\text{East}} \ V_{\text{Down}}] \Big|_{\text{INS}[k]}. \quad (18.12)$$

The covariance is updated using

$$\begin{aligned} \mathbf{H} &= \begin{bmatrix} \mathbf{I}_{3 \times 3} & \mathbf{0}_{3 \times 3} & \mathbf{0}_{3 \times 9} \\ \mathbf{0}_{3 \times 3} & \mathbf{I}_{3 \times 3} & \mathbf{0}_{3 \times 9} \end{bmatrix} \\ \mathbf{K}[k] &= \mathbf{P}^{(-)}[k] \mathbf{H}^T (\mathbf{R} + \mathbf{H} \mathbf{P}^{(-)}[k] \mathbf{H}^T)^{-1} \\ \mathbf{P}^{(+)}[k] &= (\mathbf{I} - \mathbf{K}[k] \mathbf{H}) \mathbf{P}^{(+)}[k] (\mathbf{I} - \mathbf{K}[k] \mathbf{H})^T + \mathbf{K}[k] \mathbf{R}[k] \mathbf{K}[k]^T. \end{aligned} \quad (18.13)$$

The state is updated according to:

$$\delta \mathbf{x} = \mathbf{K}[k] \delta \mathbf{y} \quad (18.14)$$

Position:

$$\begin{aligned} h^{(+)}[k] &= h^{(-)}[k] - \delta \mathbf{x}(3) \\ \Lambda^{(+)}[k] &= \Lambda^{(-)}[k] + \frac{\delta \mathbf{x}(2)}{R_E + h^{(+)}[k]} \\ L^{(+)}[k] &= L^{(-)}[k] + \frac{\delta \mathbf{x}(1)}{R_E + h^{(+)}[k]}. \end{aligned} \quad (18.15)$$

Velocity:

$$\begin{aligned} V_{\text{North}}^{(+)}[k] &= V_{\text{North}}^{(-)}[k] + \delta \mathbf{x}(4) \\ V_{\text{East}}^{(+)}[k] &= V_{\text{East}}^{(-)}[k] + \delta \mathbf{x}(5) \\ V_{\text{Down}}^{(+)}[k] &= V_{\text{Down}}^{(-)}[k] + \delta \mathbf{x}(6). \end{aligned} \quad (18.16)$$

When using Euler angle representation, the attitude is updated using the transformation matrix C_B^N .

$$C_B^N(+) = (\mathbf{I} - [\delta \mathbf{x}(7 : 9) \times]) \cdot C_B^N(-) \quad (18.17)$$

where $[\cdot \times]$ indicates the skew-symmetric matrix operator. Euler angles can be derived from the updated transformation matrix, $C_B^N(+)$. Accelerometer and gyros bias are updated as follows:

$$\mathbf{b}_a^{(+)}[k] = \mathbf{b}_a^{(-)}[k] + \delta \mathbf{x}(10 : 12). \quad (18.18)$$

$$\mathbf{b}_g^{(+)}[k] = \mathbf{b}_g^{(-)}[k] + \delta \mathbf{x}(13 : 15). \quad (18.19)$$

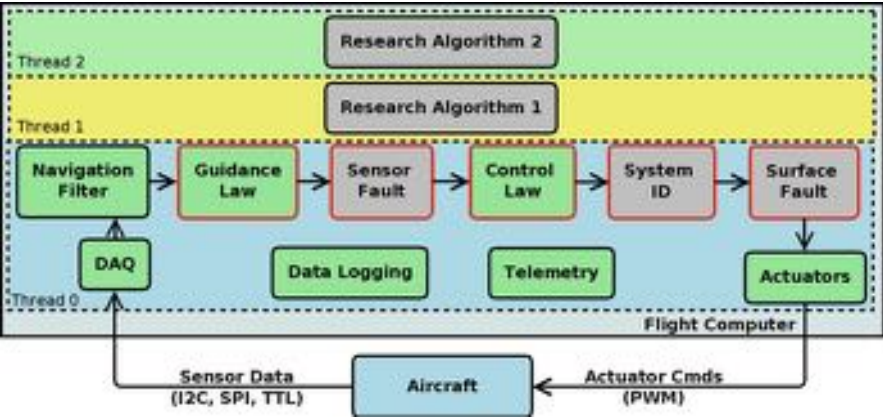

Fig. 18.7 Flight software architecture

18.2.2 Implementation and Practical Challenges

The avionics suite in the UMN’s UAV is implemented on a 32-bit PowerPC Phytec MPC5200B-tiny SoM. It utilizes a real-time operating system (RTOS) and flight software written in C. This computer handles data acquisition; performs guidance, navigation, and control tasks; stores relevant data; and sends information to the ground control station via the telemetry modem. The flight software uses a multi-threaded architecture in which all of the flight critical tasks execute in the highest priority thread at 50 Hz, while additional tasks (i.e., those not required to control the aircraft, such as a fault detection filter) are executed in separate, lower-priority threads (Murch 2012a). As shown in Fig. 18.7, there are ten modules executed in the highest-priority thread (thread 0). Navigation tasks are executed immediately after data acquisition (DAQ). It starts as valid GPS measurements are available. The position and velocity are initialized at the reported position and velocity. Since this initialization occurs on the ground, attitude is initialized to a known attitude of the aircraft on the ground.

One of the key aspects to the correct fusion of inertial sensors and GPS information is aligning data acquisition from non-timing sensors, such as an IMU, with sensors that have inherent timing capability such as GPS. Data acquisition to an IMU is achieved by polling the IMU at the desired sample rate. GPS receivers, however, stream out their navigation solutions (position and velocity) at a preset rate (e.g., 1 Hz). This rate is usually driven by a receiver clock that has been steered to the GPS time. Despite being precise, the flight computer clock might be running at a different rate from that of the GPS clock. When the IMU data stream is not aligned with the GPS output, incorrect measurements are fed to the EKF with resulting errors in the vehicle state estimates. The magnitude of the error depends on the acceleration experienced by the aircraft and the clock rate difference.

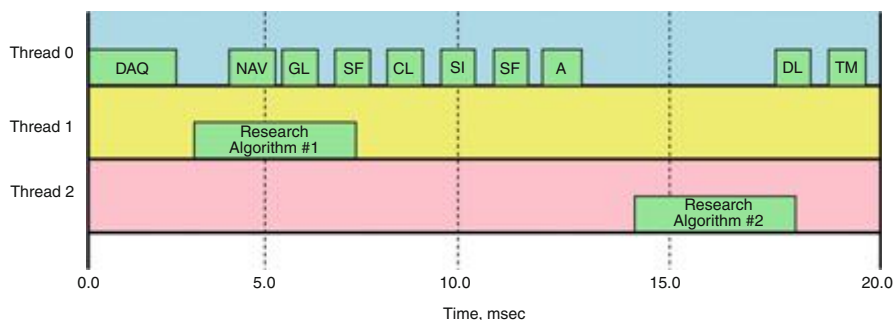

Fig. 18.8 Flight software timing diagram

There are many ways to synchronize IMU and GPS outputs. One way to do this is by performing data acquisition at a deterministic sample rate. By checking the availability of GPS solution at the highest rate available in the flight computer, IMU and GPS data are always synchronized within the resolution of one sampling interval. In this architecture, this is achieved by using the alarm functions provided by the RTOS kernel which are used to trigger module execution. The timing diagram that shows the execution time of each module is shown in Fig. 18.8.

Tuning the extended Kalman filter is known to improve filter convergence time and short-term accuracy (Gleason and Gebre-Egziabher 2009). However, in order to tune the filter, a truth reference is needed so that a comparison can be made to the resulting filter estimate. Although tuning the filter is an art, experience can help smooth the process. Having a truth reference system might be prohibitive for most small scale UAVs; it is recommended that the data set used for tuning is from a known trajectory. This helps to develop a feeling for how the errors grow and how effective is the bias compensations. Since the states' observability depends highly on the acceleration experienced by the vehicle, it is important that a trajectory with sufficient acceleration is used: acceleration and deceleration on a straight line path and frequent turns should be included. It might also be worth testing the filter performance both during powered and gliding operation since structural vibration might adversely affect the filter performance. Adding damping to the system or simply moving the IMU placement on the UAV can often alleviate vibration problems.

Lastly, when the IMU is not collocated with the GPS antenna, the distance between the IMU and the GPS antenna results in different velocity and position measured by both sensors. This is known as the lever arm problem, and the Kalman filter must account for it to make correct state estimates. There are generally two ways to account for this error. The first way is to transfer the GPS measurement to the location of the IMU by using the information of the aircraft attitude and the known lever arm vector in the body frame. The dependency on estimated attitude to transfer this measurement might lead to inaccurate GPS position and velocity estimates. The second way is by inflating the GPS measurement covariance. This method fails when the inflation factor is so large that it renders the GPS position

and velocity useless. For most UAV applications, however, the distance between the GPS antenna and the IMU is not large, thus only a very small inflation required to compensate for this error. In this work, the latter method is employed.

18.2.3 Flight Test Result

Figure 18.9 shows the trajectory flown during one of FASER's flight test. The navigation data are extracted from the flight computer's data recorder and are plotted on Fig. 18.10. During the flight, there were several GPS outages, and the navigation state estimates during these period of free inertials are plotted in green. When bias corrections are continuously fed to the IMU, this inflight calibration improves the performance of the inertial navigation and slows down error growth during these GPS outages.

In Fig. 18.10a, b, the position and velocity estimates from INS/GPS integration system are differenced with the velocity from the GPS measurement. Due to lack of a reference (truth) system, it is not possible to compare the attitude and bias estimates. Hence, the attitude and bias estimates from the INS/GPS filter are plotted on Fig. 18.10c, d. Qualitative evaluation of the filter performance indicates good performance. This can be seen from the smoothness of the INS/GPS solution and good convergence of the inertial sensor bias estimates. As such, the INS/GPS integration provides a high-bandwidth solution with long-term stability suitable for UAV control.

18.3 Inner Loop Control

In order to fly an aircraft, a low-level control system must stabilize the airframe using available sensor inputs and actuators. A higher-level outer loop control will implement path following (see Sect. 18.4) while the inner loop keeps the aircraft flying.

There are myriad ways to implement an inner loop control on a UAV. In this chapter the inner loop controller is based on the SLUGS autopilot (details at Lizarraga (2009), ASL, and SLU), which uses relatively simple PID controllers in the inner loop. The PID-based inner loop control that has flown on the SLUGS platform is presented, and actual flight data of the implementation is included.

The UCSC SLUGS autopilot is divided into two hardware sections: a control processor and a sensor processor. The sensor processor is tasked with taking the raw sensor measurements and fusing them into a high-quality position and attitude estimate (similar to Sect. 18.2). The control processor is tasked with both the inner loop (stabilization) and the outer loop (guidance). The SLUGS implementation is illustrated in Fig. 18.11.

While there are many different ways to implement a low-level control system, the one presented is based on decoupling the longitudinal and lateral flight dynamics into two separate control systems (Stewart 2001). The lateral control channel

Fig. 18.9 Flight test trajectory

controls rudder and ailerons, while the longitudinal control handles throttle and elevator. While this is reasonable for traditional aircraft-like UAV’s flying gentle maneuvers, it is not appropriate for aircraft with high degrees of lateral-longitudinal cross coupling, nor for aircraft performing aggressive aerobatic maneuvers.

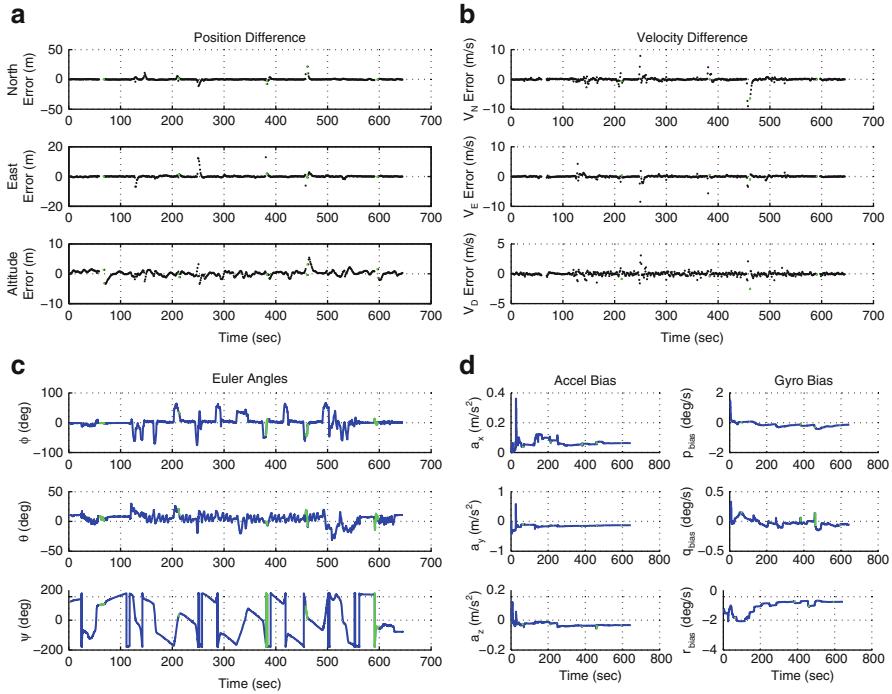

Fig. 18.10 INS/GPS solution: position error (a), velocity error (b), attitude estimate (c), and sensor bias estimate (d)

Furthermore, each of the two main (lateral and longitudinal) controllers is divided into successive loop closure using proportional-integral-derivative (PID) controllers. PID controllers are simple to tune experimentally, and while they can theoretically perfectly stabilize a second-order plant, in practice they work quite well with higher-order plants. Some attention must be paid to integrator windup, and the use of a numerical derivatives in the PID loop, or the resulting controller will have poor performance. Lastly, these controllers are implemented digitally, in order to accommodate the actual autopilot hardware.

18.3.1 PID Control

As stated above, the proportional-integral-derivative (PID) control can perfectly stabilize a second-order plant, given the right gains. However, in practice, it can usually perform well in a variety of settings without the need for a precise model of the underlying plant (a large advantage when system identification is either difficult or imprecise). The classical PID controller consists of an input derived from the measurement of the system and the desired reference for it to track and an actuator signal on the output. The difference between the measurement and the reference,

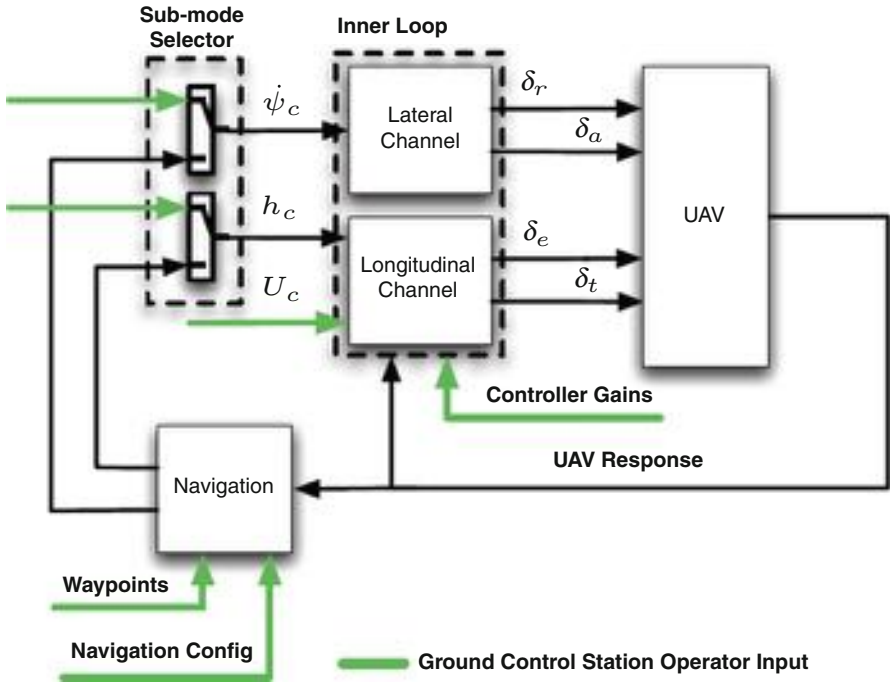

Fig. 18.11 SLUGS block diagram of inner loop and guidance

referred to as the error, is fed into the PID block, and an output is generated from the three gains: K_p , the proportional gain is multiplied directly by the error; K_d , the derivative gain is multiplied by the time rate of change of the error; and lastly, K_i , which multiplies the integral of the error.

At its most basic form, the PID control simply consists of three gains, with a first-order difference for the derivative and a running sum for the integral. Several embellishments are used to make the PID controller behave better at the corner cases. Firstly, the derivative is changed from the time rate of change of the error to the time rate of change of the measurement; this is done so that the PID controller does not throw the output due to a reference change. If a direct derivative signal is available (for instance, pitch rate gyro), then that is used in preference to the first-order difference. Also, the first-order difference can be changed to longer time steps if noise sensitivity is an issue.

Secondly, saturation limits are included to clip the output if it would saturate the actuator. The integral is changed from a running sum to trapezoidal integration, and anti-windup logic is included. Integral state windup is caused by the integrator continuing to integrate even after the control is saturated. This creates a memory effect within the controller that causes overshoot and degrades the controller performance when coming out of saturation. In order to prevent this, an anti-windup scheme is implemented which checks if the actuator would saturate on the current time step and does not perform the integration if this is the case.

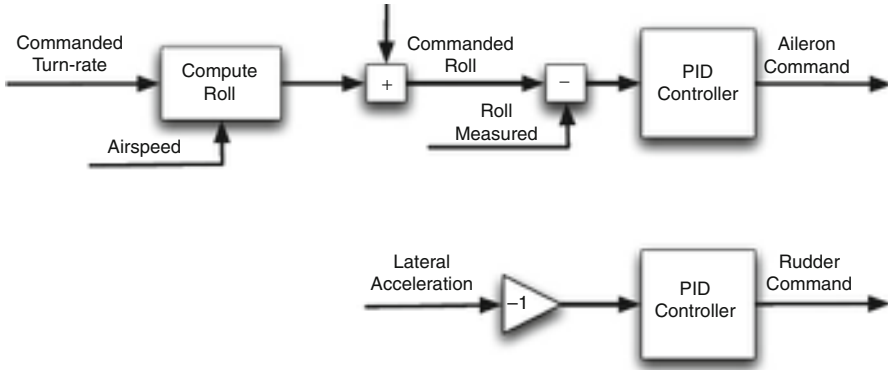

Fig. 18.12 SLUGS lateral inner loop control

The integrator state can be reset under software control, such that when the control is engaged, a bumpless transfer is achieved. Furthermore, the integral state can be manipulated when changing the control gains, such that the output remains stable as the new gains are latched into the controller. Again, all of this is done to maintain smooth control for flight.

18.3.2 Lateral Control

The lateral controller (Fig. 18.12) uses the rudder and ailerons to keep the aircraft flying in a coordinated turn and following a commanded turn rate (including a zero turn rate for straight flight). The lateral dynamics of an aircraft include the roll-rate damping mode, a spiral mode, and the dutch roll mode (yaw-roll coupling). In this formulation of the inner loop control, yaw rate, $\dot{\psi}_c$, is commanded and is converted to a commanded roll angle, ϕ_c , using the formulation

$$\phi_c = \arctan \left(\frac{\dot{\psi}_c U_m}{g} \right) \quad (18.20)$$

where U_m is the measured airspeed and g is gravity. Equation 18.20 assumes that the aircraft is flying in a coordinated turn, that is, where the turn rate is constant and the body-fixed lateral acceleration, a_y , is zero.

The commanded roll angle, ϕ_c , is used as the reference to the PID control, with the plant output being the actual roll angle, ϕ , that comes from the attitude estimation algorithm. The commanded bank angle is limited with a saturation block to keep the roll angle from becoming too extreme. In the case of the SLUGS small UAV, this is limited to $\pm 40^\circ$.

The output generated by the PID block is to the ailerons, which are used to drive the roll error (commanded – actual) to zero. In this case, the derivative of the roll

error is taken directly from the body-fixed gyros (with the bias again taken care of by the attitude estimation algorithm). That is, while the full derivative of roll rate

$$\dot{\phi} = p + (q \sin \phi + r \cos \phi) \tan \theta \quad (18.21)$$

where $[p, q, r]$ are the body-fixed roll, pitch, and yaw rates and ϕ, θ are the roll and pitch euler angles, respectively. Note that with a small pitch angle and yaw rate, this can be approximated as

$$\dot{\phi} \simeq p. \quad (18.22)$$

Lastly, when the roll angle command, ϕ_c , is the opposite polarity from the previous command, the integral state is reset to improve roll tracking performance.

The above describes the turn rate command to aileron control system, which will drive the roll error to zero. However, Eq. 18.20 depends on coordinated flight to be effective. In order to ensure coordinated flight, a second PID loop is closed around to rudder. The commanded input to the turn coordinator PID block is the negative of the lateral acceleration (this accounts for the fact that the rudder is behind the center of mass of the aircraft and has a negative sign in the transfer function), and the output is the rudder actuator command.

The PID loop will actuate the rudder in order to drive the body-fixed lateral acceleration, a_y , to zero. Here, again, the fact that the output of the aircraft affected by the rudder has a direct measurement of its derivative from the body-fixed gyros can be used for the D term. That is,

$$\dot{\psi} = \frac{1}{\cos \theta} (q \sin \phi + r \cos \phi) \quad (18.23)$$

which for small angles of pitch and roll, can be reliably approximated as

$$\dot{\psi} \simeq r. \quad (18.24)$$

Note that the turn coordinator, with the derivative feedback from the body-fixed yaw rate gyro, r , has the effect of also acting as a yaw damper for the aircraft. More traditional autopilots often use the rudder solely as a yaw damper, without the turn coordination function, and rely on the directional stability of the aircraft to keep the turns coordinated. In that case, the rudder feedback command would be based on a high-passed version of the yaw rate gyro. Experience with small UAVs indicates that the former approach works better for model scale aircraft, giving both coordinated turns and decent yaw damping.

18.3.3 Longitudinal Control

The longitudinal low-level control loops (Fig. 18.13) operate similarly to the lateral ones, with the other two flight controls being throttle and elevator. There are two

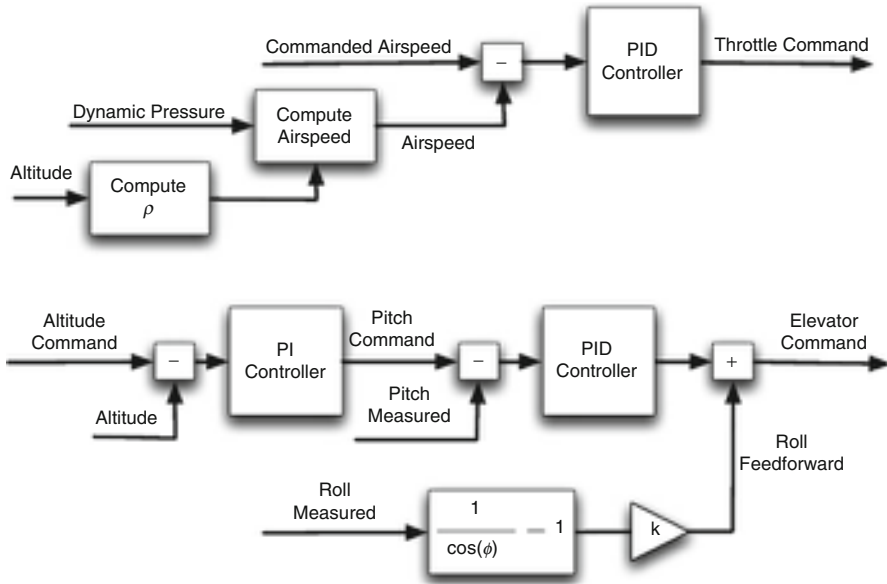

Fig. 18.13 SLUGS longitudinal inner loop control

modes of operation for a longitudinal low-level controller: *climb/descent* and *level flight*. In *climb/descent* mode, the throttle is set to a fixed value (high for climb, low for descent), and the airspeed and climb rate are controlled through the aircraft pitch via the elevator.

In *level flight* mode, airspeed is controlled directly by the throttle and altitude by aircraft pitch via the elevator. Since airspeed is being kept constant, the altitude responds rapidly to even small changes in aircraft pitch. As a design choice, only the *level flight* mode is implemented, given that the UAV will spend most of its mission in level flight at constant altitude following waypoints.

The airspeed hold control loop takes in a commanded airspeed, U_c , and compares this to the measured airspeed. Note that the airspeed control uses airspeed, and not ground speed (as available from GPS). Compensation for wind is handled within the higher-level guidance controller rather than in the low-level stabilizing controllers.

The aircraft does not, however, have an onboard measurement of airspeed. Rather, it has an onboard measurement of dynamic pressure, q , and altitude, from which the airspeed can be extracted. That is,

$$U_m = \sqrt{\frac{2q}{\rho}} \quad (18.25)$$

where q is the dynamic pressure and ρ is the atmospheric density. However, ρ is a function of altitude, such that

$$\rho = \rho_0 \left(1 - \frac{h_m}{44331}\right)^{4.255876} \quad (18.26)$$

where ρ_0 is the sea-level air density (1.025 Kg/m^3) and h_m is the measured altitude in meters. This approximation is good for most altitudes reachable by UAVs and is sufficient for control. The output of the PID block is the throttle actuator. In the case of the airspeed, there is no direct derivative to be used in the throttle loop (though the body-fixed longitudinal acceleration could be used). As such, some care must be used in both the derivatives and in tuning the airspeed hold loop in general.

Too aggressive gains on the airspeed hold loop causes the throttle to surge and cut in flight, with unpleasant results. This is due both to the noise on measured airspeed and also due to the lag in response to the throttle input. Here tuning the gains for an acceptable error and relying on the integral term to close the error works well.

The altitude control loop consists of two chained PID controllers. The first is a straight PI controller (the derivative gain is set to 0) that takes in commanded altitude, h_c , and measured altitude, h_m , as its error and outputs a pitch command. The pitch command is saturated at $\pm 15^\circ$ with the integral windup stopped if the saturation is reached. The limited pitch command is used as a reference input for the second PID loop and is compared to the aircraft pitch, θ , from the attitude estimation to generate the error. The output of the second PID loop drives the elevator, which works to match the aircraft pitch attitude to the commanded one. Here, the derivative term comes straight from the body-fixed gyros, with the full equation

$$\dot{\theta} = q \cos \phi - r \sin \phi \quad (18.27)$$

which for small bank angles can be reduced to

$$\dot{\theta} \simeq q. \quad (18.28)$$

The direct derivative term allows the pitch to elevator PID control to be aggressive, yet still retain good damping characteristics. This PID controller will drive the aircraft pitch to the commanded pitch until the desired altitude is reached.

While the aircraft is flying straight and level, this control works very well. However, while the aircraft is in a turn, the aircraft will descend. This is because the lift from the wings must match the aircraft weight, but in a turn part of the lift is directed inwards to cause the turn itself. More precisely, in order not to lose altitude in a turn, the lift is related to the weight and the bank angle as

$$L = \frac{W}{\cos \phi} \quad (18.29)$$

where L is lift, W is aircraft weight, and ϕ is roll angle. This is a simplified model assuming lift only from the wings and not accounting for sideslip angles of the fuselage for knife-edge type flight. Using this model, the change in lift is:

$$\Delta L = W \left(\frac{1}{\cos \phi} - 1 \right) \quad (18.30)$$

which indicates how much the lift must be increased to maintain altitude in a coordinated circular turn. Pilots are trained to increase elevator (back stick) when entering a turn to maintain altitude. In order to ensure that the UAV holds altitude during turns, a feedforward gain proportional to the increase in lift is included:

$$\delta e_{ff} = K_{ff} \left(\frac{1}{\cos \phi} - 1 \right) \quad (18.31)$$

where δe_{ff} is the additional elevator command due to the feedforward term. Note that in the implementation, the roll angle, ϕ , is low pass filtered to reduce unwanted pitch oscillations resulting from attitude estimation noise and is also limited to $\pm 60^\circ$. At angles beyond this amount, the UAV will simply enter into an accelerated stall trying to hold altitude, and the low-level control system will no longer be able to stabilize the aircraft.

18.3.4 Trim Conditions

Before leaving the subject of the low-level inner loop controllers, it is necessary to discuss aircraft trim conditions. In the case of the SLUGS small-scale UAV, trim is established by the safety pilot before the autopilot is engaged. At the moment the autopilot is switched on, the inner control loops assume the aircraft is currently trimmed for straight and level flight.

The inner PID control loops above each output a *change* in actuator output summed with the original trim condition. Note again that for the SLUGS autopilot, this trim is established by a human safety pilot. The trim could just as easily be established using a conventional 6DOF model of the airframe and computing trim for various flight conditions. That is, for every combination of airspeed, climb rate, and altitude, there is a throttle and elevator setting that will keep the UAV flying in steady state at those conditions. The ailerons and rudder surfaces are assumed to be set at zero for straight flight.

18.3.5 Simulation and Flight Test Results

In order to validate the inner loop control, data from the hardware-in-the-loop (HIL) simulation is presented showing the results of the inner loop PID controllers. [Figure 18.14a](#) shows the lateral controller. Note that at every change in commanded roll angle, the lateral acceleration receives a large disturbance, which must be washed out. In panel (b) is the longitudinal control, with both pitch and airspeed control. Again, note that the spikes in airspeed are due to large climb or descent inputs to the controller.

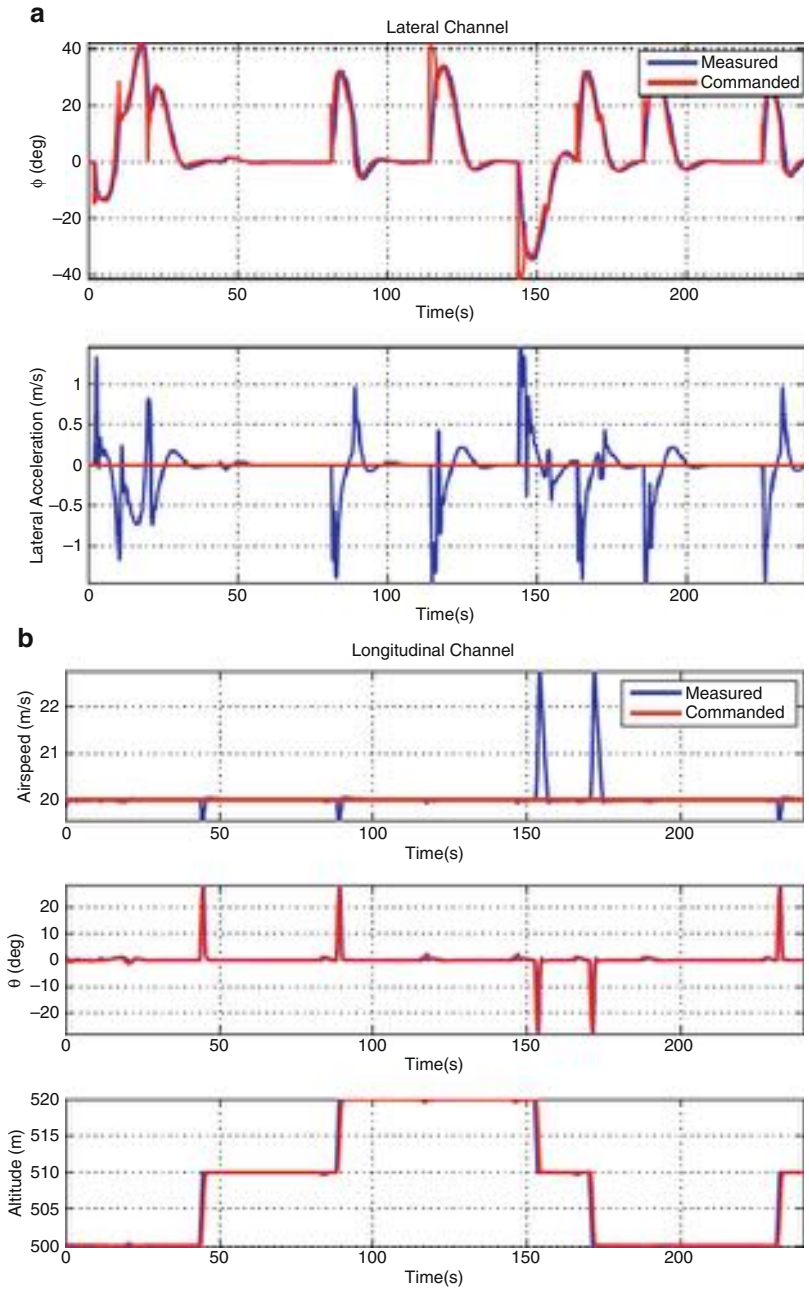

Fig. 18.14 Simulation of the inner loop control using the HIL simulator: (a) the lateral channel, (b) the longitudinal channel

Fig. 18.15 SLUGS inner loop flight test data

Flight test data from the inner loop control is presented in Fig. 18.15, which shows excellent performance on pitch and roll commands, a reasonable attenuation of lateral acceleration (with a limit to less than 1 g for most of the flight time) and a fairly good airspeed hold. This is in the presence of wind, gusts, and other disturbances. Note that the bias on the lateral acceleration is most likely from the accelerometer being mounted with a slight tilt on the airframe.

18.4 Guidance

UAV guidance, navigation, and control (GNC) ultimately signifies the ability to follow a desired trajectory through the sky. With attitude estimation established (Sect. 18.2), and inner loop stabilizing the aircraft (Sect. 18.3), what is left is to guide the UAV along the desired trajectory rejecting disturbances such as wind.

Again, while there are several ways to implement this guidance control, this section discusses the guidance algorithms implemented on the SLUGS autopilot (Lizarraga 2009). In order to deliver a mission to the UAV from the ground station, a simple set of GPS-based waypoints, along with an altitude and speed for each leg of the mission, is transmitted to the UAV via telemetry link. Furthermore, the interest

is in flying the aircraft on the trajectory, and thus the legs are blended into each other using circular arcs rather than forcing the UAV to overfly each waypoint. Note that this is a design choice, and both variants have a utility depending on the specific mission.

The SLUGS guidance algorithm is based on an extension of a simple line-of-sight guidance law originally developed for ground robotics. Much of the art of waypoint guidance consists of determining which leg of the trajectory the UAV is on and when to switch to the next leg of the trajectory.

The basic approach is to define a Serret-Frenet frame which points from the current waypoint to the next (\vec{T} , along the current leg), with one axis down and the third defined by the cross product between the along track, \vec{T} , and down, \vec{B} , unit vectors. The projection of the UAV position onto the \vec{T} direction is used to determine when to switch to the next leg. In practice this is better than using a distance from the next waypoint to switch (especially in very windy conditions).

18.4.1 General Tracking

The outer loop guidance law follows closely the work developed in Amidi and Thorpe (1991), Park et al. (2004), and Park et al. (2007). The original derivation is presented here for completeness. The guidance algorithm steers the velocity vector toward the line of sight; this is one form of pursuit guidance. Making the commanded acceleration proportional to $\sin \eta$ is only one of number of possible guidance laws. The basic guidance algorithm is to determine an aim point and steer the velocity vector toward it.

Referring to Fig. 18.16, V_g is the UAV's ground speed, and C is a circular arc of radius R that originates at the UAV and intercepts the desired path. L_1 is a constant look-ahead distance from the UAV to the path in the desired direction of travel. From elementary trigonometry:

$$\frac{|L_1|}{2} = R \sin \eta. \quad (18.32)$$

Fig. 18.16 Navigation control law geometry (Reproduction of Fig. 1 in Park et al. 2004)

Additionally, from elementary kinematics, it is known that the centripetal acceleration, a_c , required for a point mass to follow the circular arc C is given by

$$a_c = \frac{|V_g|^2}{R}. \quad (18.33)$$

Thus the UAV must command a lateral acceleration of a_c . Solving Eq. 18.32 for R and substituting it into Eq. 18.33 produces the following control law for commanded acceleration:

$$a_{cmd} = 2 \frac{|V_g|^2}{|L_1|} \sin \eta. \quad (18.34)$$

The only requirements for the implementation of this control law are to select the lookahead distance $|L_1|$ and determine $\sin \eta$, the sine of the angle from the velocity vector to L_1 . η is sometimes called the line of sight angle. Choice of $|L_1|$ is analogous to feedback gain, with a larger L_1 corresponding to smaller gains; $\sin \eta$ is found from the vector cross product of V_g and L_1 .

$$\sin \eta = \frac{|V_g \times L_1|}{|V_g||L_1|}. \quad (18.35)$$

For the UAV to actually track the desired trajectory, the lateral acceleration command must be converted to an appropriate bank angle command using the steady-state turn equation:

$$\phi_{cmd} = \tan^{-1} \frac{a_{cmd}}{g}. \quad (18.36)$$

18.4.2 Straight Line Tracking

The guidance algorithm is most easily described using a straight line (though it is certainly not limited to such). In Fig. 18.17, the UAV is following a straight line segment from waypoint P_0 to P_1 . A Serret-Frenet coordinate frame (Etkin 2005) is attached to the initial waypoint, P_0 , such that the calculations are always in local path coordinates.

Fig. 18.17 Geometry description of the angle η computation

$$\begin{aligned}
T &= [x_T, y_T, z_T] = \frac{(P_1 - P_0)}{|P_1 - P_0|}, \\
N &= \frac{1}{[[-y_T \ x_T \ 0]]} [-y_T \ x_T \ 0]^\top, \\
B &= T \times N.
\end{aligned} \tag{18.37}$$

Given that e_N is the the error in the N direction. Then

$$|e_N| = N^\top (P_{uav} - P_0), \tag{18.38}$$

E is the closest point on the path to the UAV. The intersection of L_1 with the desired path is shown by the point F . The down-track distance or EF separation, denoted D_{dt} , can be computed as

$$D_{dt} = \sqrt{|L_1|^2 - |e_N|^2}, \tag{18.39}$$

with the vectors E and F given by

$$E = P_{uav} - |e_N|N, \tag{18.40}$$

$$F = E + D_{dt}T. \tag{18.41}$$

From these relations, the vector L_1 can then be computed as

$$L_1 = F - P_{uav} = D_{dt}T - |e_N|N, \tag{18.42}$$

which is then used in Eq. 18.35 to determine η and hence the commanded acceleration. For sufficiently small tracking errors, the L_1 guidance looks like a PD controller on lateral error (Park et al. 2007).

18.4.3 L_2^+ Control

The SLUGS autopilot extends the L_1 pursuit guidance to account for some shortcomings of the control law (and for clarity refers to this as L_2^+ control). Firstly, it was noticed during flight test experiments that the L_1 guidance exhibited large overshoots when turning downwind (hence an increasing V_g). Analysis showed that in order to solve this, the new L_2 vector should be a function of ground speed. Thus, $|L_2| = \mathcal{T}^*|V_g|$, where \mathcal{T}^* is a constant and the commanded acceleration becomes

$$a_{cmd} = 2 \frac{|V_g|}{\mathcal{T}^*} \sin \eta. \tag{18.43}$$

Fig. 18.18 L_2^+ geometry

Furthermore, when the lateral error, $|e_N|$, is larger than $|L_2|$, the aim point cannot be found. To enforce that an aim point is always found, define a maximum intercept angle, γ_{\max} ; the down-track distance to the aim point defined by γ_{\max} is

$$D_{dt} = \frac{|e_N|}{\tan \gamma_{\max}}, \quad (18.44)$$

as shown in the lower aircraft in Fig. 18.18.

When $|e_N|$ is greater than $|L_2|$, such as during initial intercept, D_{dt} may become too large. For example, the aim point may go beyond the next waypoint. To prevent this a bound is placed on the down path distance of the aim point. This bound is set to be a constant, $\mathcal{M}_{\mathcal{DP}}^*$, times $|L_2|$:

$$D_{dt_{\min}} = \min(D_{dt}, |L_2| \cdot \mathcal{M}_{\mathcal{DP}}^*). \quad (18.45)$$

This is shown for the upper aircraft in Fig. 18.18. The down-track distance of the aim point is

$$D_{dt_{\min}}^* = \begin{cases} D_{dt_{\min}} & |e_N| > |L_2| \\ \max(D_{dt_{\min}}, \sqrt{|L_2|^2 - |e_N|^2}) & |e_N| \leq |L_2| \end{cases} \quad (18.46)$$

If the aim point gets beyond P_1 , the UAV will continue along this line without ever changing direction. First compute D_{wp1} , the along-track distance from the UAV to P_1 :

$$D_{wp_1} = T^\top (P_1 - P_{uav}). \quad (18.47)$$

This will be a negative number if the UAV is beyond P_1 . The distance from P_1 back along T to the aim point is

$$D_a = D_{wp_1} - D_{dt_{\min}}^*. \quad (18.48)$$

The final aim point P_a is then computed:

$$P_a = -T_1 \cdot \max(0, D_a) - P_{wp_1}. \quad (18.49)$$

The *max* operation ensures that the aim point does not extend beyond P_1 , i.e., if D_a ever becomes negative due to UAV position or failure of the waypoint switching logic, the acceleration command is then computed with Eq. 18.43, where the $\sin \eta$ is obtained from the cross product of V_g and P_a , Eq. 18.35.

Note that when the aircraft is initially pointed in the opposite direction from T , η is greater than 90° . In this case, a maximum lateral acceleration is imposed to return the vehicle to the correct flight path, where:

$$a_{\max} = g \tan \phi_{\max} \quad (18.50)$$

and ϕ_{\max} is the maximum bank angle permitted (typically set to 30 – 60° for a small UAV). In order to use the L_2^+ controller in this condition, a maximum allowable η is required:

$$\eta_{\max} = \min\left(\frac{\pi}{2}, \mathcal{T}_{LEAD} \frac{a_{\max}/2}{U_{\text{comm}}}\right) \quad (18.51)$$

where U_{comm} is the commanded airspeed from the inner loop controller, and \mathcal{T}_{LEAD} is the lead time required for the aircraft to roll out of a steep bank (and determined experimentally for the airframe).

18.4.4 Waypoint Switching

As previously stated, the guidance strategy is to move from one segment to the next of the flight mission by connecting the two segments with a circular arc. There are myriad ways to switch between segments; this is simply the one implemented on the SLUGS. The L_2^+ implementation uses a policy of early waypoint switching to prioritize path following instead of waypoint precision.

Let C be a circle of radius R given by

$$R = \frac{(U_c + |wind|)^2}{a_{\max}}. \quad (18.52)$$

Here U_c is the commanded airspeed, $|wind|$ is the windspeed, and a_{\max} is the maximum acceleration for the UAV. In the presence of wind the actual radius of

$$p = \mathcal{T}_{LEAD} \cdot |V_g| + \frac{R}{\tan \delta}. \quad (18.58)$$

Finally, the vector position of the switch point P_{sw1} is given by

$$P_{sw1} = P_1 - pT_1 \quad (18.59)$$

Note that during the transition from missions leg, the L_2 vector intercepts the circular arc, not the straight line segments. Also, depending on the exact geometry of the waypoints, and the aircraft speed, it may be that just after switching legs, the aircraft is already beyond the next segment switching point. In this case, the logic immediately switches again to the next leg.

18.4.5 Point Acquisition and RTB

One advantage of the L_2^+ controller is that it is quite robust. For instance, without any change in the logic, the same controller (with its commanded lateral acceleration/bank angle) can just as easily drive the UAV to a point as well as follow an arbitrary curve.

For the case of an acquisition point, P_a , the angle η is computed from the current UAV position and P_a :

$$\sin \eta = \frac{|V_g \times (P_a - P_{uav})|}{|V_g| |(P_a - P_{uav})|}. \quad (18.60)$$

Again with the limits of η_{\max} and downrange distance imposed to limit bank angle and lateral acceleration, implemented in Eqs. 18.33 and 18.36. This controller will essentially “point at the point” until it overflies the acquisition point, P_a , at which point the switch logic will cause it to circle the point. Of interest is that nowhere in the formulation does the point P_a have to be fixed; the same L_2^+ controller can track a moving target using its same logic assuming you have a position estimate of the target. Simulations have shown that for target speeds moving at or below the ground speed of the UAV, the UAV always acquires the target.

The *initial mission point*, P_I , before the first waypoint is determined using concept borrowed from instrument flying in which all aircraft must first fly to a well-defined point before proceeding to land. The initial point is determined by projecting a fixed point in front of the first leg of the mission a constant distance in front of the initial waypoint, Fig. 18.20:

Fig. 18.20 Initial point geometry

$$P_I = P_a = P_0 - T_1 \cdot (\mathcal{I}_P^* \cdot |L_2|) \quad (18.61)$$

where \mathcal{I}_P^* is simply a constant tuned to the specific aircraft.

Lastly, the L_2^+ controller implements a *return to base* (RTB) functionality by simply recording the original base position, P_b , and using this as the acquisition point if either the mission waypoints are completed or if communication to the UAV fails.

18.4.6 Simulation and Flight Test Results

The SLUGS autopilot has both a full simulation (based on MATLAB's Simulink) and a hardware-in-the-loop (HIL) simulation with the algorithms running on the SLUGS embedded hardware, while the aircraft is simulated through a full 6DOF model running on a separate computer. Figure 18.21 demonstrates the full L_2^+ running in simulation, showing the initial point, transitions, and a RTB at the end of the flight.

The SLUGS-based UAV, a small electric RC aircraft (Multex Mentor), was flown at UCSC, using both the inner loop control and outer loop guidance described above. Figure 18.22a shows the flight test results (Lizarraga 2009) in the presence of strong winds and real flight disturbances. Panel (b) shows the L_2 vector in real time as the aircraft transitions through the waypoints.

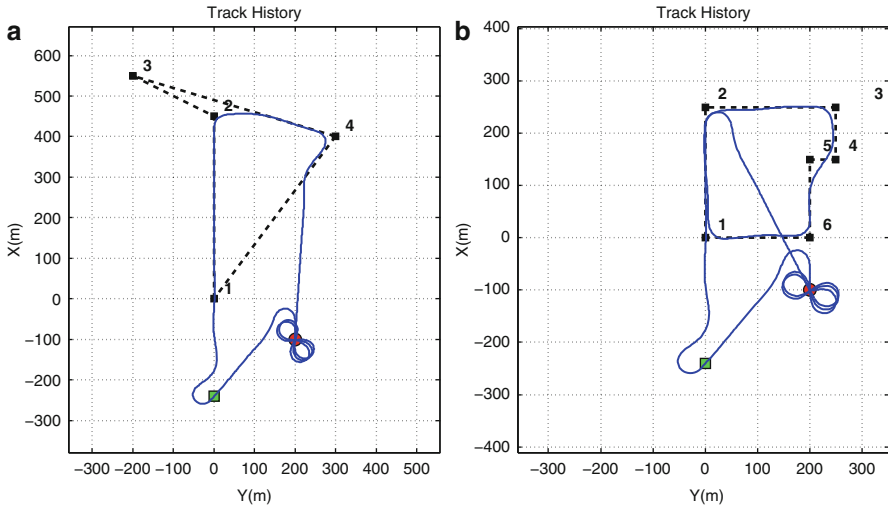

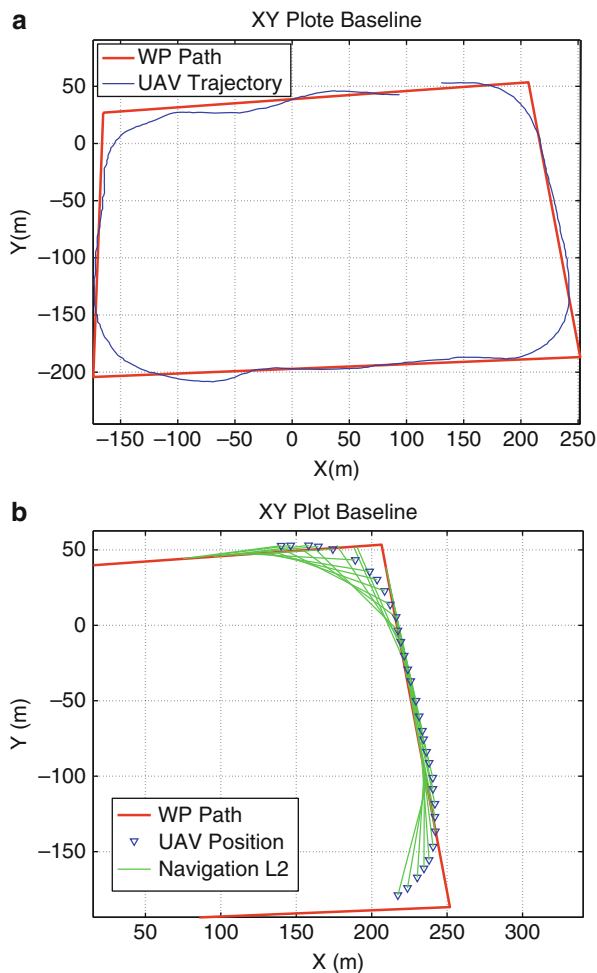

Fig. 18.21 Return to base implementation in two different waypoint paths. Both have an initial point (green square) and return to the base (red circle). Note the logic skips the waypoint 2 in (a) and waypoint 5 in (b)

Fig. 18.22 Flight data for the L_2^+ controller on the Mentor platform, showing path tracking performance in (a) and the evolution of the L_2 vector at the waypoint switches in (b)

18.5 Conclusion

In this chapter the complete system architecture for two UAV GNC solutions is described. The systems described a low-cost and easily reconfigurable solution which is intended to support research efforts associated with guidance, navigation, and control of small UAVs. The purpose of the description and discussion provided was to show how to implement (hardware and software) a low-cost GNC solution. It was not intended, however, to be the definitive GNC solution for small UAVs. Such solutions do not exist, and this fact was the impetus for writing this chapter. Size, weight, and power constraints associated with small UAVs preclude a “one size fits all” GNC solution. Thus, while the guidance, navigation, and control solutions presented in the chapter were suited for the two UAVs described and the mission

they were intended for (flight control and guidance research), it does not mean they are ideal for application based on other sensors, vehicles, or mission. However, they are flexible enough that they can be adapted to support other missions.

Section IV

Sensors and Sensing Strategies

Ben Upcroft and Salah Sukkarieh

Kimon P. Valavanis and George J. Vachtsevanos

Sensors and Sensing Strategies enable an unmanned aircraft to “sense,” “see,” “hear,” and “understand” the world around it so that it may function intelligently in an unknown and cluttered environment and in the absence of an onboard pilot. In essence, sensors and sensing strategies are crucial since they provide the technologies that will result in “unmanned aircraft operating as if there were a human pilot onboard.”

► [Sensors for Missions](#) by Mejias, Lai, and Bruggemann sets the tone for sensors used on UAVs that are assigned complex missions. The sensor suite onboard a UAV is tightly coupled with payload capabilities, as payload dictates UAV usability and market value. However, advances in miniaturization of electronics are enabling replacement of multiprocessing, power-hungry general-purpose processors with more integrated and compact electronics that contribute to more onboard sensors. Several common payload sensors are described along with their usefulness to solve real-world problems.

► [Inertial Sensor-Based Simultaneous Localisation and Mapping for UAVs](#) by Bryson and Sukkarieh provides an overview of algorithms for inertial sensor-based simultaneous localization and mapping (SLAM) within the context of UAVs, using the extended Kalman filter (EKF) and the extended information filter (EIF) due to their ease of understanding, applicability to online implementation, and prevalence in airborne localization applications outside of SLAM.

► **UAV Localisation Using Inertial Sensors and Satellite Positioning Systems** by Bryson and Sukkarieh provides an overview of UAV localization with a focus on aided inertial localization, that is, algorithms for fusing data from, for example, satellite positioning systems, barometric sensors, and magnetometers with inertial sensors to provide real-time position and orientation. An example implementation of aided inertial localization on a UAV is presented as a tutorial to understand key concepts in airborne localization and as a basic guide toward more complicated implementations.

► **Data Fusion and Tracking with Multiple UAVs** by Ridley, Upcroft, and Sukkarieh describes decentralized data fusion (DDF) algorithms for a team of multiple autonomous platforms. It is shown how through the DDF algorithms each platform can maintain a consistent global solution from which decisions may be made. The overall system design is detailed, providing insight into the overall complexity of implementing a robust DDF system for use in information-gathering tasks in outdoor UAV applications.

Collectively, after reading and understanding the first four sections of the handbook, the reader, novice, or expert will be ready to continue with the actual control of UAVs and all other more advanced technical aspects.

Abstract

An onboard payload may be seen in most instances as the “Raison d’Etre” for a UAV. It will define its capabilities, usability and hence market value. Large and medium UAV payloads exhibit significant differences in size and computing capability when compared with small UAVs. The latter has stringent size, weight, and power requirements, typically referred as SWaP, while the former still exhibit endless appetite for compute capability. The tendency for this type of UAVs (Global Hawk, Hunter, Fire Scout, etc.) is to increase payload density and hence processing capability. An example of this approach is the Northrop Grumman MQ-8 Fire Scout helicopter, which has a modular payload architecture that incorporates off-the-shelf components. Regardless of the UAV size and capabilities, advances in miniaturization of electronics are enabling the replacement of multiprocessing, power-hungry general-purpose processors with more integrated and compact electronics (e.g., FPGAs).

The payload plays a significant role in the quality of ISR (intelligent, surveillance, and reconnaissance) data, and also in how quickly that information can be delivered to the end user. At a high level, payloads are important enablers of greater mission autonomy, which is the ultimate aim in every UAV.

This section describes common payload sensors and introduces two cases in which onboard payloads were used to solve real-world problems. A collision avoidance payload based on electro optical (EO) sensors is first introduced, followed by a remote sensing application for power line inspection and vegetation management.

20.1 Introduction

There are two main categories of payloads onboard a UAV: those that allow the vehicle to navigate and those that allow the vehicle to perform its main task. The distinction between them is sometimes very subtle. In some cases, a payload aimed to perform a task can be used for navigation purposes (e.g., cameras), and navigation payloads may in some instances be integrated with other sensors to perform a specific task (e.g., GPS/INS with LIDAR). This section will describe common sensors that are used in many typical payloads onboard UAVs.

20.2 Navigation Sensors

At the core of most UAV guidance and navigation systems, one can find Global Navigation Satellite Systems (GNSS) (including the Global Positioning System – GPS) and Inertial Navigation Systems (INS). Their complementary nature has been recognized, and as a result, GPS and INS sensors are the preferred sensor couple for the majority of autopilot systems.

The integration of GPS and INS is without doubt the area in which researchers have spent considerable efforts proposing approaches such as uncoupled integration, loosely coupled integration, tightly coupled integration, and deeply coupled integration (Grewal et al. 2007). GPS and INS are not the only two sensors used for navigation. They can be complemented with altimeters (laser-based, barometric, etc.) to enhance the estimation of the vehicle state. Additionally, infrared attitude sensors are typically found in micro UAVs. Recently in Cao et al. (2010), a survey of UAV autopilot alternatives and typical sensor combinations was presented.

At the heart of the integration scheme lies a estimator (usually a form of Kalman filter) which estimates position, velocity, attitude, GPS errors and inertial sensor errors. Due to their complementary nature, GPS and INS are often the preferred core sensor suite. However, researchers have also investigated the integration of other sensor combinations, such as GPS with computer vision (Dusha et al. 2011; Wein et al. 2011; Dusha and Mejias 2012) and INS with computer vision (Merz et al. 2006). Additionally, factors such as the trade-off between cost and accuracy

of INS sensors and the susceptibility of GPS to spoofing and jamming have also contributed to increased interest in alternative sensor combinations.

While alternative integration schemes using other sensors is an attractive option, the low cost and future navigation availability and integrity that Space-Based Augmentation Systems (SBAS) such as WAAS, EGNOS, GAGAN, and MSAS will provide cannot be ignored. Submeter accuracy for civilian users will also be possible with the commissioning of Galileo, Compass, and the modernization of GLONASS. This in turn will encourage interoperability and the possibility of a triple-frequency civilian-band GPS over the next decades.

20.2.1 Electro-Optical (EO)

Nowadays, it is difficult to realize a UAV without an EO sensor. They have become standard fit-out onboard many aerial vehicles. The challenge is now in the processing and interpretation of the information acquired by EO sensors. Perception through EO sensors can be seen as one of the most important tasks in a UAV. Whether it is performed for navigation or for surveillance (as an end application), it defines the necessary peripherals to process the EO data. This section will introduce some of the most common EO sensors typically found in UAVs.

20.2.1.1 Visible Spectrum

A visible-spectrum camera operates about 390 nm (3.9 μm)–750 nm (7.5 μm) wavelength. These cameras can be found in two main categories: digital still cameras and machine vision cameras (including surveillance and webcam). Digital still cameras offer very high resolution, but cannot provide a continuous stream of images. The amount of images they can provide usually depends on the amount of internal memory. This type of camera sees application in remote sensing and aerial photography. Machine vision cameras have relatively lower resolution but can provide a continuous stream of images up to a few hundred frames per second. The speed is related with the resolution and output format used (digital or analog). They are suitable for processes or tasks that require very fast perception of environment. Common output protocols and interfaces for machine vision cameras include IEEE 1394, Camera Link, SD/HD Analog, USB, GigE Vision, and in coming years Thunderbolt cameras.

They can provide color or gray level (or both) images. The data representation or color space usually varies from one manufacturer to another. Typical color spaces or models used in most machine vision cameras are RGB, YUV, YPbPr, and YCbCr, etc.

Regardless of its end use and camera type, camera geometric models are necessary. They provide parameters that are needed to correct lens distortions, perform the mapping or representation of 3D objects onto the 2D surface called *image*, and overall allow manipulation of the data acquired by these devices. These parameters are normally estimated through a calibration process that is regularly

performed. For more details on camera models and calibration theory, refer to Forsyth and Ponce (2002) and Szeliski (2011).

20.2.1.2 Infrared

An infrared (IR) camera is a device that detects and converts light in the same way as common visible-spectrum cameras, but is sensitive to light at longer wavelengths. They form an image using infrared radiation in the spectrum at wavelengths from 5,000 nm (5 μ m) to 14,000 nm (14 μ m). Infrared cameras are used to convey a measure of thermal radiation of bodies. The intensity of each pixel can be converted for use in temperature measurement, where the brightest parts of the image (colored white) represent the warmest temperatures. Intermediate temperatures are shown as reds and yellows, and the coolest parts are shown in blue. Often, IR images are accompanied by a scale next to a false color image to relate colors to temperatures. The resolution of IR cameras (up to a maximum of 640×480 pixels) is considerably lower than the resolution of optical cameras. Furthermore, the price of IR cameras is considerably higher than their visible-spectrum counterparts.

Infrared cameras can be categorized in two main groups:

Cooled Infrared Detectors

Cooled IR detectors are normally inside a vacuum-sealed container that is cryogenically cooled. Cooling is needed for the efficient operation of the semiconductor used. Typical operating temperatures (in Kelvin degrees (K)) range from 4 to 293 K. Most modern IR detectors operate in 60–100 K range. The operating temperature is related with the type of technology used and performance expected. Cooled infrared cameras provide superior image quality compared to uncooled ones. They provide greater sensitivity that allows the use of higher F-number lenses, making high-performance long focal length lenses both smaller, and cheaper for cooled detectors. The drawbacks of cooled infrared cameras are that they are expensive both to produce and to run. Cooling is power hungry and time consuming. A camera may need several minutes to cool down before it can begin working.

Uncooled Infrared Detectors

This type of camera use sensors that are at or close to room temperature. For this reason, they do not require bulky, expensive cryogenic coolers, and therefore are smaller and cheaper than cooled ones, but with the drawback that their resolution and image quality tend to be lower than cooled detectors. This is due to a difference in their fabrication processes, limited by currently available technology.

Given the ability of IR cameras to reveal the hidden world not perceived by the human eye or visible-spectrum camera, they see application in tasks that are visibly challenging such as night vision or bad weather scenarios, inspection tasks, surveillance (bushfire monitoring), search, and rescue.

20.2.1.3 Hyperspectral Imaging

Sensors in this category acquire image data simultaneously in multiple adjacent spectral bands. This gives a wealth of data, but its processing and interpretation

require good knowledge of what specific properties are to be measured and how they relate to the actual measurement made from the sensor. For example, a single cell position in an image will have a set of brightness (or intensity) levels for each wavelength (spectral band). Different materials under examination by a hyperspectral sensor will often exhibit different intensity versus wavelength relationships. Hence, with some prior knowledge, hyperspectral image data can be useful for identifying the type or composition of materials.

Cost and complexity are the two major drawbacks of this technology. Storage is another limiting factor given the multidimensional nature of hyperspectral datasets. The availability of graphics processing units (GPU) as powerful parallel processing hardware could bring this technology a step closer to widespread adoption. However, further research efforts are needed to create analytical techniques and algorithms to unleash the full potential of hyperspectral imaging.

20.2.2 Radio-Wave Sensors

20.2.2.1 Airborne Radio Detection and Ranging (Radar)

Radar is a radio system used to determine range, altitude, direction, or speed of objects. The system transmits controlled radio pulses which are reflected back by objects. The distance to objects is estimated by measuring the signal return time. The received power declines as the fourth power of the range, assuming transmitting and receiving antennas are in the same location, hence the need for high transmitting power in most cases. Speed can be estimated by tracking the change in distance with time or by exploiting the Doppler effect (Stimson 1998).

Airborne radar has been in operation since WWII, and can be considered as an integral part of systems such as Ground Proximity Warning Systems (GPWS) or TCAS. In the automotive industry, radar is starting to appear in the form of collision warning systems (www.ford.com).

In a UAV context, the main drawback of radar is the high power consumption. The size, weight, and power (SWaP) challenges that are faced by UAVs are well known. However, new systems such as Synthetic-Aperture Radar (SAR) (Soumekh 1999) are beginning to make radar technology a feasible option onboard UAVs (Hanlon 2008).

20.2.2.2 Light Detection and Ranging (LIDAR)

LIDAR operates in a similar manner to radar, in that it can estimate distance by measuring the time of return of a signal reflected from an object. LIDARs have been widely used in atmospheric and meteorology research (Couch et al. 1991; Kiemle et al. 1997) and remote sensing (Dubayah and Drake 2000; Lefsky et al. 2002). Given its ability to provide very high definition (under 2.5 cm (Terranean 2011)), LIDAR has become a common sensor for mapping and infrastructure inspection (Yuee et al. 2009).

However, LIDAR shares many of the SWaP obstacles that are faced by radar technology. Hence, LIDARs are not often found in micro/small size UAVs, but have been flown in light general aviation aircraft (Ara 2011). Recent advances in technology have been made, an example of which is the Riegl LMS-Q160 LIDAR in <15 kg and 60 W range (Riegl 2011), which is paving the path for the use of LIDARs in smaller UAVs in the future.

The pace of innovation seems to be accelerating lately. Perhaps this is a result of the challenging economy, but without doubt, the miniaturization of electronics and the availability of small, power-efficient and computationally capable hardware will facilitate the adoption of UAVs in many civilian contexts.

20.3 Applications

20.3.1 Collision Avoidance

A sense-and-avoid capability equivalent to the human pilot see-and-avoid is one of the key prerequisites for UAVs gaining routine access to civil airspace. Sense-and-avoid begins with the detection of potential conflicting air traffic, and as a result, considerable research and development has been dedicated to addressing the “sensing” aspect of sense-and-avoid.

An important design choice in the development of sensing and detection systems is the type of sensor used to collect information about the surrounding environment; this is a choice that must account for the physical and resource limitations of the UAV platform and has implications for the target detection algorithms and other data processing techniques that are employed. Furthermore, the cooperative or uncooperative nature of the system will have also an impact in the choice of sensors. Cooperative implies that all vehicles in the air share information through common communication links. Uncooperative denotes the issue that vehicles in the sky do not communicate with each other and therefore implies that there is no other way to detect other vehicles than a self-contained passive detection system.

20.3.1.1 Vision-Based Collision Avoidance

Electro-optical (EO) sensors possess a unique combination of characteristics that make them an attractive sensor type to utilize in the sense-and-avoid application. The passive means by which EO sensors obtain information about the environment allows EO-based sense-and-avoid systems to detect other aircraft regardless of their onboard equipment. In contrast, the Traffic Alert and Collision Avoidance System (TCAS) is an active sensing approach that relies on the presence of transponder equipment onboard other aircraft (FAA 2000). Robustness against noncooperative threats is one of the key advantages of an EO sensing approach.

The maturity of EO sensor technology is also at a stage suitable for the UAV sense-and-avoid application. The current state-of-the-art EO sensors tend to be compact, light, and low power (due to their passive nature of operation), allowing them to be operationally feasible even in relatively small UAV platforms with

conservative size, weight, and power (SWaP) budgets. Furthermore, sensors supporting high-speed IEEE 1394 and IEEE 802.3-2008 (Gigabit Ethernet) communication interfaces are readily accessible as commercial off-the-shelf (COTS) products and can easily facilitate real-time capture and transfer of image data at high resolutions. Currently, the market offers four preferred standards for transferring digital video signals from the camera to the image-processing computer or workstation, FireWire (IEEE 1394), USB 2.0, Gigabit Ethernet, and Camera Link. Although not covered in this section, analog interfaces have constituted the backbone of the imaging industry, as it is known it today. They are still present in analog video links in many UAVs payloads.

The information provided by EO sensors can be exploited for purposes other than the detection and localization of targets in the image plane. Relative bearing information derived from target location on the image plane can be used to evaluate the risk of collision (constant relative bearings correspond to high risk, whereas large variations in relative bearings correspond to low risk) (Angelov et al. 2008). Furthermore, range information useful for control purposes can be derived from a single sensor when combined with appropriate aircraft maneuvers (Karlsson and Gustafsson 2005).

An EO sensing approach offers many benefits, and studies have suggested that EO-based sense-and-avoid systems hold the greatest potential for gaining regulatory approval (Karthoff et al. 2006). However, there are also many challenges associated with an EO sensing approach. One of the most significant challenges lies in the unpredictable and constantly changing nature of the airborne environment. In particular, for visible light spectrum EO sensors, detection algorithms must be able to handle a variety of image backgrounds (from blue-sky to cloud and ground clutter), lighting conditions, and possibly image artifacts (e.g., lens flare).

Another factor to contend with when using an EO sensing approach is the presence of image jitter noise. Image jitter is caused by movement of the camera sensor and hence is exacerbated in an airborne environment where the platform is in constant motion and subject to unpredictable aerodynamic disturbances. For detection algorithms that exploit target motion dynamics in the image plane, image jitter represents an undesirable noise component that can have significant impact on performance (Utt et al. 2004; Lai et al. 2011a). Various jitter compensation techniques based on aircraft state information and image features have been proposed to reduce the effects of image jitter (but it cannot be completely eliminated).

Finally, it can also be a challenge to achieve real-time processing of EO sensor image data, given the computationally intensive nature of image-processing algorithms. However, this is gradually being overcome with the development of specialized parallel processing hardware (such as graphics processing units (GPU), field-programmable gate arrays (FPGA), and dedicated digital signal processors (DSP)). Several attempts have been made, aiming to characterize the performance of these specialized parallel processing hardware (Chase et al. 2008; Thomas et al. 2009), but their utility is highly dependent on the application and its degree of parallelization.

Over the past decade, government, university, and private research groups have demonstrated EO-based sense-and-avoid technologies of varying levels of sophistication (Lai et al. 2012). One of the most mature EO-based sense-and-avoid technology programs has been conducted by a partnership between Defense Research Associates, Inc. (DRA), the Air Force Research Laboratory (AFRL), and Aeronautical Systems Center (ASC) (Utt et al. 2004, 2005). Over a number of development phases, detection and tracking of noncooperative general aviation aircraft to a range of approximate 7 nautical miles has been demonstrated onboard an Aerostar UAV. The program aims to ultimately provide a combined cooperative and noncooperative collision avoidance capability for seamless integration onto Department of Defense platforms.

Concurrently, the Australian Research Centre for Aerospace Automation (ARCAA) has been undertaking a program to develop a cost-effective vision-based sense-and-avoid system for civilian UAV applications (Lai et al. 2011a,b). Extensive air-to-air target image data as well as nontarget data has been collected to characterize the detection range and false alarm performance of the proposed detection subsystem. Furthermore, closed-loop flight trials have been conducted, demonstrating the ability of the prototype system to automatically detect intruder aircraft and command the host aircraft autopilot to perform avoidance maneuvers. These development programs and other studies over the past decade have advanced the knowledge and understanding of trade-offs between EO sensor parameters (such as camera field of view) and system performance measures (such as detection range, detection probability, and false alarm rate) to a large extent. For example, many studies have shown that, in general, increasing the field of view reduces detection range and vice versa (Geyer et al. 2009; Lai et al. 2012).

However, the knowledge so far gained is far from complete, and more research and experimentation is required to determine the design trade-offs that will allow an EO-based sense-and-avoid system to demonstrate an equivalent level of safety to human pilot see-and-avoid. Figure 20.1 presents two examples of images taken from an onboard collision avoidance system.

20.3.1.2 Collision Avoidance Using Traffic Alert and Collision Avoidance System (TCAS)

TCAS is a system designed to reduce the incidence of air-to-air collisions and hence improve overall aircraft safety. TCAS was originally designed for manned aviation; however, its adoption for unmanned aviation is feasible and will be dictated by the degree of integration of UAVs in the civil airspace. However, its current cost (between \$25,000 and \$150,000) might prevent widespread adoption of TCAS in the UAV sector. TCAS consists of electronics that generate and interpret radio signals of the transponders from nearby aircraft. TCAS can provide auditory alarms and visual information through cockpit displays. The capabilities of the system in terms of the type of information provided to pilots and the conflict resolution strategies employed are defined by the TCAS generation (e.g., TCAS I or II). TCAS can provide *Traffic Advisories* (TA) that warn pilots of aircraft flying in the vicinity. Furthermore, the system can issue *Resolution Advisories* (RA) that suggest actions

Fig. 20.1 Images example of EO target detection taken from a collision avoidance system onboard a Cessna 172 (Greer et al. 2010). Detected aircraft is highlighted by the rectangular boxes (large box is zoomed version for clarity)

the pilot should follow to avoid a collision. These might be corrective or preventive, depending on whether a deviation in course is suggested or not, respectively. For full technical details and capabilities of TCAS, readers are referred to Harman (1989) and FAA (2000).

TCAS can only be fully effective as a means for collision avoidance if it is equipped in all aircraft in any given airspace, as one might expect with any cooperative collision avoidance system.

20.3.1.3 Automatic Dependent Surveillance-Broadcast (ADS-B) for Collision Avoidance

ADS-B is a relatively new technology that offers great promise for collision avoidance. ADS-B is not restricted to air-to-air surveillance (unlike TCAS), as it can also be utilized in air-to-ground communications with the potential to replace secondary surveillance radars. It resembles TCAS in the way that radio signals are used to transmit and receive information from nearby aircraft. One important and distinctive feature of ADS-B is the type of information exchanged. Each

aircraft would have the capability to share messages including 3D position, speed, heading, time, and intent. This information is highly valuable in the design of collision avoidance systems. However, ADS-B is often criticized for its excessive verbosity, which is not always necessary for collision avoidance. The high volume of information exchanged in ADS-B limits the number of aircraft that can use the system in a given time due to channel data bandwidth constraints. Nonetheless, the affordability of ADS-B will continue to motivate future research and development into its application for UAVs (Lai et al. 2009).

There are ADS-B systems already in the market for under U.S. \$3,000 (Kunzi 2009; NavWorx 2011). A detailed description of ADS-B systems, including its operational capabilities, can be found in RTCA (2002).

20.3.2 Remote Sensing: Power Line Inspection and Vegetation Management

Power line infrastructure is a large and costly asset to manage, costing many millions of dollars per year. Inspecting the power lines for failures (or worn, broken parts) and vegetation encroachment is a significant task particularly for electricity companies such as Ergon Energy who manages one of the largest networks in the world, consisting of over 150,000 km of power lines covering an area of 120,000 km² of Queensland, Australia (Li et al. 2012).

Traditionally, power line inspection is carried out by manned crews visiting the power lines by ground vehicle. However, this is time consuming, and due to terrain or proximity limitations, this task can be difficult. Unpiloted aircraft is an ideal technology for streamlining the inspection task carried out by ground crews. UAVs can achieve similar results to ground inspection but with greater efficiency. In many cases, UAVs can gain visibility of power lines in difficult locations which are inaccessible by ground vehicle.

Alternatively, inspecting power lines with a manned aerial inspection aircraft involves precise flying at low altitude above the infrastructure to be inspected. This is a potentially hazardous task for a human pilot due to fatigue from sitting in aircraft for long periods of time and the intense concentration and effort required to ensure that the infrastructure to inspect is within the sensor swath or field of view (usually LIDAR and high-resolution camera) (Li et al. 2012). A LIDAR and camera combination provides excellent sources of data with complementary characteristics. However, LIDAR data files are large due to the amount of data it can capture, often in the order of hundreds of Gigabytes or more. The processing of LIDAR captured by UAV is an important task which currently must be done after flight missions.

A future avenue is to perform LIDAR processing onboard the aerial vehicle. Processing may be done by a number of techniques. During the processing, one of the tasks is to distinguish the wanted feature from unwanted features in the data. For example, trees, building, and other obstacles which are not near the power line infrastructure are unwanted. Information such as the precise height, location

Fig. 20.2 Typical infrared image with 10 cm spatial resolution taken from an aircraft onboard camera (image courtesy of Ergon Energy and the Cooperative Research Centre for Spatial Information (CRCSI))

of power lines and their displacement from potentially hazardous objects such as vegetation (which may start bushfires) is among some of the wanted data to be extracted.

LIDAR and images (IR or visible spectrum) might be combined to provide a comprehensive analysis of the area under examination. Figure 20.2 shows a typical infrared image taken from an aircraft. Vegetation and other objects are clearly distinguishable; this facilitates the identification of potentially dangerous vegetation (in the vicinity of power lines). Image data can be combined in a multilayered processing approach with other sources of information as depicted in Fig. 20.3. Here, an image (top left) has been used to detect power lines, creating a region of interest around the lines; the same image after georeferencing is then merged with LIDAR data (top right) to improve feature detection rates. Typical LIDAR data representation can be seen in the middle, while in the bottom, an example representation of the merged data can be observed.

Because the task requires tracking of linear infrastructure from the air (not merely enroute waypoint-to-waypoint navigation), specialized UAV control systems may be required (Bruggemann and Ford 2011; Bruggemann et al. 2011; Li et al. 2012). Without a human pilot to control the aircraft, the stabilization and control of the platform such that the assets to be inspected fall within the field of view of the LIDAR or EO sensor becomes more challenging. The control system must also maintain steady altitude and speed as per LIDAR/camera scan/frame rate and swath/field-of-view requirements. Also, accurate spatial knowledge of the power-line infrastructure to be tracked is required, and the UAVs own flight management, navigation, and sensing systems must be capable for the task.

Fig. 20.3 Example of data merging image and LIDAR (Source data courtesy of Ergon Energy and the Cooperative Research Centre for Spatial Information (CRCSI))

However currently, there are a number of outstanding challenges impeding the use of UAVs for power line inspection. The UAV has to be dynamically capable to fly at low altitudes in windy or turbulent conditions and be able to carry a sizeable navigation and sensor payload system (including onboard power and LIDAR/image data storage systems) while keeping the UAV steady while flying over the power line infrastructure.

Intuitively, this means the UAV must be of reasonably large size. This is for a number of reasons. Firstly, unless the sensor payload can compensate for unwanted dynamic motion, there is a requirement for stable flight over the power lines. This means many small to medium UAVs which are sensitive to wind and turbulence at low altitudes are not suitable. Secondly, the size of the LIDAR/camera sensor payloads to capture fine details (such as tree branches and leaves, wires, and bolts) is quite large (can be in the order of 80 kg weight and of large volume). This also rules out many smaller UAV platforms. Thirdly, the use of a large UAV in civilian airspace weighing 100 kg or more presents its own technical, legal, and regulatory challenges to overcome. In future, smaller and lighter LIDAR/camera sensor payloads that have the required resolutions for power line inspection could help to facilitate the use of smaller UAV platforms for this task. This application illustrates the important coupling between the UAV platform and the sensor payload.

Conclusion

This chapter has outlined some of the most common payloads for civilian applications. Two examples of the use of sensors for missions such as collision avoidance and remote sensing were presented also. These are two examples of experimental use of sensors for civilian mission. Collision avoidance represents one of the critical capabilities for UAVs in order to allow these systems to routinely perform missions in shared airspace. In a civilian context, the remote sensing field is considered as the one that can benefit the most for UAV technology.

However, the establishment of UAVs in the civilian arena will be dictated by how the regulators define and establish requirements and guidelines for UAVs. This will affect similarly payload manufacturers, UAV manufacturers, and UAV service providers.

Overall, the UAV sector is increasingly demanding sensors that can provide more onboard autonomy, less unnecessary weight, and more ISR capabilities without an exponential increase in costs or weight. Applications such as ISR will require or emphasize sensors like cameras or signal intelligence receivers, robust radio relay, etc. Commercial payloads will emphasize very high data rate communications and sensors such as visible light and multispectral (hyperspectral) cameras.

In the near future, enduring and persistent UAVs flying for days, months, or years at high altitude will require a completely new approach to design and manufacture of payloads. These new payloads will form new communications and sensing infrastructures. UAVs flying in the upper atmosphere will behave much like satellites, but with the clear advantage that if something goes wrong the vehicle might be commanded to land, at the same time that its replacement is sent to continue the mission. This capability will be very difficult to replicate in traditional satellites. Hence, the gain is using UAVs for missions traditionally assigned to satellites.

Abstract

This chapter provides an overview of algorithms for inertial sensor-based Simultaneous Localization and Mapping (SLAM) within the context of Unmanned Aerial Vehicles (UAVs). The presentation in this chapter is based on the use of the Extended Kalman Filter (EKF) and the Extended Information Filter (EIF) due to their ease of understanding, applicability to online implementation, and prevalence in airborne localization applications outside of SLAM (such as aided inertial localization). The discussion here includes an examination of SLAM for both small- and large-scale operation over the surface of the Earth, inertial SLAM using both range-bearing and bearing-only observations of the terrain, and a look at several different centralized and decentralized architectures for performing multi-vehicle SLAM.

21.1 Introduction

Simultaneous Localization and Mapping (SLAM) is the process of determining the position and orientation of a moving platform within an environment, while also building a map of the environment, primarily using observations of environmental features measured from and with respect to the moving platform. Since the seminal work by Smith et al. (1990), there have been several demonstrated implementations of SLAM using land (Bosse et al. 2003; Gutmann and Konolige 1999; Dissanayake et al. 2001; Guivant and Nebot 2001; Thrun and Lui 2003b) and underwater vehicles (Williams et al. 2001; Olson et al. 2004) where two-dimensional, horizontal localization and mapping is performed. In each of these implementations, SLAM involves the fusion of two particular sets of information usually coming from sensors onboard the vehicle; firstly the vehicle uses exteroceptive sensors to sense the terrain/landmarks relative to the vehicle (such as vision, laser, and radar sensors), and secondly the vehicle uses proprioceptive sensors and information to sense its own motion (such as wheel encoders, inertial sensors, and vehicle model information such as holonomic/nonholonomic constraints).

In the context of Unmanned Aerial Vehicles (UAVs), where the platform undergoes rapid six degree-of-freedom (6-DoF) motion, inertial sensors are a logical choice for the proprioceptive core of a SLAM implementation, due to their high frequency of information and ability to track platform motion in 6-DoF without relying on external information such as a vehicle dynamic model. Exteroceptive sensors (i.e., terrain sensors) come in a variety of forms depending on the application, including RADio Detection And Ranging (RADAR), LIght Detection And Ranging (LIDAR), and electro-optical sensors such as cameras. Such sensors provide a variety of different observations of the terrain including range and bearing to features and bearing-only observations of features (i.e., camera images), necessitating SLAM algorithms that account for this variability.

The utility of SLAM in the context of UAV operations can be considered from both a localization and a mapping perspective. Traditionally, airborne localization has relied on external navigation aids such as satellite/radio positioning

systems (i.e., the Global Positioning System (GPS)) or terrain/landmark maps (i.e., in terrain-aided navigation systems (TANS)). SLAM allows for intermittent localization when external navigation aids fail due to, for example, satellite signal occlusion/jamming or when operating over unknown terrain, thus improving localization system robustness. During mapping and surveying tasks, a UAV uses terrain observations (e.g., aerial photography) along with information about the UAV's own position and orientation at the time of the observation to construct a map. Consistent and accurate mapping relies on accounting for the correlation between the errors in multiple features in the map, induced by a common error in the estimate of the platform's position and orientation; SLAM maintains these relationships, computing a joint estimate of the localization and mapping states, improving accuracy in the platform's localization estimates and thus in the final map. Large-scale mapping tasks may also necessitate the use of multiple aerial platforms; algorithms for multi-vehicle inertial SLAM are a natural extension of the single-vehicle case where shared map information can be used to assist in localization across platforms and to build more accurate maps than achievable with a single UAV.

This chapter provides an overview of algorithms for inertial sensor-based SLAM within the context of UAVs. The presentation in this chapter is based on the use of the Extended Kalman Filter (EKF) and the Extended Information Filter (EIF) due to their ease of understanding, applicability to online implementation, and prevalence in airborne localization applications outside of SLAM (i.e., aided inertial localization, see Giovanni 1979; Bar-Itzhack et al. 1982; Meyer-Hilberg and Jacob 1994). The discussion here includes an examination of SLAM for both small- and large-scale operation over the surface of the Earth, inertial SLAM using both range-bearing and bearing-only observations of the terrain and a look at several different centralized and decentralized architectures for performing multi-vehicle SLAM. Section 21.2 provides an overview of the equations of motion and sensor models used in inertial SLAM with an examination of the issue of SLAM in both global and local coordinate systems and how this affects the way in which inertial SLAM is implemented. Section 21.3 examines the structure of the inertial SLAM algorithm when terrain observations are made using a range/bearing sensor. Section 21.4 examines a special case of inertial SLAM when only bearing observations of the terrain are available, such as in the case of electro-optical sensing. Section 21.5 examines the inertial SLAM algorithm when applied to multiple vehicles where vehicles share map information with each other.

21.2 Inertial SLAM Sensor Equations

The inertial SLAM algorithm is formulated using an EKF and uses information from inertial sensors and from feature observations from onboard terrain sensors in order to estimate the vehicle's position, velocity, attitude, inertial sensor biases, and map feature locations. The algorithm works on a two-stage process of state prediction (where equations for predicting the vehicle states from inertial sensor data are used)

Fig. 21.1 Vectors and frames of reference in the inertial SLAM algorithm. The Earth-Centered, Earth-Fixed (ECEF) frame (e), local-level navigation frame (n), body-fixed frame (b), and sensor-fixed frame (s) and the relationship between the vehicle position (p^n, p^e), feature position (m^n, m^e), and sensor observation are shown. Also shown is the observation of a terrain feature coming from an example terrain sensor (in this case a vision camera)

and state observation/update (where equations describing the geometry of terrain feature observations are used).

This section describes the background equations behind inertial sensor-based SLAM algorithms, including equations of motion for inertial localization and sensor equations for terrain-observing sensors. Figure 21.1 illustrates the relevant relationships between the frames of reference and vectors used in the SLAM algorithm. The structure of the process and observation model equations for both global and local SLAM is discussed in the following subsections.

21.2.1 Global Vs. Local SLAM

Localization and mapping tasks vary in environmental scale depending on the application. Some tasks require knowledge of the location of each feature in the map with respect to global co-ordinates (such as an ECEF coordinate system (see Fig. 21.1)). This form of localization and mapping requires external information either in the form of global position information (such as from GPS) or global map information (i.e., the global position of one or more features in the map). Other

tasks may only require a map of the environment in which the positions of features are known only with respect to one another or with respect to the starting location of the vehicle, a task which when using SLAM does not require external map or navigation aids.

These two forms of SLAM are referred to as “global SLAM” or “local SLAM” depending on whether map and location information must be referenced to a global coordinate system or merely and local arbitrary coordinate system (such as the starting position of the UAV). This issue is particularly important when using inertial sensors as inertial localization relies to some degree on global information about the local coordinate system’s motion with the rotation of the Earth. Local SLAM using inertial sensors is therefore only possible when certain assumptions are made which treat the local map coordinates as an inertial frame of reference by ignoring the effect of the Earth’s rotation.

21.2.2 Inertial Localization and SLAM Process Model Equations

The presentation here begins by considering the process model equations from a global SLAM perspective. In this case, the location of the vehicle and the terrain is estimated with respect to the center of the Earth. The estimated state vector $\hat{\mathbf{x}}(k)$ at time step k in this case contains the three-dimensional vehicle position (\mathbf{p}^e), velocity (\mathbf{v}^e) and Euler angles ($\Psi^n = [\phi, \theta, \psi]^T$), IMU sensor biases ($\delta \mathbf{f}^b$ and $\delta \omega_{ib}^b$), and the N three-dimensional feature locations (\mathbf{m}_i^e) in the environment:

$$\hat{\mathbf{x}}(k) = [\mathbf{p}^e(k), \mathbf{v}^e(k), \Psi^n(k), \delta \mathbf{f}^b(k), \delta \omega_{ib}^b(k), \mathbf{m}_1^e(k), \mathbf{m}_2^e(k), \dots, \mathbf{m}_N^e(k)]^T \quad (21.1)$$

where $i = 1, \dots, N$, the superscript e indicates Earth-Centered, Earth-Fixed (ECEF) frame referenced vectors, the superscript b indicates body-fixed frame referenced vectors and the superscript n indicates the Euler angles Ψ^n parameterize the body-fixed to local navigation frame Direction Cosine Matrix (DCM) transformation \mathbf{C}_b^n (see Chapter 3 of this book for details on frames of reference). Figure 21.1 illustrates the relevant relationships between the frames of reference and vectors used in the SLAM algorithm.

Euler angles are used to represent the attitude of the platform rather than quaternions in order to reduce the number of parameters in the estimator. It is assumed that the vehicle’s pitch angle is constrained so as to avoid the Euler angle singularity at $\theta = 90^\circ$; however, the process model could be adapted to implement quaternions for the parameterization of \mathbf{C}_b^n in the event that the platform motion is not constrained in such a way.

The state estimate $\hat{\mathbf{x}}$ is predicted forward in time by integrating the first-order nonlinear dynamic equation:

$$\dot{\hat{\mathbf{x}}}(t) = \mathbf{F}_c[\hat{\mathbf{x}}(t), \mathbf{u}(t)] + \mathbf{G}_c[\mathbf{w}(t)] \quad (21.2)$$

where $\mathbf{F}_c[.,.]$ is the continuous-time process model function, $\mathbf{G}_c[.]$ is the continuous-time input function, $\mathbf{u}(t)$ is the system input (which is comprised of inertial sensor readings), and $\mathbf{w}(t)$ is uncorrelated, zero-mean vehicle process noise vector of covariance \mathbf{Q} (which is comprised of inertial sensor noise errors). The process model equations for the vehicle position, velocity, and attitude are based on the 6-DoF inertial localization equations in which an Earth-frame mechanization (Titterton and Weston 1997) is applied:

$$\dot{\mathbf{p}}^e = \mathbf{v}^e \quad (21.3)$$

$$\dot{\mathbf{v}}^e = \mathbf{C}_b^e \hat{\mathbf{f}}^b - \mathbf{C}_b^e \delta \mathbf{f}^b - \mathbf{C}_b^e \mathbf{w}_{\text{accel}} - 2(\omega_{ie}^e \times \mathbf{v}^e) + \mathbf{g}_l^e \quad (21.4)$$

$$\dot{\Psi}^n = \mathbf{E}_b^n (\hat{\omega}_{ib}^b - \delta \omega_{ib}^b - \mathbf{w}_{\text{gyro}} - \mathbf{C}_n^b \omega_{ie}^n) \quad (21.5)$$

where ω_{ie}^e and ω_{ie}^n are the Earth's rotation rate vectors measured in the ECEF and local navigation frames, respectively:

$$\omega_{ie}^e = \begin{bmatrix} 0 \\ 0 \\ \omega_{\text{Earth}} \end{bmatrix} \quad (21.6)$$

$$\omega_{ie}^n = \begin{bmatrix} \omega_{\text{Earth}} \cos(\lambda) \\ 0 \\ -\omega_{\text{Earth}} \sin(\lambda) \end{bmatrix} \quad (21.7)$$

where λ is the latitude angle of the vehicle and $\omega_{\text{Earth}} = 7.292115 \times 10^{-5}$ rad/s is the rotation rate of the Earth. \mathbf{E}_b^n is the body to navigation frame rotation rate transformation matrix:

$$\mathbf{E}_b^n = \begin{bmatrix} 1 & \sin \phi \tan \theta & \cos \phi \tan \theta \\ 0 & \cos \phi & -\sin \phi \\ 0 & \sin \phi \sec \theta & \cos \phi \sec \theta \end{bmatrix} \quad (21.8)$$

\mathbf{g}_l^e is the local gravity term:

$$\mathbf{g}_l^e = \mathbf{g}^e - \omega_{ie}^e \times (\omega_{ie}^e \times \mathbf{p}^e) \quad (21.9)$$

$$= -g \begin{bmatrix} \frac{\mathbf{p}_x^e}{|\mathbf{p}^e|} \\ \frac{\mathbf{p}_y^e}{|\mathbf{p}^e|} \\ \frac{\mathbf{p}_z^e}{|\mathbf{p}^e|} \end{bmatrix} - [\times \omega_{ie}^e]^2 \mathbf{p}^e \quad (21.10)$$

where g is the acceleration acting on the vehicle due to gravity, referenced in ECEF coordinates and $[\times \omega_{ie}^e]$ is the skew symmetric matrix of the Earth's rotation rate vector. \mathbf{C}_b^n is the DCM transformation from the body to local navigation frame, and \mathbf{C}_b^e is the DCM transformation from the body to ECEF frame which are related via

$$\mathbf{C}_b^e = \mathbf{C}_n^e \mathbf{C}_b^n \quad (21.11)$$

$$\mathbf{C}_n^e = \begin{bmatrix} -\sin(\lambda) \cos(l) & -\sin(l) & -\cos(\lambda) \cos(l) \\ -\sin(\lambda) \sin(l) & \cos(l) & -\cos(\lambda) \sin(l) \\ \cos(\lambda) & 0 & -\sin(\lambda) \end{bmatrix} \quad (21.12)$$

where l is the longitude angle of the vehicle's position. The vectors $\hat{\mathbf{f}}^b$ and $\hat{\omega}_{ib}^b$ are the accelerometer specific force vector reading and gyroscope rotation rate reading, respectively (where $\mathbf{u}(t) = [\hat{\mathbf{f}}^b(t), \hat{\omega}_{ib}^b(t)]^T$), $\delta \mathbf{f}^b$ and $\delta \omega_{ib}^b$ are the accelerometer and gyro biases, respectively, and $\mathbf{w}_{\text{accel}}$ and \mathbf{w}_{gyro} are the accelerometer and gyro noise values. The true acceleration and rotation rates, \mathbf{f}^b and ω_{ib}^b , are defined:

$$\mathbf{f}^b = \hat{\mathbf{f}}^b - \delta \mathbf{f}^b - \mathbf{w}_{\text{accel}} \quad (21.13)$$

$$\omega_{ib}^b = \hat{\omega}_{ib}^b - \delta \omega_{ib}^b - \mathbf{w}_{\text{gyro}} \quad (21.14)$$

Accelerometer and gyro biases are known to fluctuate by very small amounts due to temperature changes and bias wander, particularly in low-cost IMUs. The accelerometer and gyro bias process models are given by

$$\delta \dot{\mathbf{f}}^b = \mathbf{w}_{b,\text{accel}} \quad (21.15)$$

$$\delta \dot{\omega}_{ib}^b = \mathbf{w}_{b,\text{accel}} \quad (21.16)$$

where $\mathbf{w}_{b,\text{accel}}$ and $\mathbf{w}_{b,\text{gyro}}$ are bias drift noises for the accelerometers and gyros, respectively. The complete noise vector $\mathbf{w}(t)$ for the process model based on errors from the IMU is composed:

$$\mathbf{w}(t) = [\mathbf{w}_{\text{accel}}(t), \mathbf{w}_{\text{gyro}}(t), \mathbf{w}_{b,\text{accel}}(t), \mathbf{w}_{b,\text{gyro}}(t)]^T \quad (21.17)$$

Finally, map feature locations are estimated in the ECEF frame and are also assumed to be constant as the state of the terrain is stationary and the process model of the i th feature is given by

$$\dot{\mathbf{m}}_i^e = \mathbf{0} \quad (21.18)$$

Equations 21.3–21.5, 21.15, 21.16, and 21.18 can also be expressed in discrete-time, recursive form by assuming a first-order Euler integration step:

$$\hat{\mathbf{x}}(k) = \mathbf{F}[\hat{\mathbf{x}}(k-1), \mathbf{u}(k), k] + \mathbf{G}[\mathbf{w}(k)] \quad (21.19)$$

where $\mathbf{F}[\cdot, \cdot, k]$ is the nonlinear state transition function at time k and $\mathbf{G}[\cdot, k]$ is the input model transition function at time k . The discrete process model thus becomes

$$\mathbf{p}^e(k) = \mathbf{p}^e(k-1) + \mathbf{v}^e \Delta t \quad (21.20)$$

$$\mathbf{v}^e(k) = \mathbf{v}^e(k-1) + [\mathbf{C}_b^e \hat{\mathbf{f}}^b - \mathbf{C}_b^e \delta \mathbf{f}^b - \mathbf{C}_b^e \mathbf{w}_{\text{accel}} - 2(\omega_{ie}^e \times \mathbf{v}^e) + \mathbf{g}_l^e] \Delta t \quad (21.21)$$

$$\Psi^n(k) = \Psi^n(k-1) + [\mathbf{E}_b^n (\hat{\omega}_{ib}^b - \delta \omega_{ib}^b - \mathbf{w}_{\text{gyro}} - \mathbf{C}_n^b \omega_{ie}^n)] \Delta t \quad (21.22)$$

$$\delta \mathbf{f}^b(k) = \delta \mathbf{f}^b(k-1) + \mathbf{w}_{b,\text{accel}}(k) \quad (21.23)$$

$$\delta \omega_{ib}^b(k) = \delta \omega_{ib}^b(k-1) + \mathbf{w}_{b,\text{gyro}}(k) \quad (21.24)$$

$$\mathbf{m}_i^e(k) = \mathbf{m}_i^e(k-1) \quad (21.25)$$

where Δt is the time difference between the k and $k-1$ discrete-time segments.

21.2.2.1 Process Model Equation Approximations for Local SLAM

When performing SLAM with respect to a local coordinate system where no global information is available, several approximations must be made in the inertial SLAM equations. In local SLAM, the position and orientation of the vehicle is maintained with respect to a local navigation frame which is fixed to an arbitrary and unknown location on the Earth's surface rather than the ECEF frame. The local SLAM equations are thus derived under the assumption that local navigation frame is an inertial frame of reference by ignoring the small Coriolis and centripetal accelerations which are incurred by the Earth's rotation.

In local SLAM, the estimated state vector is $\hat{\mathbf{x}}_{\text{local}}(k)$, in which the vehicle position and velocity and the position of map features are now reference in local navigation frame coordinates:

$$\hat{\mathbf{x}}_{\text{local}}(k) = [\mathbf{p}^n(k), \mathbf{v}^n(k), \Psi^n(k), \delta \mathbf{f}^b(k), \delta \omega_{ib}^b(k), \mathbf{m}_1^n(k), \mathbf{m}_2^n(k), \dots, \mathbf{m}_N^n(k)]^T \quad (21.26)$$

The continuous-time and discrete-time process models for local SLAM are thus given by

$$\dot{\hat{\mathbf{x}}}_{\text{local}}(t) = \mathbf{F}_{c,\text{local}}[\hat{\mathbf{x}}_{\text{local}}(t), \mathbf{u}(t)] + \mathbf{G}_{c,\text{local}}[\mathbf{w}(t)] \quad (21.27)$$

$$\hat{\mathbf{x}}_{\text{local}}(k) = \mathbf{F}_{\text{local}}[\hat{\mathbf{x}}_{\text{local}}(k-1), \mathbf{u}(k), k] + \mathbf{G}_{\text{local}}[\mathbf{w}(k)] \quad (21.28)$$

The vehicle process model equations in continuous-time form are the following:

$$\dot{\mathbf{p}}^n = \mathbf{v}^n \quad (21.29)$$

$$\dot{\mathbf{v}}^n = \mathbf{C}_b^n \hat{\mathbf{f}}^b - \mathbf{C}_b^n \delta \mathbf{f}^b - \mathbf{C}_b^n \mathbf{w}_{\text{accel}} + \mathbf{g}^n \quad (21.30)$$

$$\dot{\Psi}^n = \mathbf{E}_b^n (\hat{\omega}_{ib}^b - \delta \omega_{ib}^b - \mathbf{w}_{\text{gyro}}) \quad (21.31)$$

where $\mathbf{g}^n = [0, 0, g]^T$ is the vector of acceleration due to gravity in the local navigation frame and $g = 9.81 \text{ m/s}^2$. Terrain map features are now referenced in local navigation frame coordinates, and their process model is given by

$$\dot{\mathbf{m}}_i^n = \mathbf{0} \quad (21.32)$$

The complete form of the discrete-time process model equations in local SLAM are thus

$$\mathbf{p}^n(k) = \mathbf{p}^n(k-1) + \mathbf{v}^n \Delta t \quad (21.33)$$

$$\mathbf{v}^n(k) = \mathbf{v}^n(k-1) + [\mathbf{C}_b^n \hat{\mathbf{f}}^b - \mathbf{C}_b^n \delta \mathbf{f}^b - \mathbf{C}_b^n \mathbf{w}_{\text{accel}} + \mathbf{g}^n] \Delta t \quad (21.34)$$

$$\Psi^n(k) = \Psi^n(k-1) + [\mathbf{E}_b^n (\hat{\omega}_{ib}^b - \delta \omega_{ib}^b - \mathbf{w}_{\text{gyro}})] \Delta t \quad (21.35)$$

$$\delta \mathbf{f}^b(k) = \delta \mathbf{f}^b(k-1) + \mathbf{w}_{b, \text{accel}}(k) \quad (21.36)$$

$$\delta \omega_{ib}^b(k) = \delta \omega_{ib}^b(k-1) + \mathbf{w}_{b, \text{gyro}}(k) \quad (21.37)$$

$$\mathbf{m}_i^n(k) = \mathbf{m}_i^n(k-1) \quad (21.38)$$

21.2.3 Landmark/Terrain Sensor Equations

The observation model equations describe the relationship between the sensor observation of a map feature in the sensor coordinates of the terrain sensor to the estimated states in SLAM. Figure 21.1 illustrates the relevant relationships between the sensor frame, sensor observation and map, and vehicle positions. The observation $\mathbf{z}_i(k)$ is related to the estimated states using Eq. 21.39 for global SLAM and Eq. 21.40 for local SLAM:

$$\mathbf{z}_i(k) = \mathbf{H}_i(\mathbf{p}^e(k), \Psi^n(k), \mathbf{m}_i^e(k), k) + \mathbf{v}(k) \quad (21.39)$$

$$\mathbf{z}_i(k) = \mathbf{H}_{i, \text{local}}(\mathbf{p}^n(k), \Psi^n(k), \mathbf{m}_i^n(k), k) + \mathbf{v}(k) \quad (21.40)$$

where $\mathbf{H}_i(\cdot, \cdot, \cdot, k)$ and $\mathbf{H}_{i, \text{local}}(\cdot, \cdot, \cdot, k)$ are functions of the feature location, vehicle position, and Euler angles and $\mathbf{v}(k)$ is uncorrelated, zero-mean observation noise errors of covariance \mathbf{R} .

Terrain observations could come from a variety of different sensors such as RADAR, LIDAR, or an electro-optical camera. The SLAM algorithm requires that point features can be extracted from the observation sensor data which go on to be mapped terrain features. In the case of large objects that do not show up as a “point” in sensor data, the centroid of the object is found or else several points can be used to represent a single object. Example feature extraction algorithms for vision include Scale-Invariant Feature Transform (SIFT) features (Lowe 2004) or model-based feature matching (Nixon and Aguado 2001). Features in this sense are points in the sensor data that are distinct and easily recognizable or else points in

the sensor data that appear to correlate well with a given feature model or template that is specified offline.

Sensor observations can be broken up into two types: firstly range/bearing observations (as might be available from RADAR or a LIDAR) and secondly bearing-only observations (as might be available from an electro-optical sensor such as a camera). When both range and bearing observations are made, the observation model is given by

$$\mathbf{z}_i(k) = \begin{bmatrix} \rho_i \\ \varphi_i \\ \vartheta_i \end{bmatrix} = \begin{bmatrix} \sqrt{(x_i^s)^2 + (y_i^s)^2 + (z_i^s)^2} \\ \tan^{-1} \left(\frac{y_i^s}{x_i^s} \right) \\ \tan^{-1} \left(\frac{z_i^s}{\sqrt{(x_i^s)^2 + (y_i^s)^2}} \right) \end{bmatrix} \quad (21.41)$$

where ρ_i , φ_i , and ϑ_i are the observed range, azimuth, and elevation angles to the feature and x_i^s , y_i^s , and z_i^s are the Cartesian coordinates of $\mathbf{p}_{ms,i}^s$, the relative position of the i th feature with respect to the sensor, measured in the sensor frame.

There are two forms that can be used to represent a bearing-only observation. The observation $\mathbf{z}_i(k)$ can be represented by azimuth (φ_i) and elevation angles (ϑ_i):

$$\mathbf{z}_{i,\text{ang}}(k) = \begin{bmatrix} \varphi_i \\ \vartheta_i \end{bmatrix} = \begin{bmatrix} \tan^{-1} \left(\frac{y_i^s}{x_i^s} \right) \\ \tan^{-1} \left(\frac{z_i^s}{\sqrt{(x_i^s)^2 + (y_i^s)^2}} \right) \end{bmatrix} \quad (21.42)$$

where \mathbf{R}_{ang} is the angular noise covariance. For vision camera, the observation is better represented as pixels in the image of the camera, using a pinhole camera model:

$$\mathbf{z}_{i,\text{pix}}(k) = \begin{bmatrix} u \\ v \end{bmatrix} = \begin{bmatrix} f_u \left(\frac{y_i^s}{x_i^s} \right) + u_0 \\ f_v \left(\frac{z_i^s}{x_i^s} \right) + v_0 \end{bmatrix} \quad (21.43)$$

where u_0 , v_0 , f_u , and f_v are calibration parameters for the camera and the pixel noise covariance is \mathbf{R}_{pix} . The relationship between the pixel coordinates and the azimuth and elevation angles is given by Eq. 21.44

$$\begin{bmatrix} \varphi \\ \vartheta \end{bmatrix} = \begin{bmatrix} \tan^{-1} \left(\frac{(u-u_0)}{f_u} \right) \\ \tan^{-1} \left(\frac{(v-v_0)}{f_v} \cos \varphi \right) \end{bmatrix} \quad (21.44)$$

$\mathbf{p}_{ms,i}^s$, the relative position of the i th feature with respect to the sensor, measured in the sensor frame is given by:

$$\begin{aligned} \mathbf{p}_{ms,i}^s &= \mathbf{C}_b^s \mathbf{C}_n^b [\mathbf{m}_i^n - \mathbf{p}^n - \mathbf{C}_b^n \mathbf{p}_{sb}^b] \\ &= \mathbf{C}_b^s \mathbf{C}_e^b [\mathbf{m}_i^e - \mathbf{p}^e - \mathbf{C}_b^e \mathbf{p}_{sb}^b] \end{aligned} \quad (21.45)$$

where \mathbf{C}_b^s is the transformation matrix from the body frame to the sensor frame and \mathbf{p}_{sb}^b is the sensor offset from the vehicle center of mass, measured in the body frame, otherwise known as the “lever arm” and $\mathbf{C}_e^b = (\mathbf{C}_b^e)^T$.

21.3 Inertial SLAM with Range and Bearing Sensors

When both range and bearing observations to features are available, the inertial SLAM algorithm is broken up into the following processes:

1. *State Prediction.* The process model equations in Sect. 21.2.2 are used to “predict” forward in time the estimated state vector and state covariance matrix in an EKF prediction step.
2. *Data Association.* Every time a new feature observation is made, the data association step is used to determine whether the observation is of a new feature or a known feature, and which feature it is of.
3. *Feature Initialization.* When a feature is observed by the terrain sensor for the first time, its position is computed and augmented into the estimated state vector and its initial position uncertainty augmented into the state covariance matrix.
4. *State Update.* Each time an observation is made of a previously seen feature, it is used in an EKF update step to correct the value of the estimated state and update the state covariance matrix.

Figure 21.2 provides an overview of the range/bearing inertial SLAM algorithm. At each time step, inertial sensor data is used for the prediction stage. When features are extracted from the sensor data, they are run through a data association stage. New features are augmented into the state vector and state covariance matrix, and observations of existing features are used to update the estimated state vector and state covariance matrix. The following subsections summarize the equations and methods in each step of the algorithm. For further details of inertial SLAM with range and bearing sensors and an implementation example, the reader is referred to Kim and Sukkarieh (2003).

21.3.1 State Prediction

The state prediction stage is run recursively each time a new reading is taken from the inertial sensors. In the case of global SLAM, the estimated state vector $\hat{\mathbf{x}}(k+1)$ is predicted from the previous time step state estimate using Eqs. 21.20–21.25. The state covariance $\mathbf{P}^-(k+1)$, which is the state covariance at time step k after prediction, is computed as

$$\mathbf{P}^-(k+1) = \nabla \mathbf{F} \mathbf{P}(k) \nabla \mathbf{F}^T + \nabla \mathbf{G} \mathbf{Q}(k) \nabla \mathbf{G}^T \quad (21.46)$$

where $\nabla \mathbf{F}$ and $\nabla \mathbf{G}$ are the Jacobians of the state transition function $\mathbf{F}[\cdot, \cdot, k]$ with respect to the state vector $\hat{\mathbf{x}}(k+1)$ and input model transition function $\mathbf{G}[\cdot, k]$ with

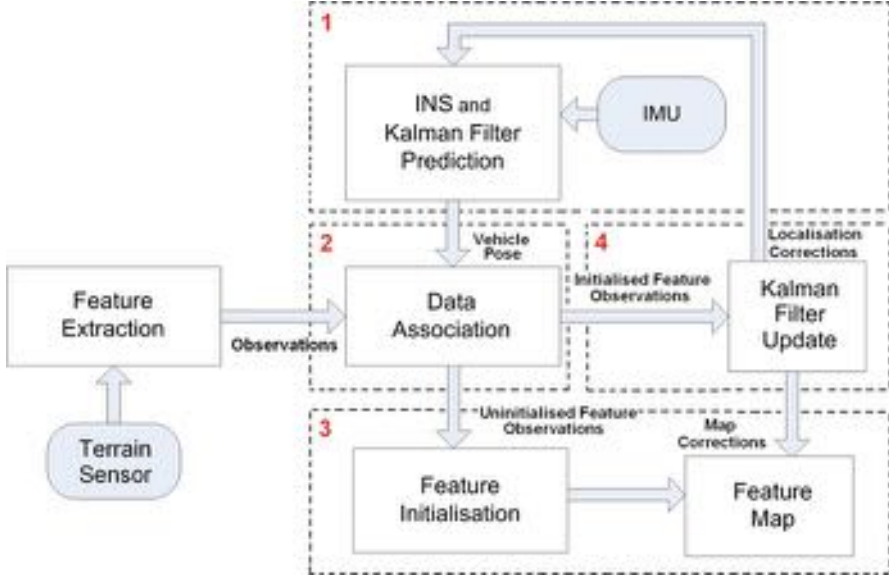

Fig. 21.2 Overview of the range/bearing inertial SLAM algorithm. the algorithm is recursive; EKF state prediction (1) is performed when inertial sensor data is available. Data association (2), feature initialization (3), and EKF state update (4) are performed when terrain sensor observations are made

respect to the noise input $\mathbf{w}(k+1)$, respectively. In the case of local SLAM, the estimated state vector $\hat{\mathbf{x}}_{\text{local}}(k)$ is predicted forward using Eqs. 21.33–21.38. The state covariance $\mathbf{P}^-(k+1)$ is computed as

$$\mathbf{P}^-(k+1) = \nabla \mathbf{F}_{\text{local}} \mathbf{P}(k) \nabla \mathbf{F}_{\text{local}}^T + \nabla \mathbf{G}_{\text{local}} \mathbf{Q}(k) \nabla \mathbf{G}_{\text{local}}^T \quad (21.47)$$

where $\nabla \mathbf{F}_{\text{local}}$ and $\nabla \mathbf{G}_{\text{local}}$ are the Jacobians of the state transition function $\mathbf{F}_{\text{local}}[\cdot, \cdot, k]$ with respect to the state vector $\hat{\mathbf{x}}_{\text{local}}(k+1)$ and input model transition function $\mathbf{G}_{\text{local}}[\cdot, k]$ with respect to the noise input $\mathbf{w}(k+1)$, respectively.

21.3.2 Feature Initialization

When the first range/bearing observation of a particular feature is obtained, its position is calculated using the initialization function $\mathbf{J}_1[\hat{\mathbf{x}}(k), \mathbf{J}_2(\mathbf{z}_i(k))]$ which is given as

$$\mathbf{J}_1[\hat{\mathbf{x}}(k), \mathbf{J}_2(\mathbf{z}_i(k))] \longrightarrow \mathbf{m}_i^e = \mathbf{p}^e + \mathbf{C}_n^e \mathbf{C}_b^n \mathbf{p}_{sb}^b + \mathbf{C}_n^e \mathbf{C}_b^n \mathbf{C}_s^b \mathbf{p}_{ms}^s \quad (21.48)$$

for the case of global SLAM and

$$\mathbf{J}_{1,\text{local}}[\hat{\mathbf{x}}_{\text{local}}(k), \mathbf{J}_2(\mathbf{z}_i(k))] \longrightarrow \mathbf{m}_i^n = \mathbf{p}^n + \mathbf{C}_b^n \mathbf{p}_{sb}^b + \mathbf{C}_b^n \mathbf{C}_s^b \mathbf{p}_{ms}^s \quad (21.49)$$

for the case of local SLAM, where

$$\mathbf{J}_2(\mathbf{z}_i(k)) \longrightarrow \mathbf{p}_{ms,i}^s = \begin{bmatrix} \rho_i \cos(\varphi_i) \cos(\vartheta_i) \\ \rho_i \sin(\varphi_i) \cos(\vartheta_i) \\ \rho_i \sin(\vartheta_i) \end{bmatrix} \quad (21.50)$$

for both the global and local SLAM cases. The state vector and covariance are then augmented to include the new feature position:

$$\hat{\mathbf{x}}_{\text{aug}}(k) = \begin{bmatrix} \hat{\mathbf{x}}(k) \\ \mathbf{m}_i^e(k) \end{bmatrix} \quad (21.51)$$

$$\mathbf{P}_{\text{aug}}(k) = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \nabla \mathbf{J}_x & \nabla \mathbf{J}_z \end{bmatrix} \begin{bmatrix} \mathbf{P}(k) & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_k \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \nabla \mathbf{J}_x & \nabla \mathbf{J}_z \end{bmatrix}^T \quad (21.52)$$

for the case of global SLAM and

$$\hat{\mathbf{x}}_{\text{local,aug}}(k) = \begin{bmatrix} \hat{\mathbf{x}}_{\text{local}}(k) \\ \mathbf{m}_i^n(k) \end{bmatrix} \quad (21.53)$$

$$\mathbf{P}_{\text{local,aug}}(k) = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \nabla \mathbf{J}_x & \nabla \mathbf{J}_z \end{bmatrix} \begin{bmatrix} \mathbf{P}_{\text{local}}(k) & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_k \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \nabla \mathbf{J}_x & \nabla \mathbf{J}_z \end{bmatrix}^T \quad (21.54)$$

for the case of local SLAM where $\nabla \mathbf{J}_x$ and $\nabla \mathbf{J}_z$ are the Jacobians of the initialization function \mathbf{J}_1 with respect to the state estimate $\hat{\mathbf{x}}(k)$ and the observation $\mathbf{z}_i(k)$, respectively. The position of this feature becomes correlated to all of the vehicle states including position, velocity, and attitude along with inertial sensor biases and also to the position of other features in the map.

21.3.3 Data Association

Data association is the process of matching observations of features from the terrain sensor with the estimated 3D position of the feature within the map. The validity of potential associations between observations and features is assessed using the Mahalanobis distance (γ) (Neira and Tardos 2001) in the sensor space (range, azimuth, and elevation):

$$\gamma_i = v_i(k)^T \mathbf{S}_i(k)^{-1} v_i(k) \quad (21.55)$$

where $v_i(k)$ and $\mathbf{S}_i(k)$ are the innovation and innovation covariance (see Sect. 21.3.4) for an observation of the i th feature in the map at time segment k .

When checking the association of a given observation with the initialized features in the map, γ_i is calculated for each initialized feature. Matchings that fall within a defined threshold of γ_i corresponding to a 95 % level of confidence are considered

acceptable, in which case the observation is associated to a known feature in the map and an EKF state update is performed (see Sect. 21.3.4 below). If the observation does not fall within the threshold of an existing map feature, it is assumed that the feature has not been seen before, and thus the observation data is used to initialize the feature into the map as is shown in Sect. 21.3.2.

This method of data association works well when feature observations are well spaced in the sensor coordinates with respect to the uncertainty of the vehicle position and orientation. In the case of very dense feature observations, it may be necessary to consider not only matches of individual features to individual sensor observations but also the joint compatibility of several features to several observations simultaneously as to overcome association ambiguity. For efficient techniques for joint compatibility data association based on the innovation gate in Eq. 21.55, the reader is referred to Neira and Tardos (2001).

21.3.4 State Update

Once a feature has been initialized into the state vector, subsequent observations of this feature are used to update the entire state vector consisting of the vehicle pose, velocity, inertial sensor biases, and the position of this feature and other features in the environment. The state estimate is updated in an EKF update step where the updated state estimate and state covariance matrix after the update are as follows:

$$\hat{\mathbf{x}}^+(k+1) = \hat{\mathbf{x}}^-(k+1) + \mathbf{W}(k+1)\mathbf{v}(k+1) \quad (21.56)$$

$$\mathbf{P}^+(k+1) = \mathbf{P}^-(k+1) - \mathbf{W}(k+1)\mathbf{S}_i(k+1)\mathbf{W}(k+1)^T \quad (21.57)$$

$$\mathbf{v}_i(k+1) = \mathbf{z}_i - \mathbf{H}_i(\hat{\mathbf{x}}^-(k+1)) \quad (21.58)$$

$$\mathbf{S}_i(k+1) = \nabla \mathbf{H}_i \mathbf{P}^-(k+1) \nabla \mathbf{H}_i^T + \mathbf{R}(k+1) \quad (21.59)$$

$$\mathbf{W}(k+1) = \mathbf{P}^-(k+1) \nabla \mathbf{H}_i^T \mathbf{S}_i^{-1}(k+1) \quad (21.60)$$

for the case of global SLAM and

$$\hat{\mathbf{x}}_{\text{local}}^+(k+1) = \hat{\mathbf{x}}_{\text{local}}^-(k+1) + \mathbf{W}(k+1)\mathbf{v}(k+1) \quad (21.61)$$

$$\mathbf{P}_{\text{local}}^+(k+1) = \mathbf{P}_{\text{local}}^-(k+1) - \mathbf{W}(k+1)\mathbf{S}_i(k+1)\mathbf{W}(k+1)^T \quad (21.62)$$

$$\mathbf{v}_i(k+1) = \mathbf{z}_i - \mathbf{H}_{i,\text{local}}(\hat{\mathbf{x}}_{\text{local}}^-(k+1)) \quad (21.63)$$

$$\mathbf{S}_i(k+1) = \nabla \mathbf{H}_{i,\text{local}} \mathbf{P}_{\text{local}}^-(k+1) \nabla \mathbf{H}_{i,\text{local}}^T + \mathbf{R}(k+1) \quad (21.64)$$

$$\mathbf{W}(k+1) = \mathbf{P}_{\text{local}}^-(k+1) \nabla \mathbf{H}_{i,\text{local}}^T \mathbf{S}_i^{-1}(k+1) \quad (21.65)$$

for the case of local SLAM where $\mathbf{H}_i(\hat{\mathbf{x}}^-(k+1))$ or $\mathbf{H}_{i,\text{local}}(\hat{\mathbf{x}}_{\text{local}}^-(k+1))$ is the predicted feature observation which is computed from the estimated vehicle

position and attitude and estimate map location using Eqs. 21.41 and 21.45. $\nabla \mathbf{H}_i$ and $\nabla \mathbf{H}_{i,\text{local}}$ are the Jacobians of the observation function with respect to the predicted state vector. Once a feature leaves the field of view of the sensor, its position remains in the state vector and continues to be updated via its correlations to other visible features in the state vector.

21.4 Inertial SLAM with Bearing-Only Sensors

When bearing-only observations are made using a terrain sensor such as in the case of a vision system, additional elements must be added to the SLAM algorithm. Performing SLAM with bearing-only observations poses two main additional challenges to the range and bearing case. Firstly, a single bearing-only observation provides insufficient information alone to localize a feature in 3D. Instead observations from two sufficiently different poses are required. Secondly, data association is complicated by bearing-only observations. Since the 3D position of the feature is not known from a single observation, the Mahalanobis distance (Neira and Tardos 2001), commonly used for validation gating in tracking tasks, and as shown for the range-bearing case in Sect. 21.3.3, cannot be calculated in the standard way.

This section details variations to the inertial SLAM algorithms that account for complications arising from the use of bearing-only terrain sensors. The bearing-only inertial SLAM algorithm is broken up into the following processes:

1. *State Prediction.* The prediction step in the bearing-only case is performed in a similar manner as in the range/bearing case.
2. *Data Association.* Data association for initialized features follows the same methods as shown in the range/bearing case. Data association of uninitialized features is tackled by creating multi-hypothesis distributions of the possible feature locations in 3D (i.e., along the line of sight of an observation). Subsequent observations of the same feature can be associated by matching the most likely hypotheses and culling the hypotheses that do not match.
3. *Feature Initialization.* A delayed initialization technique is used to store information from bearing-only observations until there exists two observations with a sufficient baseline from which to initialize the 3D position of the feature. Once this is available, all of the information contained in stored observations is recovered.
4. *State Update.* The update step in the bearing-only case is performed in a similar manner as in the range/bearing case where bearing-only observations are used to update the estimated state which includes vehicle states, stored pose data, and features whose 3D positions have been initialized into the map.

Figure 21.3 provides an overview of the bearing-only inertial SLAM algorithm. The following subsections summarize the equations and methods in each step of the algorithm. For further details of inertial SLAM with bearing-only sensors and an implementation example, the reader is referred to Bryson and Sukkarieh (2007).

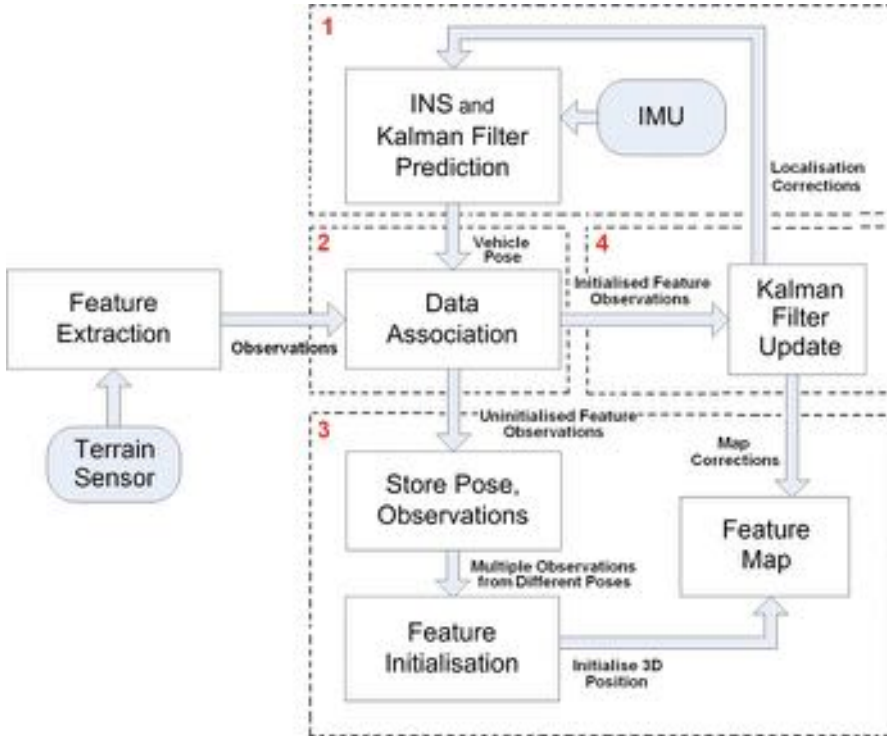

Fig. 21.3 Overview of the bearing-only inertial SLAM algorithm. The algorithm is recursive; EKF state prediction (1) is performed when inertial sensor data is available. Data association (3) and EKF state update (4) are performed when terrain sensor observations are made of features that have been already initialized into the map. Observations of new features are stored until enough observations exist to initialize the position of the feature into the state vector (2)

21.4.1 State Prediction and Update

The bearing-only SLAM equations rely on the storing of vehicle pose data into the estimated state vector. The methods for storing pose data is shown below in Sect. 21.4.2. The state prediction for the bearing-only case follows the same equations and methods as shown in the range/bearing observation case as shown in Sect. 21.3.1 except that stored pose data is predicted forward in the predict step in the same way as stored map features. The only difference in the state update between the bearing-only case and range/bearing case (shown in Sect. 21.3.4) is that now no range information is available in the observation. Equations 21.56–21.65 are used for the update where Eqs. 21.42 or 21.43 is used to compute $\mathbf{H}_i(\hat{\mathbf{x}}^-(k+1))$ or $\mathbf{H}_{i,\text{local}}(\hat{\mathbf{x}}_{\text{local}}^-(k+1))$, the predicted feature observation, depending on the exact form of bearing observation from the terrain sensor (i.e., bearing angles or pixels).

21.4.2 Feature Initialization

A single bearing-only observation is insufficient to initialize the 3D position of a feature into the SLAM filter with Gaussian uncertainty. The following subsection outlines a method for delayed initialization of a feature into the filter by using stored observations and vehicle pose information. For simplification, the feature position is always initialized into the local navigation frame first before being transformed into the ECEF frame if global SLAM is performed. Otherwise, the feature position remains in the local navigation frame.

21.4.2.1 Storing Feature Observations and Vehicle Pose Information

When an observation of an uninitialized feature is made, the current bearing-only observation is stored, and the SLAM state vector is augmented to include the current vehicle pose (three position states and three Euler angle states):

$$\hat{\mathbf{x}}_v = \begin{bmatrix} \mathbf{p}^e(k) \\ \mathbf{v}^e(k) \\ \boldsymbol{\Psi}^n(k) \\ \delta \mathbf{f}^b(k) \\ \delta \omega_{ib}^b(k) \end{bmatrix}, \hat{\mathbf{x}}_p = \begin{bmatrix} \mathbf{C}_e^n \mathbf{p}^e(k) \\ \boldsymbol{\Psi}^n(k) \end{bmatrix} = \begin{bmatrix} \mathbf{p}^n(k) \\ \boldsymbol{\Psi}^n(k) \end{bmatrix} \quad (21.66)$$

$$\hat{\mathbf{x}}_{\text{aug}} = \begin{bmatrix} \hat{\mathbf{x}}_v(k) \\ \mathbf{m}^n(k) \\ \hat{\mathbf{x}}_p(k) \end{bmatrix} \quad (21.67)$$

The state covariance matrix is then augmented with the stored vehicle pose:

$$\mathbf{P}_{\text{aug}}(k) = \begin{bmatrix} \mathbf{P}_{vv} & \mathbf{P}_{vm} & \mathbf{P}_{vp} \\ \mathbf{P}_{mv} & \mathbf{P}_{mm} & \mathbf{P}_{mp} \\ \mathbf{P}_{pv} & \mathbf{P}_{pm} & \mathbf{P}_{pp} \end{bmatrix} \quad (21.68)$$

$\hat{\mathbf{x}}_v$ is the concatenation of the vehicle position, velocity, attitude, and inertial sensor bias states where $\hat{\mathbf{x}}_p$ is the concatenation of the vehicle position and attitude (i.e., the vehicle pose states) at the time of the observation. $\hat{\mathbf{x}}_{\text{aug}}$ is the augmented state vector which is comprised of the vehicle states ($\hat{\mathbf{x}}_v$), the 3D positions of all of the map features (\mathbf{m}^n), and the added vehicle pose states ($\hat{\mathbf{x}}_p$). The observation (coordinates of the feature in the image plane) is stored separately from the EKF state vector.

In local SLAM, the covariance term \mathbf{P}_{pp} (covariance of the pose states) is derived by taking the position and attitude covariance matrix subblocks from within \mathbf{P}_{vv} (since these states have the same value and the same covariance as the current vehicle position and attitude). Similarly the covariance subblock \mathbf{P}_{pm} is taken from the existing cross correlations between the current vehicle states and map states (i.e., subblocks of \mathbf{P}_{vm} corresponding just to position and attitude). \mathbf{P}_{pv} is the cross correlation between all of the current vehicle states (i.e., position, attitude, velocity,

and inertial sensor biases) and the current pose states. This is thus taken from subblocks of \mathbf{P}_{vv} itself since there are states in common (position and attitude), and thus parts of the added vehicle pose states ($\hat{\mathbf{x}}_p$) are completely correlated to the current vehicle state ($\hat{\mathbf{x}}_v$). In the case of global SLAM, a \mathbf{C}_e^n transformation is applied to the vehicle position covariances in order to represent the stored pose in the local navigation frame.

As the process model of the vehicle comes into play and the filter moves forward in time, the correlations between the stored pose and the new time vehicle states (i.e., $\hat{\mathbf{x}}_v(k+1)$) will decrease (due to the process noise on $\hat{\mathbf{x}}_v(k+1)$).

21.4.2.2 Deciding When to Initialize a Feature

Eventually enough feature observations will be made from varying vehicle poses to initialize the position of the feature. Initializing a feature too early (i.e., by not using enough observations or observations with insufficient separating angle) can result in inconsistency as the true probability distribution of the feature location is not well represented by a Gaussian. The disadvantage with overdelaying the initialization is that the uncertainty in the vehicle states continues to grow before the initialization. As the uncertainty in the current vehicle state grows, linearization errors can affect the consistency of the filter. The information should be initialized and recovered as quickly as possible to limit the effect the inconsistency can have. Additionally, it may be desired to quickly recover the stored information which contributes toward the accuracy of the vehicle localization estimates which may be used as feedback for the control of the vehicle. Another upper limit on deciding how long to delay the initialization is driven by reducing the increased computational burden imposed by adding stored observations to the state vector.

In Bailey (2003), the author discusses a method for testing the conditioning of the initialization by using a Kullback-Leibler distance measure between the linearized update and an approximation of the update using particles to represent the final probability distribution of the feature position. This method however is very computationally intensive; instead, a more practical approach is to set a conservative threshold for the minimum angle between observations necessary to initialize a feature.

21.4.2.3 Initializing a 3D Feature Position Estimate

When it is decided to initialize the 3D position of a feature into the map, the two stored observations of the feature which are separated by the largest angle are used to create an initial estimate of the feature position. Each bearing-only observation can be represented by a 3D point in space \mathbf{y}^n from where the observation was made (at the origin of the sensor) along with a unit vector $\bar{\mathbf{u}}^n$ pointing along the line of sight of the observation; thus,

$$\mathbf{y}^n = \mathbf{p}^n + \mathbf{C}_b^n \mathbf{p}_{sb}^b \quad (21.69)$$

$$\bar{\mathbf{u}}^n = \mathbf{C}_b^n \mathbf{C}_s^b \bar{\mathbf{p}}_{ms}^s \quad (21.70)$$

where $\bar{\mathbf{x}}$ indicates the unit vector of a vector \mathbf{x} . \mathbf{p}^n and C_b^n are determined from the stored pose data associated to each observation, and $\bar{\mathbf{p}}_{ms}^s$ is determined from the observation data itself using Eq. 21.44 to convert the pixel observation to azimuth and elevation angles and Eq. 21.71 to convert to a unit vector:

$$\bar{\mathbf{p}}_{ms}^s = \begin{bmatrix} \cos(\varphi_i) \cos(\vartheta_i) \\ \sin(\varphi_i) \cos(\vartheta_i) \\ \sin(\vartheta_i) \end{bmatrix} \quad (21.71)$$

The lines of sight generated by each observation should intersect at one point in 3D space corresponding to the feature location. Since the observations and stored vehicle pose information is noisy, the lines of sight will generally not intersect perfectly. Instead, the initial feature position is computed as the closest point between the two lines for each observation:

$$\begin{aligned} \mathbf{m}_i^n &= \mathbf{G}(\mathbf{p}_1^n, \mathbf{p}_2^n, \Psi_1^n, \Psi_2^n, \mathbf{z}_1, \mathbf{z}_2) \\ &= \frac{1}{2}(\mathbf{y}_1^n + \mathbf{y}_2^n + p_1 \cdot \bar{\mathbf{u}}_1^n + p_2 \cdot \bar{\mathbf{u}}_2^n) \end{aligned} \quad (21.72)$$

$$p_1 = \frac{((\mathbf{y}_2^n - \mathbf{y}_1^n) \times \bar{\mathbf{u}}_2^n) \cdot (\bar{\mathbf{u}}_1^n \times \bar{\mathbf{u}}_2^n)}{|\bar{\mathbf{u}}_1^n \times \bar{\mathbf{u}}_2^n|^2} \quad (21.73)$$

$$p_2 = \frac{((\mathbf{y}_1^n - \mathbf{y}_2^n) \times \bar{\mathbf{u}}_1^n) \cdot (\bar{\mathbf{u}}_2^n \times \bar{\mathbf{u}}_1^n)}{|\bar{\mathbf{u}}_2^n \times \bar{\mathbf{u}}_1^n|^2} \quad (21.74)$$

In the event that there is a large discrepancy between the two lines (i.e., the minimum distance between the closest two points, one on each line, is larger than a threshold), the observations may be incorrect. This could be due to a misassociation of one of the observations or if the feature is moving for some reason. In this case, the observations are discarded, and the feature is not initialized. Provided there is no large discrepancy between the lines, the state vector and covariance matrix in the SLAM filter are then augmented to include the estimate of the new feature:

$$\hat{\mathbf{x}}_{\text{aug}}(k) = \begin{bmatrix} \hat{\mathbf{x}}(k) \\ \mathbf{m}_i^n(k) \end{bmatrix} \quad (21.75)$$

$$\mathbf{P}_{\text{aug}}(k) = \begin{bmatrix} \mathbf{I} & 0 \\ \nabla \mathbf{G}_p & \nabla \mathbf{G}_z \end{bmatrix} \begin{bmatrix} \mathbf{P}(k) & 0 \\ 0 & \mathbf{R}_{2 \times 2} \end{bmatrix} \begin{bmatrix} \mathbf{I} & 0 \\ \nabla \mathbf{G}_p & \nabla \mathbf{G}_z \end{bmatrix}^T \quad (21.76)$$

where $\nabla \mathbf{G}_p$ and $\nabla \mathbf{G}_z$ are the Jacobians of the initialization function $\mathbf{G}(\cdot)$ with respect to the pose states $(\mathbf{p}_1^n, \mathbf{p}_2^n, \Psi_1^n, \Psi_2^n)$ and the observations $(\mathbf{z}_1, \mathbf{z}_2)$, respectively, and $\mathbf{R}_{2 \times 2}$ is

$$\mathbf{R}_{2 \times 2} = \begin{bmatrix} \mathbf{R} & 0 \\ 0 & \mathbf{R} \end{bmatrix} \quad (21.77)$$

21.4.2.4 Recovering the Information from Remaining Stored Observations

Once two observations have been used to initialize the 3D position of the feature into the filter, the remaining stored observations ($\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_j$) are run through a batch EKF update. The update corrects not only the current feature being initialized but also the other features in the map and the current vehicle state estimates. The updated state vector and state covariance is calculated using EKF update equations described above for the range-bearing algorithm (i.e., Eqs. 21.56 and 21.57) where the innovation $\mathbf{v}(k)$ is composed using all of the stored observations for the feature:

$$\mathbf{v}(k) = \begin{bmatrix} \mathbf{z}_{1,\text{pix}} - \mathbf{H}(\mathbf{p}_1^n, \Psi_1^n, \mathbf{m}_i^n) \\ \mathbf{z}_{2,\text{pix}} - \mathbf{H}(\mathbf{p}_2^n, \Psi_2^n, \mathbf{m}_i^n) \\ \vdots \\ \mathbf{z}_{j,\text{pix}} - \mathbf{H}(\mathbf{p}_j^n, \Psi_j^n, \mathbf{m}_i^n) \end{bmatrix} \quad (21.78)$$

Once the update has been completed, pose states that no longer have any associated stored observations been removed from the state vector and their corresponding rows and columns removed from the covariance matrix. Finally, in the case of global SLAM, the newly initialized feature position is transformed from the local navigation frame into the ECEF frame. If local SLAM is performed, the feature position remains in the local navigation frame.

21.4.3 Data Association

When performing data association for features that have already been initialized into the map, the same methods are used as in the range/bearing SLAM case shown in Sect. 21.3.3. Issues arise when attempting to find a data association test that can be performed for uninitialized features. Since the exact 3D position of the feature is not known, one cannot consistently calculate the innovation or innovation covariance of the feature. Instead, from only one or a small number of observations with a small baseline, the observation could lie anywhere in 3D space along the line-of-sight of the observation.

In order to associate observations of features that have not yet been initialized into the 3D map, a multi-hypothesis of Gaussian distributions is created for the possible 3D locations of the feature along the line of sight vector for the first observation of the feature.

21.4.3.1 Starting a New Feature

When an observation is made in the image that cannot be associated to any other previously seen feature, initialized or uninitialized, it is assumed that this observation has come from a new feature that has not been seen before. The process begins by storing the observation and augmenting the EKF state vector with the current vehicle pose (see Sect. 21.4.2.1).

From the single observation, a set of equally weighted hypotheses are created for where the feature could lie in 3D space along the line of sight. The mean ($\hat{\mathbf{x}}_j$) and covariance (\mathbf{P}_j) for each hypothesis are calculated for several different values of range (r_j) in equal increments from an expected minimum and maximum sensor range as shown in the left of Fig. 21.4 using Eqs. 21.79 and 21.80:

$$\begin{aligned}\hat{\mathbf{x}}_j &= \mathbf{G}(\mathbf{p}^n(k), \Psi^n(k), \mathbf{z}_i(k), r_j) \\ &= \mathbf{p}^n + C_b^n \mathbf{p}_{sb}^b + r_j \cdot (C_b^n C_s^b \mathbf{p}_{ms}^s)\end{aligned}\quad (21.79)$$

$$\mathbf{P}_j = \nabla \mathbf{G}_v \mathbf{P}_{vv} \nabla \mathbf{G}_v^T + \nabla \mathbf{G}_z \mathbf{R}_{\text{ang}} \nabla \mathbf{G}_z^T \quad (21.80)$$

where \mathbf{p}_{ms}^s is calculated from the observation data using Eq. 21.71 and $\nabla \mathbf{G}_v$, $\nabla \mathbf{G}_z$ are the Jacobians of the function $\mathbf{G}(\cdot)$ with respect to vehicle states and the observation and range data, respectively. The number of hypotheses used and the maximum and minimum range and thus the spacing between the hypotheses depend on the desired accuracy in the initial feature position with more hypotheses resulting in a better initialization. A record of the multi-hypothesis distribution is maintained separately from the state vector and is used only to assist in associating future observations of the feature.

21.4.3.2 Associating Future Observations and Maintaining Feature Hypotheses

Since each hypothesis is Gaussian with a mean defined in 3D space, the innovation and innovation covariance can be calculated for each hypotheses for each uninitialized feature using

$$v(k) = \mathbf{z}_{i,\text{ang}}(k) - \mathbf{H}(\mathbf{p}^n(k), \Psi^n(k), \hat{\mathbf{x}}_j) \quad (21.81)$$

$$\mathbf{S}(k) = \nabla \mathbf{H}_x(k) \mathbf{P}_{\text{hyp}}(k) \nabla \mathbf{H}_x^T(k) + \mathbf{R}_{\text{ang}} \quad (21.82)$$

$$\mathbf{P}_{\text{hyp}}(k) = \begin{bmatrix} \mathbf{P}_{pp} & 0 \\ 0 & \mathbf{P}_j \end{bmatrix} \quad (21.83)$$

where \mathbf{P}_{pp} is the covariance subblock of the current vehicle position and attitude states. An approximation is made that the current vehicle state and the hypothesis are uncorrelated in order to simplify the data association process; to account for these correlations in the data association process would require a large computational resource. The result of this approximation is that during large SLAM loop closures, the EKF may not associate observations of a new feature and some observations may be discarded. It may thus take longer for new features at this time to be integrated into the map. For a given observation and for each hypothesis for a given uninitialized feature, γ is calculated using Eqs. 21.55, 21.81, and 21.82. If the value of γ is below the threshold corresponding to a 95 % confidence for at least one of the hypotheses, then the observation is matched to this uninitialized feature.

Fig. 21.4 Data association of observations to uninitialized features. When a feature is seen for the first time, a set of hypotheses for the 3D position of the feature is generated at equal range increments along the line of sight (*top*). Future observations are checked for matches to any of the hypotheses. When a match is made to one of the hypotheses, the remaining hypotheses that do not match are culled (*bottom*)

In order to simplify the association of uninitialized features, when an association is made between an observation and one of the hypotheses for a given feature, all other hypotheses of this feature for which the observation does not match are culled from the set of hypotheses from which to associate future observations. As the vehicle moves around an uninitialized feature, the number of hypotheses gradually drops until only one hypothesis matches, the one that is closest to the true 3D feature location. The bottom sub-figure of Fig. 21.4 illustrates this process.

21.4.3.3 Data Association Procedure

Each time observations from the feature extraction process are received, the procedure begins by using Eq. 21.55 to evaluate the potential matching between

each observation and each of the 3D initialized features. Observations that match 3D initialized features are associated and sent on to the SLAM filter to be updated. In the event of multiple features matching a single observation, the matching with the lowest value of γ will be accepted.

The remaining observations are tested for matches with each of the hypotheses for each uninitialized feature. Observations that match with at least one hypothesis of an uninitialized feature are associated to this feature. The observation itself is stored, and the vehicle pose at the current time is then added to the state vector (see Sect. 21.4.2.1). In the event of multiple uninitialized features matching a single observation, all matchings to this observation are rejected.

For each remaining observation not matched to an initialized or un-initialized feature, a new set of hypotheses is created (see Sect. 21.4.3.1).

The proposed multi-hypothesis method for data association could also potentially be used for initializing the feature position, as has been demonstrated in Kwok and Dissanayake (2004), where hypotheses are pruned until only one is left, which then becomes the initialized feature. In this approach, the line-of-sight intersection method is used for calculating the initial feature position; in order to achieve the same accuracy with the multi-hypothesis method, one would require a prohibitively large number of hypotheses (i.e., 1-m resolution for a feature at a range of 200 m would require 200 hypotheses).

21.5 Multi-vehicle Inertial SLAM Algorithm

In multi-vehicle SLAM, several vehicles move over a common section of terrain where the task is to build a common map of the environment while providing localization estimates to each platform. The use of multiple cooperating vehicles has many advantages over SLAM on a single vehicle. Multiple vehicles provide wider sensor coverage and thus can be used to build more extensive terrain maps in less time. The accuracy of the constructed terrain map is greater than in the single-vehicle case as multiple vehicles contribute information toward a given feature location. This increased terrain map accuracy also creates an increase in the accuracy of the localization estimates for each vehicle.

The work by Fenwick et al. (2002), Mourikis and Roumeliotis (2005), Walter and Leonard (2004), and Thrun and Lui (2003a) provides examples of multi-vehicle SLAM where all vehicles send their sensor data to a central Kalman filter. These approaches are fully centralized, involving the communication of raw sensor data from each vehicle to a central source and thus requiring a large amount of communication bandwidth. In Nettleton et al. (2003) and Ong et al. (2003), the authors demonstrate a decentralized architecture for multi-vehicle SLAM using a mathematically equivalent form of the EKF known as the Extended Information Filter (EIF). The use of the EIF in these approaches avoids the need to communicate raw sensor data, where instead this raw data is used in SLAM by each vehicle locally before communicating the map information.

In this section, data fusion architectures are considered for sharing map information built by each vehicle using the inertial SLAM algorithms discussed in Sects. 21.3 and 21.4. The core principle behind the data fusion schemes is the use of the EIF which allows for the map data contributions from each platform to be summed together where the processes of the combined estimation task are distributed among the vehicles. Both centralized and decentralized architectures are discussed in Sects. 21.5.2 and 21.5.3.

21.5.1 Global Vs. Local SLAM for Multiple Vehicles

When global SLAM is performed by each of the vehicles in the data fusion network, each vehicle uses the ECEF frame for referencing the position of terrain features in the environment. In the case of local SLAM, however, each vehicle may use its own independent local navigation frame in which it builds its local map. In order to fuse information from multiple maps, the relative transformations between each local navigation frame must be known. In the case where no localization or prior terrain reference information is available, the vehicles can compute a relative transformation by matching at least two features from each local map (for an example of this process, the reader is referred to Fox et al. (2006)). Once the transformation is known, a common representation of the environment can be built with respect to each vehicle's local navigation frame.

21.5.2 Centralized Architectures for Multi-vehicle Inertial SLAM

This section presents a centralized, distributed data fusion architecture for multi-vehicle inertial SLAM. The architecture is centralized, where some part of the data fusion process is performed at a central node. The architecture is also distributed; rather than communicate all of the raw sensor data from both the inertial and terrain sensors to a central data fusion source, each vehicle firstly performs single-vehicle inertial SLAM as shown in Sects. 21.3 and 21.4. The local terrain map built on each vehicle is then communicated in information form to a central source at regular intervals where data fusion is performed. Finally, the central data fusion node communicates the fused map information back to each vehicle, where this information is fused back into the local map. The following subsections describe the process in more detail.

21.5.2.1 Centralized, Distributed Data Fusion

The centralized, distributed data fusion is based on the independent opinion pool architecture shown in Manyika and Durrant-Whyte (1994). At regular intervals, each vehicle takes its current state estimate relating to the map estimates only, that is, $\mathbf{x}_m(k)$ and $\mathbf{P}_{mm}(k)$, where

$$\mathbf{x}_m(k) = \begin{bmatrix} \mathbf{m}_1^e(k) \\ \mathbf{m}_2^e(k) \\ \vdots \\ \mathbf{m}_N^e(k) \end{bmatrix} \quad (21.84)$$

for the case of global SLAM and

$$\mathbf{x}_m(k) = \begin{bmatrix} \mathbf{m}_1^n(k) \\ \mathbf{m}_2^n(k) \\ \vdots \\ \mathbf{m}_N^n(k) \end{bmatrix} \quad (21.85)$$

for the case of local SLAM. $\mathbf{P}_{mm}(k)$ is a $3N \times 3N$ matrix of the elements of \mathbf{P}_k relating to the map feature estimates. Each vehicle then calculates its posterior information:

$$\mathbf{Y}_j(k) = \mathbf{P}_{mm}^{-1}(k) \quad (21.86)$$

$$\mathbf{y}_j(k) = \mathbf{Y}_j(k)\mathbf{x}_m(k) \quad (21.87)$$

for the j th vehicle where $j = 1, \dots, M$, where M is the number of vehicles, and communicates this to the central map filter. The information that is sent will obviously be correlated to the information that was sent in the previous communication (since each vehicle's posterior information is based on the entire history of observations it has made). To overcome this, the central data filter maintains a record of the information that it has been sent in the previous communication ($\mathbf{Y}_j(k-1), \mathbf{y}_j(k-1)$) by each vehicle. When the new information arrives, the old information is subtracted from it before adding it to the central map information, in order to remove the correlations and only count new information. The central map information update at the central data filter is thus

$$\mathbf{Y}_{\text{central}}(k) = \mathbf{Y}_{\text{central}}(k-1) + \sum_{j=1}^M (\mathbf{Y}_j(k) - \mathbf{Y}_j(k-1)) \quad (21.88)$$

$$\mathbf{y}_{\text{central}}(k) = \mathbf{y}_{\text{central}}(k-1) + \sum_{j=1}^M (\mathbf{y}_j(k) - \mathbf{y}_j(k-1)) \quad (21.89)$$

Once the information is combined in the central filter, a state-space estimate of the map feature locations and covariance can be recovered using Eqs. 21.98 and 21.99:

$$\mathbf{P}_{mm,\text{central}}(k) = \mathbf{Y}_{\text{central}}^{-1}(k) \quad (21.90)$$

$$\mathbf{x}_{m,\text{central}}(k) = \mathbf{P}_{mm,\text{central}}(k)\mathbf{y}_{\text{central}}(k) \quad (21.91)$$

21.5.2.2 Applying Local Node Feedback to the Independent Opinion Pool

So that each vehicle's localization estimates can benefit from the observations of features made by other vehicles, information about the central map should be fed back to each of the local nodes. In the same way that was done on the central data filter, each vehicle must store the last information update that it received from the central filter ($\mathbf{Y}_{\text{central}}(k-1), \mathbf{y}_{\text{central}}(k-1)$) so as not to double count the information that has been sent to it. Thus, when each vehicle receives the communicated central information, it firstly computes its posterior information over the entire state space consisting of local vehicle estimate and map features using Eqs. 21.86 and 21.87 and updates this information using Eqs. 21.92 and 21.93:

$$\mathbf{Y}_{\text{local}}(k) = \mathbf{Y}_{\text{local}}(k) + (\mathbf{Y}_{\text{central}}(k) - \mathbf{Y}_{\text{central}}(k-1)) \quad (21.92)$$

$$\mathbf{y}_{\text{local}}(k) = \mathbf{y}_{\text{local}}(k) + (\mathbf{y}_{\text{central}}(k) - \mathbf{y}_{\text{central}}(k-1)) \quad (21.93)$$

The local information is then transformed back into state-space and covariance form to provide the updated estimate of the vehicle localization and map features, which is substituted back into the EKF in the single-vehicle SLAM architecture. The operation of the central filter with local node feedback is illustrated in Fig. 21.5.

This centralized, distributed architecture has several advantages over a completely centralized filter such as a reduction in the required communication bandwidth (as only local estimates must be communicated, not observations and process model inputs) and the ability to deal with intermittent communications and delays as the information is maintained on the local vehicle.

21.5.3 Decentralized Architectures for Multi-vehicle Inertial SLAM

The multi-vehicle inertial SLAM algorithm can be decentralized by removing the central filter, where each vehicle now communicates directly to each other vehicle in the network. This type of architecture was demonstrated for feature tracking tasks and SLAM in Nettleton (2003). At regular intervals each UAV takes its current state estimate relating to the map estimates only, that is, $\mathbf{x}_m(k)$ and $\mathbf{P}_{mm}(k)$, and calculates its posterior information using Eqs. 21.86 and 21.87. Each UAV maintains a record of the information sent during the last communication (i.e., $\mathbf{Y}_j(k-1), \mathbf{y}_j(k-1)$) which is subtracted from the current information to form the new information that UAV has about the feature map:

$$\mathbf{Y}_{j,\text{new}}(k) = \mathbf{Y}_j(k) - \mathbf{Y}_j(k-1) \quad (21.94)$$

$$\mathbf{y}_{j,\text{new}}(k) = \mathbf{y}_j(k) - \mathbf{y}_j(k-1) \quad (21.95)$$

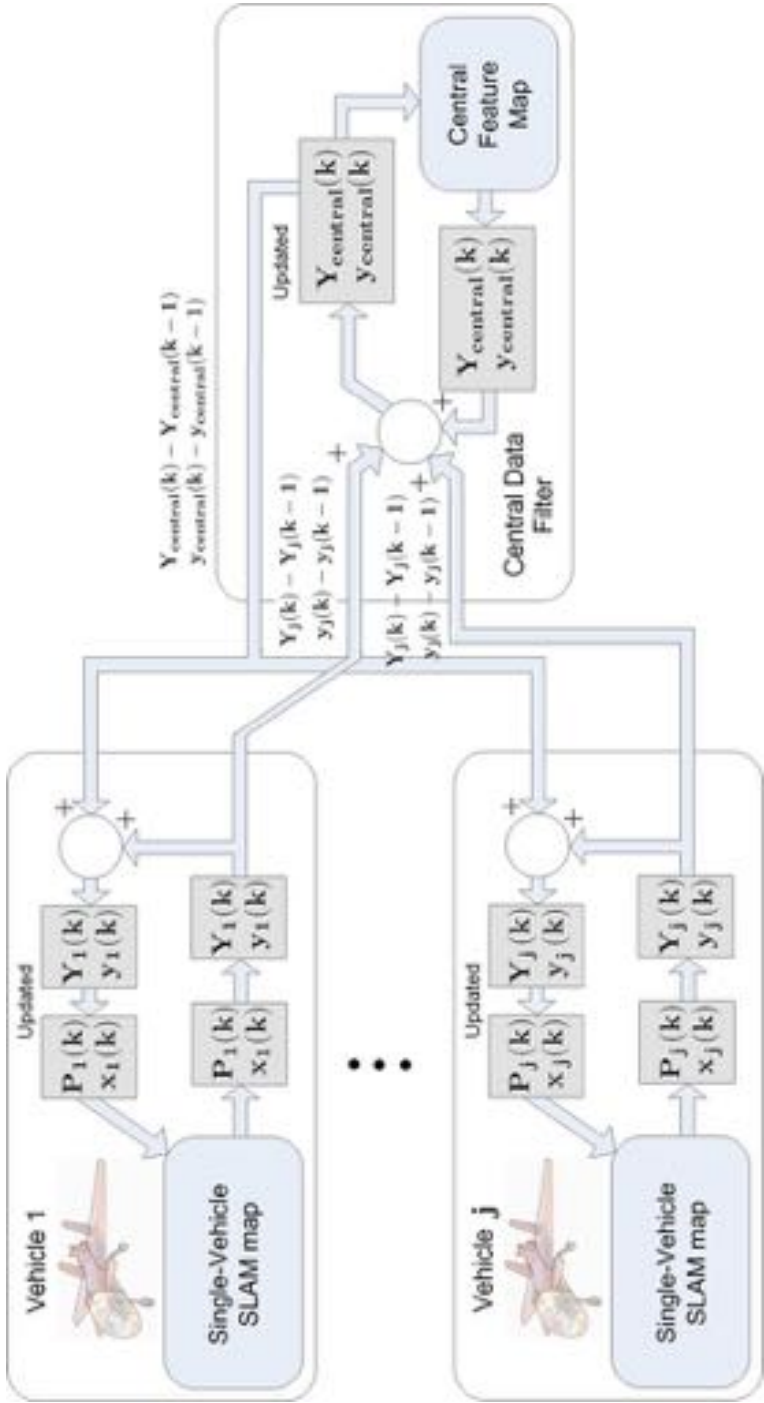

Fig. 21.5 Distributed centralized multi-vehicle SLAM: independent opinion pool architecture with local node feedback. Each vehicle communicates its posterior map estimates in information form which are added together at a central data filter. The central data filter then feeds back the information to each of the vehicles in order to update their local maps

This new information is then communicated to each of the other UAVs. When each UAV receives all of the information updates from each of the other UAVs, this information is summed together along with the current UAV information to form the updated estimate of the map features in information form:

$$\mathbf{Y}_{j,\text{update}}(k) = \mathbf{Y}_j(k) + \sum_{i=1}^M \mathbf{Y}_{i,\text{new}}(k) \quad (21.96)$$

$$\mathbf{y}_{j,\text{update}}(k) = \mathbf{y}_j(k) + \sum_{i=1}^M \mathbf{y}_{i,\text{new}}(k) \quad (21.97)$$

Once all of the information from other UAVs is combined in the update, a state-space estimate of the map feature locations and covariance can be recovered back into the EKF using Eqs. 21.98 and 21.99:

$$\mathbf{P}_{j,mm,\text{update}}(k) = \mathbf{Y}_{j,\text{update}}^{-1}(k) \quad (21.98)$$

$$\mathbf{x}_{j,m,\text{update}}(k) = \mathbf{P}_{j,mm,\text{update}}(k) \mathbf{y}_{j,\text{update}}(k) \quad (21.99)$$

The operation of the decentralized SLAM filter is illustrated in Fig. 21.6.

21.5.4 Delayed Observations, Network Outages, and Communication Bandwidth Constraints

Realistic communication networks between the vehicles will not be able to provide continuous and instantaneous communication of information. Instead, real networks will contain significant delays and outages between different nodes when vehicles move out of range of one another and will not always be able to communicate all of the map information when the map becomes very large.

Delayed observations are not a significant issue in multi-vehicle SLAM as features are considered stationary, and thus information about a feature's location is independent of time and can be added in a delayed fashion and out of order. When there are outages in the network communications, this can cause the vehicles to lose track of the common information they possess. This can be overcome by constraining the structure of the communications network to tree structures (Nettleton 2003). When communication bandwidth constraints apply across the network, the vehicles may only communicate information representing a subset of the features contained in their map. In this case, information must be fused together using the covariance intersect algorithm (Julier and Uhlmann 2001) due to correlations between the submap and the rest of the map features, which is not accounted for in further communications. These concepts are all discussed further in Nettleton (2003).

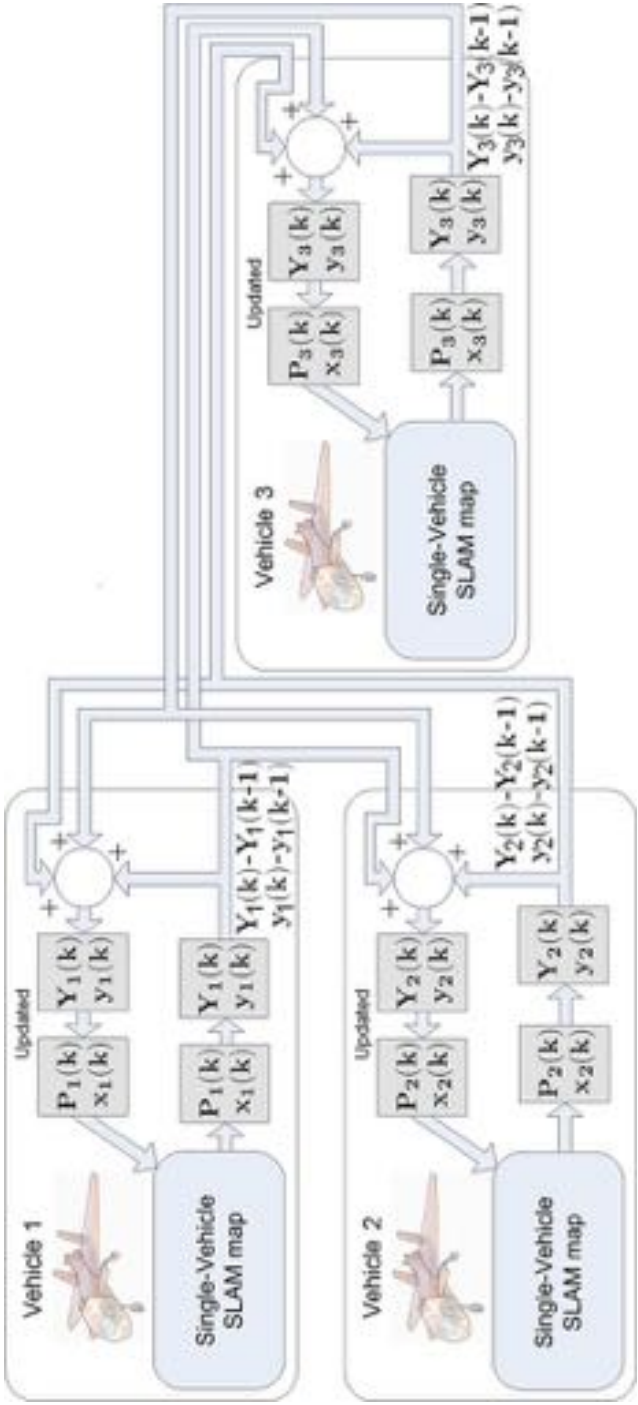

Fig. 21.6 Decentralized SLAM data fusion architecture. Each UAV communicates to each other UAV in the team its latest map state estimate in inverse covariance (information) form. Information is then added at the receiving end and converted from information space back into state space into the EKF

21.6 Conclusion

This chapter has developed the basic equations and methods for inertial sensor-based SLAM. The fundamental equations that model inertial sensors and inertial localization were analyzed; two different applications were examined for when localization and mapping is performed in either a global frame of reference or in an arbitrary local frame of reference. The inertial SLAM algorithms were examined for the case of range and bearing observations from a terrain sensor and also when terrain observations were made from a bearing-only sensor. Finally, the problem of multi-vehicle inertial SLAM was examined. Two different types of data fusion architecture were considered: firstly, centralized architectures in which map information is shared among vehicles via a central communications source and, secondly, decentralized architectures where the vehicles communicate and share data with each other directly.

Abstract

This chapter provides an overview of UAV localization with a focus on aided inertial localization, that is, algorithms for fusing data from, for example, satellite positioning systems, barometric sensors, and magnetometers with inertial sensors to provide real-time position and orientation. The presentation is based in the use of the Extended Kalman Filter (EKF) as the core tool for data fusion, which is commonly used for its simplicity, computational efficiency, and optimality (with respect to sensor noise characteristics). This chapter presents an example implementation of aided inertial localization on a UAV as a tutorial in the key concepts in airborne localization and as a basic guide toward more complicated implementation.

22.1 Introduction

Localization is the process of determining the one's position and orientation in the world, often achieved by combining various measurements together. In the context of Unmanned Aerial Vehicles (UAVs), localization is typically performed in real time onboard the platform, using information from various sensors. Tasks that require localization range from automatic stabilization and flight control of the UAV to georegistration of exteroceptive sensor data such as that performed during target tracking and mapping. UAV localization thus often requires a localization system to provide position and orientation information that has low latency, high frequency, and high accuracy, requirements that typically necessitate multiple sensors.

Inertial sensors and satellite positioning systems (such as the Global Positioning System (GPS)) have been a popular choice for UAV systems (and airborne platforms at large) that operate outdoors. Inertial sensors provide high-frequency information (typically 100–1,000 Hz) relating to the first- and second-order time derivatives of a platform's position and orientation, but the accuracy of localization provided by this sensor alone decreases during flight, due to dead reckoning. Modern satellite positioning systems provide accurate information about a platform's position but at a much lower frequency (typically 1–10 Hz) and higher latency (typically 20–200 ms); the fusion of information from both these sensors allows for both accuracy and high-rate information about location. Other localization information typically available on airborne platforms (such as barometric altitude, barometric airspeed, and magnetic field measurements) can also be used to improve the accuracy and robustness of a UAV localization system.

This chapter provides an overview of UAV localization with a focus on aided inertial localization, that is, algorithms for fusing data from, for example, satellite positioning systems, barometric sensors, and magnetometers with inertial sensors to provide real-time position and orientation. The presentation is based in the

use of the Extended Kalman Filter (EKF) as the core tool for data fusion, which is commonly used for its simplicity, computational efficiency, and optimality (with respect to sensor noise characteristics). This chapter presents an example implementation of aided inertial localization on a UAV as a tutorial in the key concepts in airborne localization and as a basic guide toward more complicated implementation, which are beyond the scope of this chapter. The presentation begins with an overview of frames of reference and representations of three-axis orientation in Sect. 22.2. Equations for inertial localization are derived in Sect. 22.3. A set of algorithms for aided inertial localization based on the EKF are presented in Sect. 22.4 including a description of various aiding sensors typically used in UAV localization. Example results of aided inertial localization taken from an experimental flight test of a UAV are provided in Sect. 22.5 and are used to demonstrate concepts developed throughout the chapter. Conclusions are presented in Sect. 22.3.6.

22.1.1 Aided Inertial Localization and Related Work

Since its initial development in the 1940s in guided rocket applications (King and Kutta 1998), inertial localization has been a popular system for localization of aerial vehicles. Originally, inertial localization systems were designed to run independently of external sensors, thus the main research interest being in increased sensor accuracy. The disadvantage of these systems was the large size, power requirements, and high cost of these units, particularly detrimental in airborne applications.

The development of the Kalman filter (Kalman 1960) in the early 1960s provided a method to optimally combine inertial sensor measurements with other localization sensors in order to reduce the drift when using low-cost sensors. Good examples of architectures for an aided inertial localization system with doppler radar, magnetic heading, and airspeed sensor measurements using the Kalman filter are provided in (Giovanni 1979) and (Bar-Itzhack et al. 1982).

Interest in guided missile applications in which external navigation signals (like those used in radio ranging, etc.) could be unreliable or jammed by interference, motivated the development of terrain-aided navigation systems. Most commonly, these systems use radar-altimeter measurements to correlate the observed terrain profile with a stored contour map of the operating area (systems such as TERCOM (TERrain CONtour Matching) (Baker and Clem 1979) and TERPROM (TERrain PROfile Matching) (Fountain 1997)).

Since the abandonment of the policy of selective availability by the United States of America and the development of Differential GPS (DGPS), GPS-aided inertial applications have become a popular choice for UAV and ground vehicle localization systems alike due to their relatively low cost and independence of platform specifics. The Kalman filter is commonly used (Meyer-Hilberg and Jacob 1994; Knight

1996); however, GPS-aided inertial applications using other filtering techniques like complimentary filters (Gebre-Egziabher et al. 1998; Yang et al. 2000), particle filters (Carvalho et al. 1997), and even fuzzy inference schemes (Hiliuta et al. 2004) have also been demonstrated.

22.2 Frames of Reference and Attitude Representation

This section describes the relevant frames of reference and attitude representations used in UAV localization. Figure 22.1 illustrates each of the frames of reference described below.

22.2.1 Earth-Centered, Earth-Fixed (ECEF) Frame

The Earth-Centered, Earth-Fixed (ECEF) frame is fixed to the center of the Earth with x-axis pointing at the intersection of the prime meridian and the equator

Fig. 22.1 Frames of reference in localization: Earth-Centered, Earth-Fixed (ECEF), local navigation, IMU-fixed, and body-fixed frames

(0° longitude, 0° latitude), z-axis pointing through the north pole and y-axis pointing along the equator, perpendicular to the other two axes. Vectors are referenced in this frame with the superscript “e,” that is, \mathbf{x}^e .

22.2.2 Local-Vertical, Local-Horizontal Navigation Frame

The Local-Vertical, Local-Horizontal (LVLH) frame has its origin at an arbitrary point on the vehicle’s body but whose axes rotate as the vehicle moves such that the x-axis points north, y-axis points east, and z-axis points downward, perpendicular to the tangent of the Earth’s surface at the frame’s origin. Vectors are referenced in this frame with the superscript “n,” that is, \mathbf{x}^n .

22.2.3 Body-Fixed Frame

The body-fixed frame is centered at an arbitrary, but fixed point on the vehicle with x-axis pointing out the aircraft nose, y-axis pointing out the right wing, and z-axis pointing downward through the bottom of the vehicle. Vectors are referenced in this frame with the superscript “b,” that is, \mathbf{x}^b .

22.2.4 IMU-Fixed Frame

The IMU-fixed frame is centered at the location of the Inertial Measuring Unit (IMU). It is assumed that the sensor placement (three accelerometers and three gyros) inside the IMU is in an orthogonal arrangement. Therefore, each axis of the sensor-fixed frame is aligned with each pair of accelerometer and gyro on each axis (i.e., x-axis is aligned with the direction of the x-accelerometer and x-gyro). Vectors are referenced in this frame with the superscript “IMU,” that is, \mathbf{x}^{IMU} .

22.2.5 Direction Cosine Matrix

The Direction Cosine Matrix (DCM) is a 3×3 matrix, denoted $\mathbf{C}_{(\cdot)}^{(\cdot)}$, used to transform a vector from one reference frame to another. For example, \mathbf{C}_b^n is the DCM used to transform a vector \mathbf{x}^b , referenced in the body frame, into local navigation coordinates as shown in Eq. 22.1.

$$\mathbf{x}^n = \mathbf{C}_b^n \mathbf{x}^b \quad (22.1)$$

Consider two reference frames A and B as shown in Fig. 22.2. The unit vectors $\mathbf{i}^a, \mathbf{j}^a$, and \mathbf{k}^a and $\mathbf{i}^b, \mathbf{j}^b$, and \mathbf{k}^b are aligned with the x-, y-, and z-axes of each reference frame. The direction cosine matrix that transforms a vector in frame A into frame B (\mathbf{C}_a^b) is given by the dot products between each unit vector as shown

Fig. 22.2 Direction cosine matrix (DCM): relationship between two frames of reference A and B

in Eq. 22.2, where the unit vectors \mathbf{i}^b , \mathbf{j}^b , and \mathbf{k}^b are along the axes of the frame A. These dot products are equal to the cosines of the relative angles between each unit vector.

$$\mathbf{C}_a^b = \begin{bmatrix} \mathbf{i}^a \cdot \mathbf{i}^b & \mathbf{j}^a \cdot \mathbf{i}^b & \mathbf{k}^a \cdot \mathbf{i}^b \\ \mathbf{i}^a \cdot \mathbf{j}^b & \mathbf{j}^a \cdot \mathbf{j}^b & \mathbf{k}^a \cdot \mathbf{j}^b \\ \mathbf{i}^a \cdot \mathbf{k}^b & \mathbf{j}^a \cdot \mathbf{k}^b & \mathbf{k}^a \cdot \mathbf{k}^b \end{bmatrix} \quad (22.2)$$

22.2.6 Euler Angles

Euler angles ($\Psi = [\phi, \theta, \psi]^T$) can be used to parameterize a DCM via the use of three successive rotations about three different axes, the order in which the rotation is applied being significant. In this presentation, a positive yaw(ψ)-pitch(θ)-roll(ϕ) (z-axis, y-axis, x-axis) ordering is used to represent the transformation from either ECEF or LVLH to body-fixed reference. When applying a transformation from the body-fixed reference to either the ECEF or LVLH frame, the sequence of rotations is applied in the opposite direction, that is, a negative roll(ϕ)-pitch(θ)-yaw(ψ) ordering. The direction cosine matrix \mathbf{C}_b^n (transformation from body to local navigation axes) is related to the Euler angles via Eq. 22.3:

$$\mathbf{C}_b^n = \begin{bmatrix} \cos \psi \cos \theta & \cos \psi \sin \theta \sin \phi - \sin \psi \cos \phi & \cos \psi \sin \theta \cos \phi + \sin \psi \sin \phi \\ \sin \psi \cos \theta & \sin \psi \sin \theta \sin \phi + \cos \psi \cos \phi & \sin \psi \sin \theta \cos \phi - \cos \psi \sin \phi \\ -\sin \theta & \cos \theta \sin \phi & \cos \theta \cos \phi \end{bmatrix} \quad (22.3)$$

22.2.7 Quaternions

Quaternions use four parameters ($\mathbf{q} = [e_0, e_1, e_2, e_3]^T$) to define a transformation between two frames of reference by using a single rotation about a defined axis with respect to the original reference frame. Quaternions are related to the Euler angles and DCM using Eqs. 22.4 and 22.5.

$$\begin{bmatrix} e_0 \\ e_1 \\ e_2 \\ e_3 \end{bmatrix} = \begin{bmatrix} \cos \frac{\psi}{2} \cos \frac{\theta}{2} \cos \frac{\phi}{2} + \sin \frac{\psi}{2} \sin \frac{\theta}{2} \sin \frac{\phi}{2} \\ \cos \frac{\psi}{2} \cos \frac{\theta}{2} \sin \frac{\phi}{2} - \sin \frac{\psi}{2} \sin \frac{\theta}{2} \cos \frac{\phi}{2} \\ \cos \frac{\psi}{2} \sin \frac{\theta}{2} \cos \frac{\phi}{2} + \sin \frac{\psi}{2} \cos \frac{\theta}{2} \sin \frac{\phi}{2} \\ -\cos \frac{\psi}{2} \sin \frac{\theta}{2} \sin \frac{\phi}{2} + \sin \frac{\psi}{2} \cos \frac{\theta}{2} \cos \frac{\phi}{2} \end{bmatrix} \quad (22.4)$$

$$\mathbf{C}_b^n = \begin{bmatrix} e_0^2 + e_1^2 - e_2^2 - e_3^2 & 2(e_1e_2 - e_0e_3) & 2(e_1e_3 + e_0e_2) \\ 2(e_1e_2 + e_0e_3) & e_0^2 - e_1^2 + e_2^2 - e_3^2 & 2(e_2e_3 - e_0e_1) \\ 2(e_1e_3 - e_0e_2) & 2(e_2e_3 + e_0e_1) & e_0^2 - e_1^2 - e_2^2 + e_3^2 \end{bmatrix} \quad (22.5)$$

22.3 Inertial Localization Equations

This section describes algorithms used to derive the position, velocity, and attitude of a platform/vehicle (i.e., a UAV) from inertial sensor readings. An Earth-frame mechanization (Titterton and Weston 1997) of the inertial localization equations is presented. The use of the Earth frame allows for localization in a global sense and over long periods and provides a convenient reference frame for all of the different sensor modalities that are used in the Kalman filter. The equations are presented as first-order differential equations that can then be numerically integrated from a known starting position and orientation to compute the position and orientation of a platform as a function of time. The use of initial estimates of position, velocity, and attitude and the continuing numerical integration of the following equations using inertial sensor readings onboard a moving platform is collectively referred to as an inertial localization system (ILS) and is a key component of a working aided inertial localization system.

22.3.1 Earth-Frame Mechanization: Position and Velocity Equations

The position of the vehicle is defined as the vector from the ECEF to the body-fixed frame (\mathbf{p}^e). It is assumed that the body frame axes are defined as being at the center of the IMU in order to simplify the equations without loss of generality.

The position vector can be described in either Cartesian or polar coordinates where Eq. 22.6 provides the relationship between each:

$$\mathbf{p}^e = \begin{bmatrix} \left(\frac{a}{\sqrt{1-e^2 \sin^2 \lambda}} + h \right) \cos(\lambda) \cos(\varphi) \\ \left(\frac{a}{\sqrt{1-e^2 \sin^2 \lambda}} + h \right) \cos(\lambda) \sin(\varphi) \\ \left(\left[\frac{a}{\sqrt{1-e^2 \sin^2 \lambda}} \right] (1-e^2) + h \right) \sin(\lambda) \end{bmatrix} \quad (22.6)$$

where $a = 6,378,137$ m is the semimajor axis and $e = 0.08181919$ is the eccentricity of the Earth's ellipsoid, h is the altitude of the vehicle (above mean sea level (MSL)), and λ, φ are the geodetic latitude and longitude of the vehicle. The rate of change of the position and velocity of the vehicle in the ECEF frame is given by Eqs. 22.7 and 22.8:

$$\dot{\mathbf{p}}^e = \mathbf{v}^e \quad (22.7)$$

$$\dot{\mathbf{v}}^e = \mathbf{C}_b^e \mathbf{f}^b - 2(\omega_{ie}^e \times \mathbf{v}^e) + \mathbf{g}_l^e \quad (22.8)$$

where \mathbf{f}^b is the specific force measurement from the IMU, transformed into body-axis coordinates:

$$\mathbf{f}^b = \mathbf{f}^{\text{IMU}} - \omega_{ib}^b \times (\omega_{ib}^b \times \mathbf{l}^{\text{IMU}}) \quad (22.9)$$

where \mathbf{f}^{IMU} is the specific force vector measurement from the IMU (corrected for IMU biases), ω_{ib}^b is the IMU gyro measurement, and \mathbf{l}^{IMU} is the lever arm of the IMU with respect to body coordinates.

ω_{ie}^e is the rotation rate vector of the Earth with respect to inertial space in the Earth frame, given by Eq. 22.10:

$$\omega_{ie}^e = \begin{bmatrix} 0 \\ 0 \\ \omega_{\text{Earth}} \end{bmatrix} \quad (22.10)$$

where $\omega_{\text{Earth}} = 7.292115 \times 10^{-5}$ rad/s, and the term \mathbf{g}_l^e is given by

$$\mathbf{g}_l^e = \mathbf{g}^e - \omega_{ie}^e \times (\omega_{ie}^e \times \mathbf{p}^e) \quad (22.11)$$

$$= -g \begin{bmatrix} \frac{\mathbf{p}_x^e}{|\mathbf{p}^e|} \\ \frac{\mathbf{p}_y^e}{|\mathbf{p}^e|} \\ \frac{\mathbf{p}_z^e}{|\mathbf{p}^e|} \end{bmatrix} - [\times \omega_{ie}^e]^2 \mathbf{p}^e \quad (22.12)$$

where g is the acceleration acting on the vehicle due to gravity, referenced in ECEF coordinates and $[\times \omega_{ie}^e]$ is the skew symmetric matrix of the Earth's rotation rate vector.

22.3.2 Earth-Frame Mechanization: Attitude Equations

The attitude equations maintain a representation of the body to LVLH frame transformation \mathbf{C}_b^n which is used to compute the body to ECEF frame transformation \mathbf{C}_b^e :

$$\mathbf{C}_b^e = \mathbf{C}_n^e \mathbf{C}_b^n \quad (22.13)$$

where \mathbf{C}_n^e is the transformation from LVLH coordinates to ECEF coordinates, dependent on the global position of the vehicle:

$$\mathbf{C}_n^e = \begin{bmatrix} -\sin(\lambda) \cos(\varphi) & -\sin(\varphi) & -\cos(\lambda) \cos(\varphi) \\ -\sin(\lambda) \sin(\varphi) & \cos(\varphi) & -\cos(\lambda) \sin(\varphi) \\ \cos(\lambda) & 0 & -\sin(\lambda) \end{bmatrix} \quad (22.14)$$

The rates of change of quaternions and Euler angles for a frame transformation \mathbf{C}_b^n are found via Eqs. 22.15 and 22.17:

$$\dot{\mathbf{q}} = \mathbf{Q}_b^n \omega_{nb}^b \quad (22.15)$$

$$\mathbf{Q}_b^n = \frac{1}{2} \begin{bmatrix} -e_1 & -e_2 & -e_3 \\ e_0 & -e_3 & e_2 \\ e_3 & e_0 & -e_1 \\ -e_2 & e_1 & e_0 \end{bmatrix} \quad (22.16)$$

$$\dot{\Psi}^n = \mathbf{E}_b^n \omega_{nb}^b \quad (22.17)$$

$$\mathbf{E}_b^n = \begin{bmatrix} 1 & \sin \phi \tan \theta & \cos \phi \tan \theta \\ 0 & \cos \phi & -\sin \phi \\ 0 & \sin \phi \sec \theta & \cos \phi \sec \theta \end{bmatrix} \quad (22.18)$$

where \mathbf{E}_b^n is the rotation rate transformation matrix and \mathbf{Q}_b^n is the quaternion rotation rate transformation matrix between the body frame and the LVLH frame and ω_{nb}^b is the rotation rate of the body frame with respect to the LVLH frame, measured in the body frame, which is computed:

$$\omega_{nb}^b = \omega_{ib}^b - \mathbf{C}_n^b (\omega_{ie}^n + \omega_{en}^n) \quad (22.19)$$

where $C_n^b = (C_b^n)^T$, ω_{ib}^b is the rotation rate measured by the gyroscopes inside the IMU, transformed into body-fixed coordinates, ω_{ie}^n , the Earth's rotation rate measured in the navigation frame, is given by

$$\omega_{ie}^n = \begin{bmatrix} \omega_{\text{EARTH}} \cos(\lambda) \\ 0 \\ -\omega_{\text{EARTH}} \sin(\lambda) \end{bmatrix} \quad (22.20)$$

and ω_{en}^n is the transport rate (rotation rate of the LVLH frame with respect to the ECEF frame as the vehicle moves around the curvature of the Earth):

$$\omega_{en}^n = \begin{bmatrix} \frac{v_y}{|\mathbf{p}^e|} \\ \frac{-v_x}{|\mathbf{p}^e|} \\ \frac{-v_y \tan(\lambda)}{|\mathbf{p}^e|} \end{bmatrix} \quad (22.21)$$

where $|\mathbf{p}^e|$ is the magnitude of the vehicle's position vector with respect to the surface of the Earth.

22.3.3 Simplification of Inertial Navigation Equations for Small Area Operation

When a platform operates over a small geographic area of the Earth's surface (with respect to the curvature of the Earth) and for a short amount of time (relative to the rotational period of the Earth), several simplifications can be made to the equations for inertial localization in order to simplify their implementation and analysis. In this case, the position and attitude of the vehicle's body-fixed frame are maintained with respect to a local navigation frame which is fixed to the Earth's surface rather than the ECEF frame. An assumption is made that the local navigation frame is an inertial frame of reference by ignoring the small Coriolis and centripetal accelerations and rotation rate which are incurred by the Earth's rotation. In this case, the position and velocity rates of change of the vehicle reduce to Eqs. 22.22 and 22.23:

$$\dot{\mathbf{p}}^n = \mathbf{v}^n \quad (22.22)$$

$$\dot{\mathbf{v}}^n = \mathbf{C}_b^n \mathbf{f}^b + \mathbf{g}^n \quad (22.23)$$

where $\mathbf{g}^n = [0, 0, g]^T$ is the vector of acceleration due to gravity in the local navigation frame (typical value for $g = 9.81 \text{ m/s}^2$ at sea level). The attitude of

the vehicle is now represented using the DCM C_b^n , and Eqs. 22.15 and 22.17 are used to find the attitude where $\omega_{ba}^a = \omega_{nb}^b$, the rotation rate of the body frame with respect to the local navigation frame measured in the body frame, which is approximated as

$$\omega_{nb}^b = \omega_{ib}^b \quad (22.24)$$

22.3.4 Numerical Integration of Inertial Equations in the ILS

The first-order differential equations described above are typically numerically integrated, starting from initial estimates of the UAV's position, velocity, and attitude and discrete-time samples of specific force and rotation rate provided by the IMU. For simplicity, a first-order numerical Euler integration step is described here which at each IMU measurement is used to predict forward the current position ($\mathbf{p}^e(k)$), velocity ($\mathbf{v}^e(k)$), and attitude ($\Psi^n(k)$ or $\mathbf{q}(k)$) estimates using Eqs. 22.7, 22.8, and 22.15 or 22.17 (depending on the use of quaternions or Euler angles):

$$\mathbf{p}^e(k) = \mathbf{p}^e(k-1) + \dot{\mathbf{p}}^e \Delta t \quad (22.25)$$

$$\mathbf{v}^e(k) = \mathbf{v}^e(k-1) + \dot{\mathbf{v}}^e \Delta t \quad (22.26)$$

$$\Psi^n(k) = \Psi^n(k-1) + \dot{\Psi}^n \Delta t \quad (22.27)$$

$$\mathbf{q}(k) = \mathbf{q}(k-1) + \dot{\mathbf{q}} \Delta t \quad (22.28)$$

where Δt is the time between subsequent inertial sensor measurements and k is used to indicate the timestep (corresponding to IMU measurements). Quaternion and/or Euler angle integration is performed before position and velocity integration in order to provide a more accurate attitude value for the computation of $\dot{\mathbf{p}}^e$ and $\dot{\mathbf{v}}^e$. If quaternions are used, they should also be normalized after each integration step:

$$\mathbf{q}(k) = \frac{\mathbf{q}(k)}{\sqrt{e_0^2 + e_1^2 + e_2^2 + e_3^2}} \quad (22.29)$$

Initial estimates of the UAV position, velocity, and attitude are usually derived from aiding sensor measurement; position and velocity are measured directly using satellite positioning systems, and attitude can be derived from a combination of IMU and magnetometer measurements while the vehicle is stationary (e.g., using the TRIAD algorithm (Shuster and Oh 1981)).

22.4 Aided Inertial Localization Using the EKF

In this section, algorithms are presented for using the EKF for fusing additional sensor measurements with position, velocity, and attitude dead reckoned by inertial localization.

22.4.1 Extended Kalman Filter Basics

The EKF is an algorithm for estimating the state of a dynamic system using noisy observations which are related to the state. The algorithm is recursive and requires a dynamic model (also known as a process model) of the estimated state and an observation model, both which are modeled as having additive noisy errors, where the noise probability distributions are white and Gaussian. The EKF works by a two-step cycle (a predict step followed by an observation step) where the estimate of the state is stored as a multivariate Gaussian probability distribution with mean $\hat{\mathbf{x}}(k)$ and covariance $\mathbf{P}(k)$ where k indicates the k th timestep in the estimation cycle:

$$\hat{\mathbf{x}}(k) = E[\mathbf{x}(k)] \quad (22.30)$$

$$\mathbf{P} = E[(\mathbf{x}(k) - \hat{\mathbf{x}}(k))(\mathbf{x}(k) - \hat{\mathbf{x}}(k))^T] \quad (22.31)$$

where $E[.]$ is the expectation operator. For more details on the operation of the EKF in general applications, the reader is referred to Gelb (1974) and Maybeck (1979).

22.4.2 Indirect Kalman Filter Architecture for Aided ILS

Although the equations that govern the process and observation models in inertial localization are nonlinear, a time-variant linear representation can be attained via the process of linearization. This can be achieved by recasting the perspective of the estimation task into an “indirect” form (Kim and Sukkarieh 2003). In the “indirect” form, a nominal system state is used which represents the position, velocity, and attitude of the UAV. This nominal system state contains an error which is the difference between the nominal state and the true state of the system (due to errors in the estimation process). In the “indirect” form, the task of the estimator is to estimate the error and thus use it to continuously correct the nominal system state computed by the inertial localization equations of motion (see Fig. 22.3). “Indirect” architectures are commonly used in aided inertial localization systems (Sukkarieh 1999; Kim and Sukkarieh 2004; Titterton and Weston 1997; Meyer-Hilberg and Jacob 1994); they provide equivalent results to the use of a “direct” EKF architecture (where the position, velocity, and attitude states themselves are estimated; see (Bar-Shalom and Fortmann 1998)) but are typically easier to implement and allow

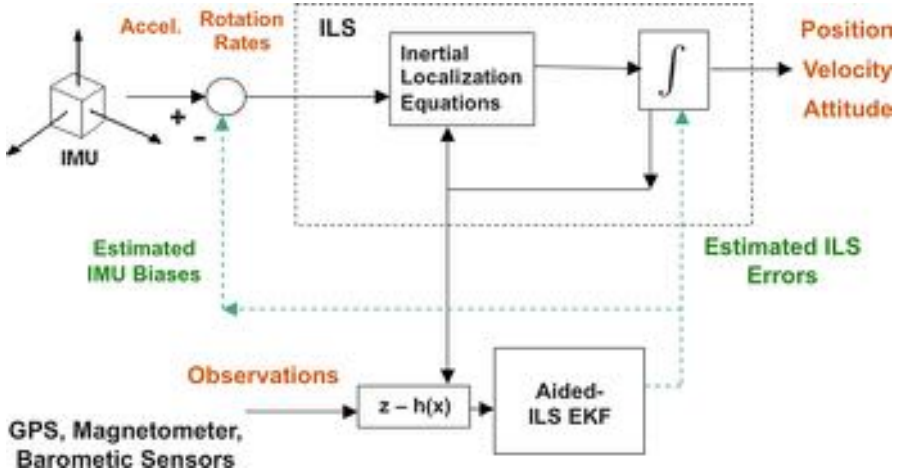

Fig. 22.3 Indirect Kalman filter architecture for aided ILS. An inertial localization system (ILS) is used to derived position, velocity, and attitude estimates through a process of state integration using measurements from an inertial measuring unit (IMU). When aiding sensor observations are available, they are used to estimate and correct for the errors in the ILS state estimates while also estimating and correcting for biases in the IMU measurements

for more flexibility in the use of different attitude representations in the inertial equations of motion through the use of an angle error model.

In this presentation, a psi-angle error model (Benson 1975) is used to represent the inertial localization equations in time-variant linear form. In the psi-angle error model, the estimated states are the vehicle position error ($\delta \mathbf{p}^e$), vehicle velocity error ($\delta \mathbf{v}^e$), and vehicle misalignment angles (or “psi angle”) ($\delta \Psi^n$). Typically inertial sensor biases must also be estimated online in practical aided inertial localization systems, due to their prevalence and time-varying nature in low-cost sensors; accelerometer bias ($\delta \mathbf{f}^b$) and gyro bias ($\delta \omega^b$) states are thus included in this presentation. Consider that the inertial sensor measurements have been made over a given time interval of flight, and by using an initial estimate of position, velocity, and attitude, a nominal set of localization states have been derived inside an ILS using Eqs. 22.25–22.28 recursively. The errors are defined as the difference between these computed states and the true state:

$$\delta \mathbf{p}^e = \hat{\mathbf{p}}^e - \mathbf{p}^e \quad (22.32)$$

$$\delta \mathbf{v}^e = \hat{\mathbf{v}}^e - \mathbf{v}^e \quad (22.33)$$

$$\delta \mathbf{f}^b = \hat{\mathbf{f}}^b - \mathbf{f}^b \quad (22.34)$$

$$\delta \omega_{ib}^b = \hat{\omega}_{ib}^b - \omega_{ib}^b \quad (22.35)$$

where $\hat{\mathbf{p}}^e, \hat{\mathbf{v}}^e, \hat{\mathbf{f}}^b, \hat{\omega}^b$ are the estimated values of the vehicle position, velocity, body-axis specific force, and rotation rates as computed in the ILS and $\mathbf{p}^e, \mathbf{v}^e, \mathbf{f}^b, \omega^b$ are the actual values of these states.

The misalignment angles ($\delta\Psi^e$) relate the true and inertial computed direction cosine matrices via

$$\mathbf{C}_b^e = [\mathbf{I}_{3 \times 3} - [\times \delta\Psi^e]] \hat{\mathbf{C}}_b^e \quad (22.36)$$

where \mathbf{C}_b^e is the true direction cosine matrix and $\hat{\mathbf{C}}_b^e$ is the computed direction cosine matrix within the ILS. In this presentation, the attitude relationship between the UAV body frame and the ECEF frame is maintained directly (i.e., using \mathbf{C}_b^e) for simplicity in the EKF model equations described in the section below. The advantage of the psi-angle model over a direct Jacobian of the Euler angle or quaternion equations (as used in a “direct” data fusion architecture) is that the error dynamics are based on the DCM, which avoids singularities during gimbal lock in Euler angles (when the UAV’s pitch equals $\pm 90^\circ$) and normalization constraints which are required when using quaternions.

The ILS maintains an internal state vector comprising the nominal states:

$$\hat{\mathbf{x}}(k) = [\mathbf{p}^e(k), \mathbf{v}^e(k), \Psi^n(k), \mathbf{f}^b(k), \omega_{ib}^b(k)]^T \quad (22.37)$$

The EKF maintains an internal state vector representing the current time (k) estimate of the ILS errors:

$$\delta\hat{\mathbf{x}}(k) = [\delta\mathbf{p}^e(k), \delta\mathbf{v}^e(k), \delta\Psi^e(k), \delta\mathbf{f}^b(k), \delta\omega_{ib}^b(k)]^T \quad (22.38)$$

Process and observation models for aided inertial localization are used in the EKF to maintain an estimate of the error states for each timestep k , which are discussed below.

22.4.3 Kalman Filter Error Process Model

The Kalman filter error process model maintains an estimate of the error and the error covariance of the ILS states in Eq. 22.37 which is used to help update and correct for the errors when additional localization sensor information is available. Based on the ILS equations in Sects. 22.3.1 and 22.3.2, an error process model that describes the propagation of the errors is used:

$$\dot{\delta\mathbf{p}}^e = \delta\mathbf{v}^e \quad (22.39)$$

$$\dot{\delta\mathbf{v}}^e = -([\times \omega_{ie}^e]^2 + \mathbf{M}_g) \delta\mathbf{p}^e - 2[\times \omega_{ie}^e] \delta\mathbf{v}^e + [\times \hat{\mathbf{f}}^e] \delta\Psi + \hat{\mathbf{C}}_b^e \delta\mathbf{f}^b + \hat{\mathbf{C}}_b^e \mathbf{w}_{\text{accel}}^b \quad (22.40)$$

$$\dot{\delta\Psi} = [\times \omega_{ie}^e] \delta\Psi + \hat{\mathbf{C}}_b^e \delta\omega^b + \hat{\mathbf{C}}_b^e \mathbf{w}_{\text{gyro}}^b \quad (22.41)$$

where $\mathbf{w}_{\text{accel}}^b$ and $\mathbf{w}_{\text{gyro}}^b$ are the accelerometer and gyro noise values, respectively, and

$$\hat{\mathbf{F}}^e = \begin{bmatrix} \hat{\mathbf{f}}_x^e & 0 & 0 \\ 0 & \hat{\mathbf{f}}_y^e & 0 \\ 0 & 0 & \hat{\mathbf{f}}_z^e \end{bmatrix} \quad (22.42)$$

where $[\hat{\mathbf{f}}_x^e, \hat{\mathbf{f}}_y^e, \hat{\mathbf{f}}_z^e]^T$ are the components of the specific force vector in ECEF coordinates. \mathbf{M}_g is the Jacobian of \mathbf{g}_l^e (see Eq. 22.12) with respect to $\delta \mathbf{p}^e$:

$$\mathbf{M}_g = \mathbf{g} \begin{bmatrix} \frac{x^2}{r^3} - \frac{1}{r} & \frac{xy}{r^3} & \frac{xz}{r^3} \\ \frac{xy}{r^3} & \frac{y^2}{r^3} - \frac{1}{r} & \frac{yz}{r^3} \\ \frac{xz}{r^3} & \frac{yz}{r^3} & \frac{z^2}{r^3} - \frac{1}{r} \end{bmatrix} \quad (22.43)$$

where $[x, y, z]^T = \mathbf{p}^e$ are the cartesian components of the ECEF position and $r = \sqrt{x^2 + y^2 + z^2}$.

The IMU measurement errors and biases can be modeled in various ways depending on the complexity of the sensors including states for biases, scale factor errors, and misalignments errors. For simplicity, a first-order, wandering bias and noise model is used:

$$\dot{\delta \mathbf{f}}^b = \mathbf{w}_{b,\text{accel}} \quad (22.44)$$

$$\dot{\delta \omega}_{ib}^b = \mathbf{w}_{b,\text{gyro}} \quad (22.45)$$

where $\mathbf{w}_{b,\text{accel}}$ and $\mathbf{w}_{b,\text{gyro}}$ are bias drift noises for the accelerometers and gyros, respectively. These first-order drift models account for slow, random drift in the biases over time.

The total error equations can thus be expressed in continuous-time form:

$$\dot{\delta \hat{\mathbf{x}}} = \mathbf{F}_c \delta \hat{\mathbf{x}} + \mathbf{G}_c \mathbf{w} \quad (22.46)$$

where

$$\mathbf{F}_c = \begin{bmatrix} \mathbf{0} & \mathbf{I}_{3 \times 3} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -([\times \omega_{ie}^e]^2 + \mathbf{M}_g) & -2[\times \omega_{ie}^e] & [\times \hat{\mathbf{f}}^e] & \hat{\mathbf{C}}_b^e & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & [\times \omega_{ie}^e] & \mathbf{0} & \hat{\mathbf{C}}_b^e \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (22.47)$$

$$\mathbf{G}_c = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \hat{\mathbf{C}}_b^e & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \hat{\mathbf{C}}_b^e & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} \end{bmatrix} \quad (22.48)$$

where \mathbf{w} is the combined state noise vector:

$$\mathbf{w} = [\mathbf{w}_{\text{accel}}^b, \mathbf{w}_{\text{gyro}}^b, \mathbf{w}_{b,\text{accel}}, \mathbf{w}_{b,\text{gyro}}]^T \quad (22.49)$$

The error equations are used to formulate a discrete process model via a first-order Euler integration:

$$\delta \hat{\mathbf{x}}(k) = \mathbf{F} \delta \hat{\mathbf{x}}(k-1) + \mathbf{G} \mathbf{w}(k) \quad (22.50)$$

where

$$\mathbf{F} = \begin{bmatrix} \mathbf{I}_{3 \times 3} & \mathbf{I}_{3 \times 3} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -([\times \omega_{ie}^e]^2 + \mathbf{M}_g) \Delta t & \mathbf{I}_{3 \times 3} - 2[\times \omega_{ie}^e] \Delta t & [\times \hat{\mathbf{f}}^e] \Delta t & \hat{\mathbf{C}}_b^e \Delta t & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} + [\times \omega_{ie}^e] \Delta t & \mathbf{0} & \hat{\mathbf{C}}_b^e \Delta t \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} \end{bmatrix} \quad (22.51)$$

$$\mathbf{G} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \hat{\mathbf{C}}_b^e \Delta t & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \hat{\mathbf{C}}_b^e \Delta t & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} \Delta t & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{3 \times 3} \Delta t \end{bmatrix} \quad (22.52)$$

22.4.4 Kalman Filter Update and Observation Models

Measurements made from other sensors onboard the UAV (satellite positioning systems and barometric and magnetic measurements) are used within the EKF update stage to estimate the error states of the ILS in Eq. 22.38 via the use of an observation model, which describes the relationship between the measurements

made and the EKF error states. The nominal form of the observation model relates the measurements to the nominal ILS states via a general function:

$$\mathbf{z}(k) = \mathbf{h}(\mathbf{x}(k)) + \mathbf{D}\mathbf{v}(k) \quad (22.53)$$

where $\mathbf{z}(k)$ is the observation data measured by the updating sensor, $\mathbf{h}(\cdot)$ is a set of functions relating the ILS state to the measurement (generally nonlinear), and \mathbf{v} is a vector which models the error, which is assumed to be a zero-mean, white Gaussian noise signal with covariance $\mathbf{R} = E[\mathbf{v}\mathbf{v}^T]$. In the “indirect” architecture, the EKF uses a form of the observation model which relates the measurements to the EKF error states:

$$\mathbf{z}(k) - \mathbf{h}(\hat{\mathbf{x}}(k)) \approx \nabla \mathbf{H} \delta \hat{\mathbf{x}}(k) + \mathbf{D}\mathbf{v}(k) \quad (22.54)$$

$$\delta \mathbf{z}(k) \approx \nabla \mathbf{H} \delta \hat{\mathbf{x}}(k) + \mathbf{D}\mathbf{v}(k) \quad (22.55)$$

where $\delta \mathbf{z}(k)$, referred to as the “error observation,” is the difference between the sensor measurement and the expected sensor measurement $\mathbf{h}(\hat{\mathbf{x}}(k))$ computed by using the latest ILS state. This subsection describes models for several types of sensors typically used in UAV localization.

22.4.4.1 Satellite Positioning System Measurements

Satellite positioning systems typically provide measurements of the UAV’s position and velocity with respect to a global coordinate system (such as ECEF coordinates). Position measurements made by the sensor are related to the nominal system state via

$$\mathbf{z}_{\text{pos}} = \mathbf{p}^e - \mathbf{C}_b^e \mathbf{I}_{\text{GPS}} + \mathbf{v}_{\text{pos}} \quad (22.56)$$

where \mathbf{z}_{pos} is the measurement provided by the satellite positioning system (in ECEF coordinates), \mathbf{p}^e is the ECEF position of the UAV, \mathbf{v}_{pos} is the measurement noise, and \mathbf{I}_{GPS} is the lever arm of the satellite positioning receiver with respect to the UAV body frame. The observation model parameters used by the EKF are given by

$$\nabla \mathbf{H}_{\text{pos}} = [\mathbf{I}_{3 \times 3} \quad \mathbf{0} \quad \mathbf{0} \quad \mathbf{0}] \quad (22.57)$$

$$\mathbf{D}_{\text{pos}} = \mathbf{I}_{3 \times 3} \quad (22.58)$$

Velocity measurements made by the sensor are related to the nominal system state via

$$\mathbf{z}_{\text{vel}} = \mathbf{v}^e - \mathbf{C}_b^e (\boldsymbol{\omega}_{ib}^b \times \mathbf{I}^{\text{GPS}}) + \mathbf{v}_{\text{vel}} \quad (22.59)$$

where \mathbf{z}_{vel} is the velocity measurement provided by the satellite positioning system (in ECEF coordinates), \mathbf{v}^e is the ECEF velocity of the UAV, and \mathbf{v}_{pos} is the measurement noise. The observation model parameters used by the EKF are given by

$$\nabla \mathbf{H}_{\text{vel}} = \begin{bmatrix} \mathbf{0} & \mathbf{I}_{3 \times 3} & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (22.60)$$

$$\mathbf{D}_{\text{vel}} = \mathbf{I}_{3 \times 3} \quad (22.61)$$

22.4.4.2 Magnetometer Measurements

Magnetometers typically provide two types of measurements: a measurement of the Earth's magnetic field vector referenced in the UAV body-fixed reference frame (\mathbf{B}_b) and a measurement of the magnetic heading angle ψ_{mag} which is derived from these first measurements. Depending on the type of information available, an aided inertial localization system may use either of these measurements.

When the complete magnetic field vector measurement is used, knowledge of the Earth's magnetic field pointing direction with respect to the ECEF frame (i.e., the vector \mathbf{B}_e) in the local region of the UAV's operation must also be known from a model of the Earth's magnetic field. The discussion of these models is beyond the scope of this chapter; the reader is referred to (Roithmayr 2004) for more details. The magnetometer measurement is related to the nominal states via

$$\mathbf{z}_{\text{mag}} = \mathbf{B}_b = \mathbf{C}_e^b \mathbf{B}^e + v_{\text{mag}} \quad (22.62)$$

$$= \hat{\mathbf{C}}_e^b [\mathbf{I}_{3 \times 3} - [\delta \Psi^e \times]] \mathbf{B}^e + v_{\text{mag}} \quad (22.63)$$

where v_{mag} is the measurement noise. The observation model parameters used by the EKF are given by

$$\nabla \mathbf{H}_{\text{mag}} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \hat{\mathbf{C}}_e^b [\mathbf{B}^e \times] & \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (22.64)$$

$$\mathbf{D}_{\text{mag}} = \mathbf{I}_{3 \times 3} \quad (22.65)$$

When only the magnetic heading measurement is known, the magnetometer measurement is related to nominal states via

$$\mathbf{z}_{\text{mag}} = \psi_{\text{mag}} + v_{\text{mag}} \quad (22.66)$$

where v_{mag} is the error in the magnetic heading reading, and ψ_{mag} has been adjusted to true north before applying the measurement in the EKF. The observation model parameters used by the EKF are given by

$$\nabla \mathbf{H}_{\text{mag}} = \begin{bmatrix} \mathbf{0}_{1 \times 3} & \mathbf{0}_{1 \times 3} & [0, 0, 1] & \mathbf{0}_{1 \times 3} & \mathbf{0}_{1 \times 3} \end{bmatrix} \quad (22.67)$$

$$\mathbf{D}_{\text{mag}} = 1 \quad (22.68)$$

22.4.4.3 Barometric Sensor Measurements

Barometric sensors derive measurements of the wind-relative airspeed and altitude of the UAV above sea level using measurement of static and dynamic air pressure typically measured using a pitot-static system. Altitude measurements are related to the ECEF position of the UAV via

$$\mathbf{z}_{\text{alt}} = \sqrt{(\mathbf{p}_x^e)^2 + (\mathbf{p}_y^e)^2 + (\mathbf{p}_z^e)^2} - R_{\text{Earth}} + v_{\text{alt}} \quad (22.69)$$

where v_{alt} is the barometric altitude measurement noise. The observation model parameters used by the EKF are given by

$$\nabla \mathbf{H}_{\text{alt}} = \begin{bmatrix} \frac{\mathbf{p}_x^e}{|\mathbf{p}^e|} & \frac{\mathbf{p}_y^e}{|\mathbf{p}^e|} & \frac{\mathbf{p}_z^e}{|\mathbf{p}^e|} & \mathbf{0}_{1 \times 3} & \mathbf{0}_{1 \times 3} & \mathbf{0}_{1 \times 3} & \mathbf{0}_{1 \times 3} \end{bmatrix} \quad (22.70)$$

$$\mathbf{D}_{\text{alt}} = 1 \quad (22.71)$$

where $|\mathbf{p}^e|$ is the magnitude of the vector \mathbf{p}^e .

Assuming the airspeed measurement is made along the noise of the UAV (i.e., the x-axis of the UAV body frame), airspeed measurements are related to the ECEF velocity of the UAV via

$$\mathbf{z}_{\text{as}} = \mathbf{v}_x^b = (\hat{\mathbf{C}}_e^b \mathbf{v}^e)_x + v_{\text{as}} \quad (22.72)$$

where $(\hat{\mathbf{C}}_e^b \mathbf{v}^e)_x$ is the x-axis component of the vector $\mathbf{v}^b = \hat{\mathbf{C}}_e^b \mathbf{v}^e$ and v_{as} is the airspeed sensor noise. The observation model parameters used by the EKF are given by

$$\nabla \mathbf{H}_{\text{as}} = [\mathbf{0}_{1,3}, \cos \psi \cos \theta, \sin \psi \cos \theta, -\sin \theta, \dots \quad (22.73)$$

$$-v_d \sin \psi \cos \theta - v_e \sin \theta, v_d \cos \psi \cos \theta + v_n \sin \theta, \dots$$

$$-v_e \cos \psi \cos \theta + v_n \sin \psi \cos \theta, \mathbf{0}_{1 \times 3}, \mathbf{0}_{1 \times 3}]$$

$$\mathbf{D}_{\text{as}} = 1 \quad (22.74)$$

where $[v_n, v_e, v_d]$ are the components of the velocity vector $\mathbf{v}^n = \mathbf{C}_e^n \mathbf{v}^e$.

22.4.5 Kalman Filter Prediction Stage

The Kalman filter prediction stage is run at the frequency of received IMU data and is used to propagate forward in time a prediction of the ILS states and predicted error covariance. At the beginning of each prediction step, the error in the ILS state, $\delta \hat{\mathbf{x}}(k)$, is assumed to have a zero-mean value (as it has been previously corrected

at the last EKF update stage or during initialization). Therefore, the estimate of the error's mean value is propagated via Eq. 22.50 such that

$$\delta \hat{\mathbf{x}}(k) = \mathbf{F} \delta \hat{\mathbf{x}}(k-1) \quad (22.75)$$

$$= \mathbf{F} \mathbf{0} \quad (22.76)$$

$$= \mathbf{0} \quad (22.77)$$

Although the mean value of the error state $\delta \hat{\mathbf{x}}(k)$ is assumed to be zero, the estimated covariance of the error representing the uncertainty in the error state value is nonzero and grows at each prediction step based on the initial error uncertainty and expected noise in the IMU measurements and is propagated forward via

$$\mathbf{P}(k) = \mathbf{F} \mathbf{P}(k-1) \mathbf{F}^T + \mathbf{G} \mathbf{Q} \mathbf{G}^T \quad (22.78)$$

where $\mathbf{Q} = E[\mathbf{w} \mathbf{w}^T]$ is the covariance of the noise on the accelerometers, gyros, and IMU bias drift noises. The EKF prediction stage is calculated each time an IMU measurement is made.

22.4.6 Kalman Filter Update Stage

When an observation from any of the aiding sensors (such as the satellite positioning system, magnetometer, barometric sensors) is available, the EKF update stage is used to estimate the EKF error state and use this estimate to correct the ILS. The mean and covariance of the EKF error states after the update are computed:

$$\hat{\delta \mathbf{x}}(k) = \mathbf{W}(k) \delta \mathbf{z}(k) \quad (22.79)$$

$$\mathbf{W}(k) = \mathbf{P}(k) \nabla \mathbf{H}^T \mathbf{S}^{-1}(k) \quad (22.80)$$

$$\mathbf{S}(k) = \nabla \mathbf{H} \mathbf{P}(k) \nabla \mathbf{H}^T + \mathbf{D} \mathbf{R} \mathbf{D}^T \quad (22.81)$$

where $\mathbf{P}(k)$ is the current value of estimate covariance given by the prediction stage and $\mathbf{R} = E[\mathbf{v}(k) \mathbf{v}(k)^T]$ is the covariance of the observation noise \mathbf{v} associated with the updating sensor making the measurement. The estimate $\hat{\delta \mathbf{x}}$ is then used to correct the inertial localization system position, velocity, attitude, and IMU bias states via

$$\mathbf{p}^e = \mathbf{p}^e - \delta \hat{\mathbf{p}}^e \quad (22.82)$$

$$\mathbf{v}^e = \mathbf{v}^e - \delta \hat{\mathbf{v}}^e \quad (22.83)$$

$$\mathbf{C}_b^e = [\mathbf{I}_{3 \times 3} + [\delta \hat{\Psi} \times]] \hat{\mathbf{C}}_b^e \quad (22.84)$$

The Euler angles or quaternions representing the orientation of the body axes with respect to the local navigation frame axes are computed from \mathbf{C}_b^n , which is computed by

$$\mathbf{C}_b^n = (\mathbf{C}_n^e)^T \mathbf{C}_b^e \quad (22.85)$$

where \mathbf{C}_n^e is computed using \mathbf{p}^e and Eq. 22.14. The estimated IMU biases and scale factors and the bias and scale factor error estimates on the other localization sensors are also fed back to the ILS and used to correct the data coming from the IMU using Eqs. 22.34–22.35.

Finally, the estimated covariance of the error state is updated from the observation:

$$\mathbf{P}(k)^+ = \mathbf{P}(k) - \mathbf{W}(k)\mathbf{S}(k)\mathbf{W}(k)^T \quad (22.86)$$

where the subscript $+$ indicates the covariance matrix after the update.

22.4.6.1 Detecting and Rejecting Measurement Outliers

In addition to sensor errors and uncertainty modeled by noise, in practice, sensor measurements may contain unmodeled error sources that occur too infrequently for incorporating into the models described in Sect. 22.4.4. The erroneous measurements can be treated as outliers and rejected from the EKF update stage during the EKF operation. When measurements are made by aiding sensors, they are tested through an “outlier gate” to test for their likelihood of being an outlier using the error observation $\delta\mathbf{z}(k)$ in the EKF update stage.

For each observation from an aiding sensor, the normalized innovation squared $\gamma(k)$ is computed:

$$\gamma(k) = \delta\mathbf{z}^T(k)\mathbf{S}^{-1}(k)\delta\mathbf{z}(k) \quad (22.87)$$

For a correctly tuned filter, $\delta\mathbf{z}(k)$ should follow a zero-mean distribution with covariance $\mathbf{S}(k)$ (i.e., the innovation covariance) which is computed using the assumed sensor uncertainty encoded in \mathbf{R} and the current time estimate of the error state covariance, encoded in $\mathbf{P}(k)$. Measurements that correspond to inliers will have normalized innovation squared $\gamma(k)$ values that average to $\gamma(k) = 1$ and follow a χ^2 distribution in the number of observation variables in $\delta\mathbf{z}(k)$ (i.e., the dimension of the observation vector). Based on confidence intervals in the χ^2 distribution, a threshold on $\gamma(k)$ is obtained such that observations whose normalized innovation squared values exceed the threshold are statistically unlikely and rejected as outliers.

22.5 Example: Inertial-GPS Localization on a UAV

In this section, results of the aided inertial localization algorithms described above when implemented onboard a small UAV are provided.

Fig. 22.4 UAV and localization sensor payload system: *left*, the J3 Cub, a small UAV used primarily for airborne photographic mapping; *right*, the sensor payload box carried onboard the UAV consisting of a triaxial IMU, GPS receiver, and PC104 computer stack for logging and processing data

22.5.1 Experimental Setup

Sensor data was collected during the flight of a small UAV, the J3 Cub (see Fig. 22.4) which carried a payload consisting of a low-cost IMU, differentially corrected GPS receiver, and a color camera system. The UAV is used primarily for photogrammetric mapping applications which require accurate estimates of the UAV's position and orientation throughout its flight path. The vehicle achieves speeds of 25 m/s and roll rates of up to 100°/s, necessitating the use of inertial sensors. The flight path of the vehicle is set by an onboard autonomous control system, with a preplanned flight pattern used to provide sensor coverage (using the onboard camera) with a fixed altitude over a region of interest for mapping.

Sensor data from the IMU and GPS was collected during a 65-min flight test of the UAV and processed using the ILS and EKF algorithms described in Sects. 22.3 and 22.4 to estimate the position, velocity, attitude, and IMU sensor biases throughout the flight. Specifications for the IMU and GPS receiver are shown in Table 22.1. Initial state estimates were computed using GPS and IMU measurements and an external heading measurement while stationary on the ground before takeoff.

22.5.2 Results and Discussion

Figure 22.5 illustrates the complete trajectory for the vehicle comparing position observations for the onboard GPS receiver, position estimates derived purely from

Table 22.1 Sensor payload specifications: the sensor payload consists of an low-cost IMU and GPS receiver

| GPS receiver | | IMU | |
|----------------|-----------------------|------------------------------|------------------------------------|
| Sampling rate | 5 Hz | Sampling rate | 100 Hz |
| Position error | 1 m (1σ) | Accelerometer noise | 0.05 m/s^2 (1σ) |
| Velocity error | 10 cm/s (1σ) | Gyro noise | 0.05 deg/s (1σ) |
| | | Accelerometer bias stability | $\pm 0.05 \text{ m/s}^2$ |
| | | Gyro bias stability | $\pm 0.05 \text{ deg/s}$ |

Fig. 22.5 Overhead view of UAV flight trajectory showing GPS-measured position, unaided ILS position, and the fused aided ILS EKF solution. Also shown is a zoomed-in section of the trajectory highlighting performance of the estimator during banking maneuvers

unaided ILS (using initial position and alignment from the IMU and GPS receiver) and the fused GPS-aided ILS solution. The origin of the displayed coordinate system is centered on the starting location of the vehicle before takeoff. The vehicle

Fig. 22.6 ECEF UAV position trajectory showing GPS-measured position, unaided ILS position, and the fused aided-ILS EKF solution

takes off and performs a series of parallel transects at a fixed altitude before returning to the origin for landing. The GPS-aided ILS trajectory remains close to the GPS measurements during the flight, indicating a constraint in the position errors, whereas the unaided ILS position estimates drift significantly over time due to unbounded growth in the ILS dead-reckoning errors.

Figure 22.6 illustrates the components of the local navigation frame position of the vehicle (north, east, altitude) over the time of the flight, with a highlighted

Fig. 22.7 ECEF UAV velocity showing GPS-measured velocity, unaided-ILS velocity and the fused aided ILS EKF solution

section of the flight shown in the second subfigure. The subfigure highlights an example of GPS outlier detection (see $t \approx 1972$ s) where a series of GPS measurements are seen to “jump” to a new position solution for a few seconds before returning to a stable position solution. Such outliers are typically observed in satellite positioning systems when, for example, satellites move in and out of view of the positioning system receiver. This series of outliers is detected by the outlier rejection process of the filter and is rejected.

Fig. 22.8 UAV Euler angles showing unaided ILS attitude and the fused aided ILS EKF solution

Figure 22.7 shows a comparison of the GPS-measured platform velocity, unaided ILS velocity, and GPS-aided ILS velocity estimates. As in the case of position estimates, the unaided velocity estimate errors grow over time due to dead reckoning, whereas the GPS-aided velocity estimate errors are constrained by the filter corrections. The error growth in the position solution is observed to be much greater than the velocity error growth due the position information being derived from velocity (as a second-order derivative of acceleration).

Figure 22.8 illustrates the estimated Euler angles of the UAV transformed as to represent the rotations between the UAV body frame and the local navigation frame. The UAV undergoes banking turns and changes in heading as it completes the parallel trajectory transects, seen by the spikes in the roll angle data and changes in the yaw angle. The unaided ILS solution exhibits only a small degree of drift, mainly observed in the yaw angle, when compared to the error growth in both the position and velocity estimates. This is firstly due to the generally higher accuracy and bias stability of the gyro sensors with respect to accelerometers and secondly, and more importantly, to the fact that position and velocity dead-reckoning errors are also attributed to attitude errors themselves due to the transformation of IMU accelerometer measurements from body-fixed coordinates into navigation coordinates, proceeding numerical integration, which is performed using the Euler angles estimates.

Figure 22.9 shows the estimated accelerometer and gyro biases computed by the EKF and used to correct the IMU measurements in a feedback loop to the ILS. Estimation of these states relies on the motion of the UAV, thus resulting in a transient period of uncertainty in these estimates seen around takeoff, followed by a more stable estimate during the rest of the flight.

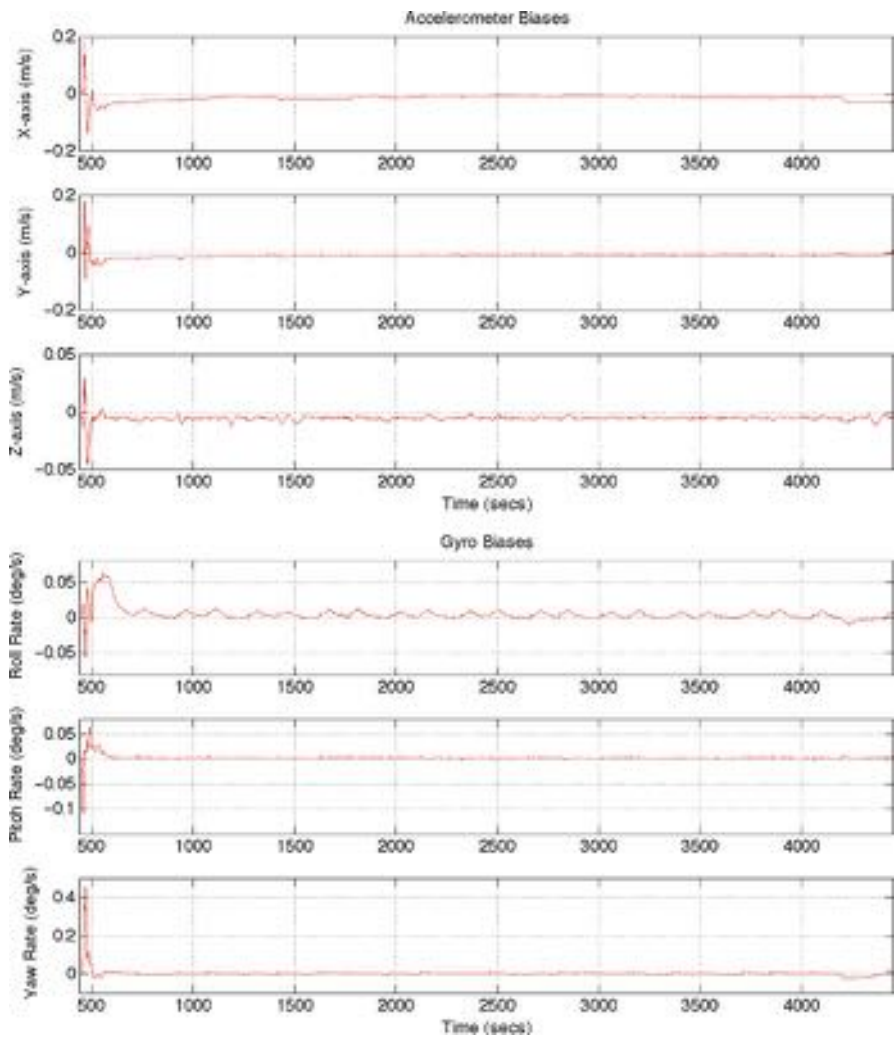

Fig. 22.9 IMU accelerometer and gyro bias estimates from the fused aided ILS EKF solution

Conclusion

This chapter has provided an overview of algorithms for aided inertial localization using the fusion of IMU measurements with measurements from sensors such as satellite positioning systems, magnetometers, and barometric sensors. The fusion of these sensors provides both accuracy and high-rate information about location including the position, velocity, and attitude of a UAV. The presentation in this chapter is based in the use of the EKF as the primary tool for data fusion and an “indirect” data fusion architecture based on an error state model, providing a simple and computationally efficient localization system.

Abstract

This chapter describes decentralized data fusion algorithms for a team of multiple autonomous platforms. Decentralized data fusion (DDF) provides a useful basis with which to build upon for cooperative information gathering tasks for robotic teams operating in outdoor environments. Through the DDF algorithms, each platform can maintain a consistent global solution from which decisions may then be made. Comparisons will be made between the implementation of DDF using two probabilistic representations. The first, Gaussian estimates and the second Gaussian mixtures are compared using a common data set. The overall system design is detailed, providing insight into the overall complexity of implementing a robust DDF system for use in information gathering tasks in outdoor UAV applications.

23.1 Introduction

Cooperative information gathering tasks involving multiple autonomous platforms can be formulated for many types of hardware and software configurations. In all cases, teams of robots must efficiently communicate their observations of the world and together build a representative map of the environment that they operate in. This chapter will describe how a team of autonomous, mobile platforms in an outdoor environment can cooperatively build a map of the observed features.

This chapter concentrates on the implementation of non-Gaussian DDF for outdoor environments using a robust software framework for team robotics, specifically the *development* and *implementation* of non-Gaussian decentralized data fusion algorithms within complex, large-scale robotic systems.

The remainder of this section outlines related research and applications. Section 23.2 describes the DDF architecture. Section 23.3 details the DDF algorithms specific for a variety of probabilistic representations. Gaussian mixture-based DDF is then focused on in Sect. 23.4. The experimental hardware and related algorithms then follow in Sect. 23.5, and results are analyzed in Sect. 23.6.

23.1.1 Related Work

Applications that benefit from multisensor data fusion include environmental sensing, surveillance, and search-and-rescue (Paskin and Guestrin 2004; Rosencrantz et al. 2003a; Bourgalt and Durrant-Whyte 2004). In each of these problems, individual nodes of the network make local measurements or observations of the common environment and attempt to combine the measurements to produce a global estimate of the observed state. The fusion approach adopted here is motivated by the need to survey and map large outdoor natural environments in which distributed sensor networks are prone to node and/or communication failure. In contrast to hierarchical and centralized distributed methods (Hashemipour et al. 1988; Nii 1986), decentralized architectures ensure robustness to communication failures while allowing scalability and modularity (Manyika and Durrant-Whyte 1994). These properties arise as there are no central nodes to which global knowledge is communicated.

Previous approaches to robust decentralized data fusion have included tracking position features provided by range devices such as radar or laser (Rosencrantz et al. 2003a), monitoring temperature (Paskin and Guestrin 2004), people movement (Brooks et al. 2004) in an office environment, or tracking artificial visual features with known range (Nettleton et al. 2000). This chapter will expand upon visual features with known range to include those with a maximum range, i.e., a more realistic bearing only sensor model.

Non-Gaussian distributed algorithms for sensor calibration have previously been developed by Ihler et al. (2004), while Rosencrantz et al. (2003a) demonstrated non-Gaussian distributed state estimation in the context of robotic laser tag. In both cases, correlated estimation errors due to common information communicated between nodes in the past (also known as data incest) (Bar-Shalom 1990; Bar-Shalom and Li 1995) were not considered. Accounting for data incest in decentralized architectures is the key problem in ensuring mathematically consistent and convergent solutions. Implemented is an approximate node-node fusion algorithm (Upcroft et al. 2005) using Gaussian mixture models (GMMs) and a variant of the covariance intersect algorithm (Julier and Uhlmann 2001b). This algorithm provides consistent estimates in practice, but like Ihler and Rosencrantz's work, there is no guarantee of a convergent solution.

23.1.2 Applications of DDF

Decentralized data fusion provides a useful basis with which to build upon for cooperative information gathering tasks. Each platform obtains a consistent global solution upon which decisions can then be made. Any given platform can then operate with the confidence that all other platforms will make complimentary decisions, due to the consistency of information across all platforms. Further discussion of the suitability of the DDF algorithm for team problems has been made

by Grocholsky (2002). In a similar light the decentralized search and rescue problem has been investigated by Bourgault et al. (2003).

23.2 Decentralized Data Fusion

Decentralized data fusion (DDF) is the process of estimating states of features by combining information from multiple sensors connected to local processing nodes that are then interconnected in such a way that the system does not depend on a single centralized fusion center. Figure 23.1 depicts the major components of several decentralized sensing nodes.

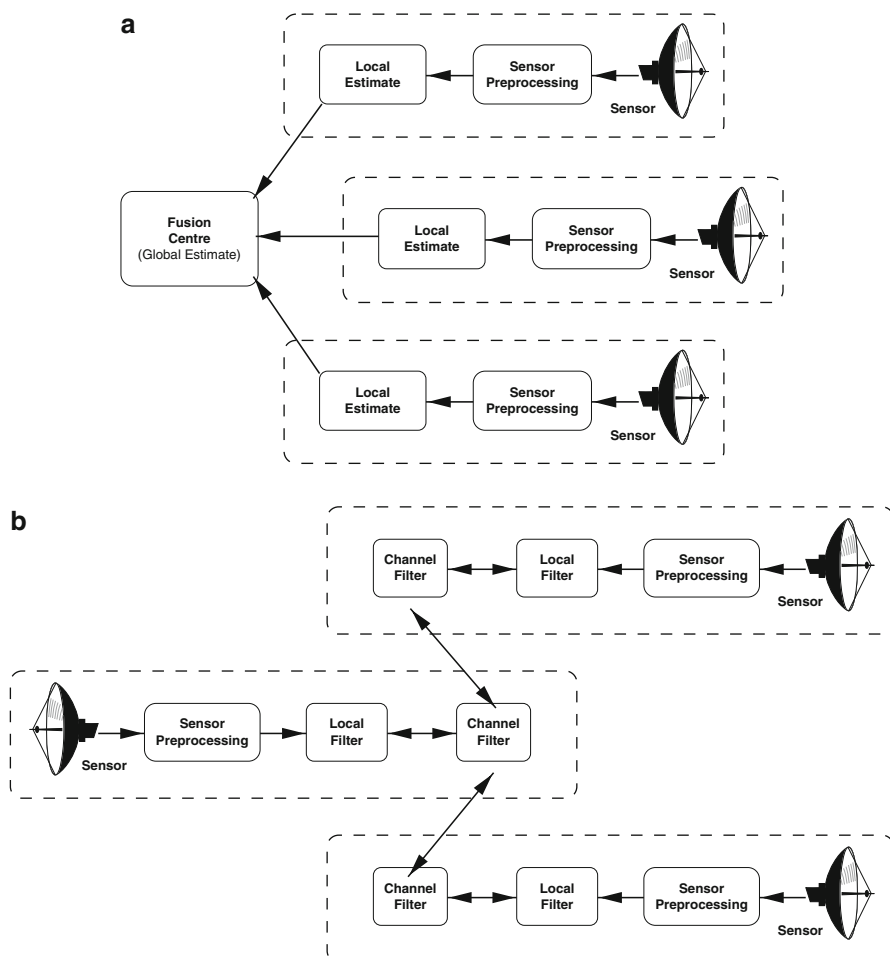

Fig. 23.1 Distributed, decentralized (with known and unknown hierarchy) data fusion architectures

Each decentralized sensor node typically has its own sensor, a local fusion center that contains global information, and a channel filter to facilitate the propagation of information throughout the network.

Decentralized systems are characterized by the following (Grime and Durrant-Whyte 1994):

- There is no single central decision center; no node should be central to the successful operation of the network.
- There is no common communication facility; nodes cannot broadcast results; and communication must be kept on a strictly node-to-node basis.
- Nodes do not have global knowledge of network topology; nodes should only know about connections in their own neighborhood.

These are considered as the three *axioms* of decentralized systems. A system cannot be considered truly decentralized if it does not adhere to these constraints.

The primary motivations to decentralize are:

Scalability The structure of communication within a decentralized system is such that communication bottlenecks are eliminated. The result is a system that scales independently of the number of nodes within the network, provided that independent communication links are available.

Robustness By removing the dependence on any centralized controller or fusion center, a decentralized system will tend toward a graceful degradation in performance rather than a system-wide failure in the case of a distributed system.

Modularity The modular nature of a decentralized system allows nodes to be added and removed at any time to suit the requirements at any given time.

Decentralized sensor nodes are required to have significantly more processing capability to provide for the fusion of both local and network information. Sensor nodes developed for distributed systems typically do not possess sufficient storage or processing capabilities to operate effectively within a decentralized sensor network.

23.2.1 The Decentralized Bayesian Estimator

This section describes the decentralized Bayesian estimation approach in the form developed by Grime (1992). The basic approach has changed little since then. However, it remains key to the successful operation of a decentralized sensor network. The following sections will describe the basic components of a decentralized sensor node and the interactions between them.

Figure 23.2 details the internal operations of a decentralized Bayesian estimator. To simplify the situation, only one channel filter is shown (there would be one for every node the node is connected to).

23.2.2 Local Filter

The local filter operates as a normal Bayesian estimator. The only difference is that there are now two sources from which new information may be gained:

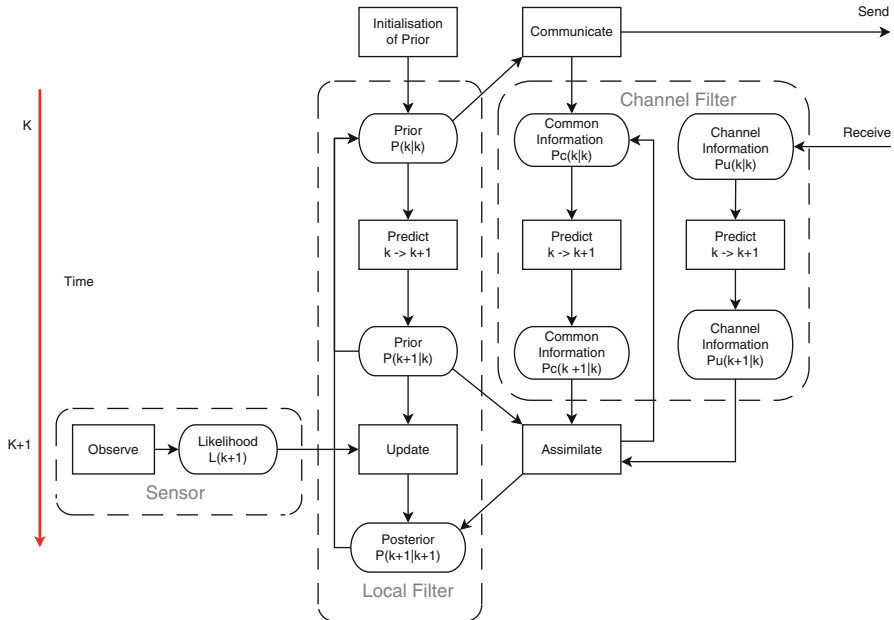

Fig. 23.2 General recursive decentralized Bayesian estimator

the local sensor and the remotely connected node. The local filter essentially operates in complete ignorance of all the decentralized aspects. The only difference being that a channel update/assimilation may occur, involving a full probability distribution as opposed to a sensor likelihood. So long as the local filter has a means to perform both likelihood updates and full state updates, no modification is required.

23.2.2.1 Local State Estimation

The recursive update after an observation is given by Bayes theorem:

$$p(x_k|Z^k) = \frac{p(z = z_k|x_k)p(x_k|Z^{k-1})}{p(z_k|Z^{k-1})} \quad (23.1)$$

where Z^k are observations of a state x_k at time t_k , $p(z|x_k)$ is the likelihood model, $p(x_k|Z^{k-1})$ is the prediction from the posterior over the previous state, and $Z^k = \{z_k, Z^{k-1}\}$ is the set of observations from all nodes in the DDF network.

The local prediction step is given by the Chapman-Kolmogorov equation:

$$p(x_k|Z^{k-1}) = \int p(x_k|x_{k-1})p(x_{k-1}|Z^{k-1}, x_0)dx_{k-1} \quad (23.2)$$

where $p(x_k|x_{k-1})$ is the transition probability density and $p(x_{k-1}|Z^{k-1}, x_0)$ is the updated estimate from the previous time step.

23.2.3 Node-Node Fusion

All local node information is transmitted to neighboring platforms as a posterior probability distribution. The net result is that each platform locally maintains a complete map (or belief) of all features observed by all nodes in the network. Multiple observations of the same feature, possibly by different platforms, result in an increasingly accurate estimate of the feature location for *all* nodes.

Use of the covariance intersect algorithm (for Gaussian distributions) as described by Julier (Julier and Uhlmann 2001b) and Sect. 23.4.3.1 provides a means to generate conservative updates between multiple decentralized nodes. This process eliminates the need for a channel filter but is typically more conservative than otherwise desirable.

Communicating increments of information updates eliminates the need for a channel filter. However, this approach is not robust to communication failure and is seldom used for this very reason. In the event of communication failure, the channel filter on a given node may become out of sync with the actual amount of common information a node contains. While this is not disastrous, the result is less than optimal as excessive information will be removed from incoming transmissions, until the channel filters realign.

23.2.3.1 The Channel Filter

The purpose of the channel filter is to maintain the information about a particular feature that a node has in common with another that it is connected to within a network. Without this, assimilation of information from the network may result in double counting of information previously sent, resulting in overconfident estimates. This is the area of primary concern, as removal of common information from communicated distributions other than Gaussians is nontrivial.

It can be shown (Bar-Shalom 1990; Bar-Shalom and Li 1995) that fusion of the raw correlated information between nodes i and j is

$$p(x|Z_i \cup Z_j) = \frac{1}{c} \frac{p(x|Z_i)p(x|Z_j)}{p(x|Z_i \cap Z_j)} \quad (23.3)$$

where $Z_{i(j)}$ are all the observations available to node i (j), $p(x|Z_i \cup Z_j)$ is the posterior probability over the unknown state given information from both nodes, $p(x|Z_{i(j)})$ are the posteriors based only on locally available information, $p(x|Z_i \cap Z_j)$ is the information the two nodes have in common, and c is a normalizing constant.

The immediate consequence of this is that channel update operations require both a multiplication and a division operation to assimilate channel information. When operating with log probabilities or an information filter, this can be accomplished with addition and subtraction operations. However, this form is seldom used (apart from the information filter) as addition and subtraction is not closed in form for most representations. Thus, the problem of constructing the union $Z_i \cup Z_j$ reduces to finding the common information $Z_i \cap Z_j$ and is the *key* to the decentralized communication problem. The incorporation of redundant information in DDF systems may lead to bias, overconfidence, and divergence in estimates.

23.2.3.2 Send Operation

As local observations are made at a sensor node, the local filter accrues information. At some point, this information will be transmitted to a remote node. This may occur periodically (as in the most simple case), or additional channel management components will determine this according to its own rules.

When a feature is communicated to a connected node, the contents of the local filter are directly copied into the corresponding channel filter, and the data is then transmitted down the link. Assuming no communication failures, the contents of the channel filter will contain all that is common between the two nodes.

The full state is always communicated, as per Nettleton (2003), as this ensures that in the event of communication failure, all sensor nodes may recover, and no information will be lost.

23.2.3.3 Receive Operation

Once a message is received, temporal alignment of any information received must be performed. Either the received information is propagated forward in time until it reaches that of the local filters, or the local filters are propagated forward to the corresponding time of the received data.

Any incoming data must first be matched against all local filters, to determine which feature the data should be associated with, i.e., data association. This incoming data will contain information that is common between the two nodes. This must now be removed prior to fusion within the local filter.

In state space this is achieved by dividing the incoming probability distribution by the distribution forming the contents of the channel filter. In Fisher space, this would correspond to subtracting the equivalent forms. The result is termed the “information gain” or “new information.”

This new information may then be fused into the local filter. At the same time, an update must be performed on the channel filter with this new information that was previously calculated. This corresponds to a multiplication in state space or an addition in Fisher space. The channel filter must again contain all information that is common between the two nodes, so the contents of the local filter are copied to the channel filter.

23.3 Representations for Implementation of DDF

This section will outline a variety of means to communicate multimodal probability distributions within a sensor network and then to assimilate this information without overconfidence into the destination nodes. Most non-Gaussian representations will require an operation that will result in a less than optimal solution. The operations of primary concern are prediction, Bayesian updates, and assimilation of channel information.

The objective of this section is to identify a *specific* representation and then develop algorithms with which to *efficiently* manipulate these representations, yet manage the expected deviation from an optimal solution.

23.3.1 General Requirements

Assimilation of information communicated within particular channels requires both a product and a division. In log space this may be achieved by addition and subtraction. As for the information filter, operating in Fisher space provides similar such benefits. Local updates from locally attached sensors require only a product or addition depending on the representation chosen.

The time evolution (or prediction) of a probability distribution must also be performed at regular intervals. This is required for both local filters and channel filters. As such it occurs more frequently than that of channel and local update operations. Prediction operations therefore need to be the most efficient of the two.

23.3.2 Approaches and Limitations

There are a variety of techniques for alternate representations of probability distributions to improve the performance of tracking algorithms for nonlinear and/or non-Gaussian sensors and/or systems. Such approaches include the particle filter by Gordon et al. (1993); Gaussian mixtures by Alspach and Sorenson (1972), Ito and Xiong (2000), and Robert (1996); support vector machines by Challa et al. (2002); or even discretized distributions by Stone et al. (1999).

The desire for richer representations in decentralized systems (Ridley et al. 2002) has been present for some time. However, decentralized data fusion techniques have generally remained exclusively tied to Gaussian representations. A method to decentralize a particle filter is described by Rosencrantz et al. (2003a,b). However, this method did not have a means to directly calculate the common information shared between the nodes, and its operation did not guarantee a consistent result at each node. The approach communicated information increments, hence not being robust to communication failure and opened the possibility of overconfidence.

23.3.3 Alternatives for Probabilistic Representation

This section will explore several possible avenues for a suitable representation and provide a selection based on algorithmic efficiency, storage requirements, and use of approximations. An assessment will be made of exponential functions, kernel methods, and Monte Carlo methods to determine what prospects exist for the use of these representations in decentralized data fusion applications.

Any number of representations may be chosen to perform DDF. However, the majority of operations required to perform DDF with these representations are not closed in form, and many require inefficient numerical approximations. This renders these representations impractical for real-world applications, with real-time constraints. With the advent of GPU-based numerical processing, this is becoming less of a concern.

Monte Carlo methods may be employed as described by Ong (2007) and Ong et al. (2005) who provide a workable solution by converting the particles to a continuous distribution using a variety of reparameterization methods. After channel filter operations are complete, the distribution is then resampled as particles.

23.3.3.1 Gaussian Representation

The baseline implementation of DDF would imply Gaussian distributions and Kalman filter-based techniques.

This is often in the form of the information filter form of the Kalman filter as described by Nettleton and Durrant-Whyte (2001). This simplifies channel updates and local updates at the expense of prediction cycles.

When the information filter is applied to a decentralized data fusion problem, the result is the decentralized information filter, defined as follows:

$$\hat{\mathbf{y}}(k|k) = \hat{\mathbf{y}}(k|k-1) + \sum_{j=1}^n \Delta \mathbf{y}_j(k) \quad (23.4)$$

$$\mathbf{Y}(k|k) = \mathbf{Y}(k|k-1) + \sum_{j=1}^n \Delta \mathbf{Y}_j(k) \quad (23.5)$$

where j is the number of nodes providing information at time k .

When considering channel updates, information held within the channel filters may be conveniently and efficiently subtracted from the information received from another node.

When considering the choice of using the Kalman filter or its information form, one would need to determine the frequency of channel updates (a function of the number of connected nodes) versus frequency of local state predictions to determine the suitability for a particular purpose.

23.3.3.2 Monte Carlo Methods

The use of particle filters in robotic applications has been successfully employed for navigation by Gustafsson et al. (2002) and many other applications. However,

the multiagent distribution of a particle sets has remained relatively limited. The concept of the assimilation of multiple independent particle sets is described by Thrun et al. (1999). However, it quickly becomes apparent that costly numerical approximations are required to perform a Bayesian update with two independent particle sets. This is due to the fact that no two samples from each set are identical, thus making it impossible to directly obtain a product.

Ong (2007) and Ong et al. (2005) provide a workable solution by converting the particles to a continuous distribution using a variety of reparameterization methods. After channel filter operations are complete, the distribution is then resampled as particles.

23.3.3.3 Gaussian Mixtures

Gaussian mixtures provide a convenient means to represent a multimodal probability distribution. The product of two Gaussian mixtures is indeed another Gaussian mixture. However, the combinatorial expansion results in a dramatic increase of the quantity of Gaussians. Use of Gaussian mixtures for Bayesian filtering is closed in form, but not closed in its dimensionality. Practical application of Gaussian mixtures is demonstrated in both recent and past works of Alspach and Sorenson (1972), Ito and Xiong (2000), and Robert (1996). The resampling of the ever-growing Gaussian mixtures may be achieved by a variety of methods such as EM (expectation maximization), importance sampling (as used by particle filters), and clustering using distance measures between Gaussians.

The assimilation of Gaussian mixtures within a DDF network can be achieved using an extension of the Gaussian covariance intersect method described by Upcroft et al. (2005). However, there is again a multiplicative increase in the number of components of the resulting distribution. The number of components must be reduced with one of the aforementioned methods. The covariance intersect method is also somewhat conservative in nature and provides a far from optimal Bayesian update.

23.3.3.4 Parzen Density Estimates

An attractive alternative for approximating a probability distribution is a Gaussian mixture consisting of the same-shaped Gaussian kernel.

Probability distributions may be represented using a variety of kernel-based methods. One such method is the Parzen density estimate (Parzen 1962). Since the kernel is Gaussian, it is a most useful implementation due to the fact that a significant number of operations are closed in form and are computationally less complicated than full Gaussian mixtures (Ridley 2005).

23.3.4 Storage Comparison

Consider the communication storage requirements of a probabilistic representation in N dimensions, with a possible M components. For the case of Gaussian distributions, Gaussian mixtures, and the Gaussian kernel of Parzen density estimates, the covariance matrix is symmetric positive definite (SPD), and as such communication

Table 23.1 Storage requirements of various probabilistic representations in N dimensions with M possible components

| Name | Samples | Kernels | Weights | Total storage |
|--------------------|---------|---------|---------|---------------------------|
| Gaussian | 1 | 1 | 0 | $(N^2 + N)/2 + N$ |
| Parzen estimate | M | 1 | M | $(N^2 + N)/2 + M(N + 1)$ |
| Weighted particles | M | 0 | M | $M(N + 1)$ |
| Particles | M | 0 | 0 | $N \times M$ |
| Gaussian mixture | M | M | M | $(N^2 + N)M/2 + M(N + 1)$ |

does not require the storage of all $N \times N$ terms. Each covariance matrix only requires the storage of $(N^2 + N)/2$ values. Table 23.1 shows the required storage in units of the floating-point values (typically 64-bit floating-point numbers).

Both Gaussian mixtures and Parzen estimates perform well. In terms of storage, Gaussian mixtures would be an obvious choice. However, when the overall computational complexity is taken into consideration, the benefits of a Parzen density estimate are significant and may be a better choice when computational resources are at a premium.

23.4 Gaussian Mixture-Based Decentralized Data Fusion

Gaussian mixture model-based decentralized data fusion is chosen for the later example due to its compact storage requirements and ability to provide a good approximation to a variety of distributions. The desire to provide capability for the characterization of natural features and the common use of GMM in machine learning problems made it difficult to overlook.

23.4.1 Introduction

Mixtures of Gaussians, otherwise known as “sums of Gaussians” (SOG) or “Gaussian mixture models” (GMM), are often used in order to represent a probability distribution that has multiple modes. A mixture of Gaussians i , each with weights γ_i , is defined as:

$$P(\mathbf{x}) = \sum_{i=1}^n \gamma_i G_i(\mathbf{x}) \quad (23.6)$$

where

$$G_i(\mathbf{x}) = \frac{1}{(2\pi)^{n/2} |\Sigma_i|^{1/2}} e^{-\frac{1}{2} [\mathbf{x} - \bar{\mathbf{x}}]^T \Sigma_i^{-1} [\mathbf{x} - \bar{\mathbf{x}}]} \quad (23.7)$$

and

$$\sum_{i=1}^n \gamma_i = 1 \quad (23.8)$$

Motivation for the use of GMMs:

- A compact representation
- Good approximation to a variety of distributions
- Well-established methods for learning models

Bayesian estimation with Gaussian mixtures has been well established with early work by Sorenson and Alspach (1971) and Alspach and Sorenson (1972); the development and implementation of DDF with such distributions was therefore a novel contribution to this field.

23.4.2 Local State Estimation

Maintaining a local estimate with Gaussian mixtures requires substantial infrastructure for sensor likelihood models, data association, and component reduction. This subsection describes the more challenging of these aspects.

23.4.2.1 Observations

A Gaussian mixture model (GMM) was used to fit the observations, and thus an approximate transformation of the likelihood from the bearing-only measurement space to a sensor-centric Cartesian coordinate space was required (Upcroft et al. 2005). In the experiments, the approximation for the GMM was learned off-line using trust region optimization (Fig. 23.3). The initial parameters for the optimization were equally weighted Gaussians spread evenly over a range of 300 m on the x-axis. Approximately 20 iterations resulted in a good fit to the distribution. The learned model was then rotated and translated appropriately for each specific observations.

Fig. 23.3 Bearing-only likelihood, learned off-line using 20 components

23.4.2.2 Local Filter

Local state estimation proceeded using a Bayesian filter (Sorenson and Alspach 1971; Alspach and Sorenson 1972; Alspach 1975; Upcroft et al. 2005). Substitution of GMMs into Bayesian theorem (Eq. 23.1) gives

$$p(\mathbf{x}_k | \mathbf{z}_k) = A \sum_{i=1}^M \pi_{zi} \mathcal{N}_{zi} \sum_{j=1}^N \pi_{xj} \mathcal{N}_{xj} \quad (23.9)$$

where $A = 1/p(\mathbf{z}_k | \mathbf{z}_{k-1})$ is a normalizing constant, the \mathcal{N}_z 's represent the likelihood distribution $p(\mathbf{z}_k | \mathbf{x}_k)$, and the \mathcal{N}_x 's represent the prediction $p(\mathbf{x}_k | \mathbf{z}_{k-1})$, similarly for π_z and π_x .

Expanding Eq. 23.9 results in $M \times N$ terms, each which involves a multiplication of two weighted Gaussians. Thus, the posterior distribution is represented by $M \times N$ weighted Gaussians.

GMMs also allow an analytical solution to the Chapman-Kolmogorov equation. Substituting GMMs into Eq. 23.2 results in a convolution between $M \times N$ weighted Gaussians with each term a Gaussian of the form (Muirhead 1982)

$$\pi \mathcal{N}(\mu_a + \mu_b, \Sigma_a^2 + \Sigma_b^2) \quad (23.10)$$

where the subscripts denote the variables for the two Gaussians and π is a constant weighting term.

23.4.2.3 Component Reduction

Figure 23.4 shows that when an update is performed, it will result in a multiplicative increase in parameters. A component-merging technique is then required to keep the update operations tractable. As many of the parameters are similar or bear little contribution to the overall distribution, it is possible to reduce the number of components without modifying the probability distribution function significantly.

While the number of components should be kept to a minimum, the overall shape of the distribution should remain the same. To achieve this, a joining algorithm is applied repeatedly until the desired level of component reduction has been achieved (West 1993; Salmond et al. 1998; Salmond 1989). The distance measure for gauging the similarity between component i and component j of the GMM is a Mahalanobis-type distance measure:

$$d_{ij}^2 = \frac{\gamma_i \gamma_j}{\gamma_i + \gamma_j} (\mu_i - \mu_j)^T \Sigma^{-1} (\mu_i - \mu_j) \quad (23.11)$$

where μ is the component state vector, Σ is the mixture covariance matrix, and γ is the component weight.

The parameters of the component that results from combining component i with the component most similar to it (component j) are:

Fig. 23.4 The first Gaussian mixture (GMM 1) consists of five components. If updated with the second Gaussian mixture (GMM 2) which also consists of five components, the multiplicative expansion of parameters occurs. The updated Gaussian mixture (*bottom left*) consists of 25 components. As many of the components are similar, the Gaussian mixture may be reduced to a lesser number of components without modifying the probability distribution significantly. The figure on the *bottom right* shows that the distribution is preserved when using West's joining algorithm to merge the components to the original number of five

$$\text{Weight} : \gamma_{ij} = \gamma_i + \gamma_j \quad (23.12)$$

$$\text{Mean} : \mu_{ij} = \frac{1}{\gamma_i + \gamma_j} \{ \gamma_i \mu_i + \gamma_j \mu_j \} \quad (23.13)$$

$$\begin{aligned} \text{Covariance} : \Sigma_{ij} = \frac{1}{\gamma_i + \gamma_j} \{ \gamma_i \Sigma_i + \gamma_j \Sigma_j + \frac{\gamma_i \gamma_j}{\gamma_i + \gamma_j} \\ (\mu_i - \mu_j)(\mu_i - \mu_j)^T \} \end{aligned} \quad (23.14)$$

23.4.3 Node-Node Fusion

Analytical solutions to the division required for consistent channel filter-based fusion using GMMs are unknown. As will be described in Sect. 23.4.3.1, a

nonoptimal solution for node-to-node fusion of Gaussian representations is the covariance intersect (CI) filter which conservatively combines the information in two incoming channels, assuming that the correlation is unknown. In addition, a variant of the covariance intersect algorithm (Upcroft et al. 2005) is applied to Gaussian mixtures. However, as in the work of Ihler et al. (2004) and Rosencrantz et al. (2003a), divergent solutions are still possible.

23.4.3.1 Covariance Intersect

Primary use of covariance intersect algorithm is for the initialization of channel filters for situations where the local filter and channel contain prior information of unknown correlation.

The covariance intersection (CI), developed by Julier and Uhlmann (2001b), is a method of data fusion that provides a robust method for fusing data from two sources with unknown correlation.

During implementation, the conditional independence of subsequent observations from a single platform resulted in overconfident and biased solutions. The solution was to employ covariance intersect on local observations and full channel filter updates between platforms as independence of observations was assured.

Consider two estimates μ_a and μ_b with covariances Σ_a and Σ_b , respectively. The CI algorithm computes an updated covariance matrix as a convex combination of the two initial covariance matrices in the form

$$\Sigma_c^{-1} = \omega \Sigma_a^{-1} + (1 - \omega) \Sigma_b^{-1} \quad (23.15)$$

$$\Sigma_c^{-1} \mu_c = \omega \Sigma_a^{-1} \mu_a + (1 - \omega) \Sigma_b^{-1} \mu_b \quad (23.16)$$

where $0 \leq \omega \leq 1$ with ω computed so as to minimize a chosen measure for the size of the covariance matrix.

The resultant estimate is based on all possible correlations and thus removes the need for the division in Eq. 23.3.

While this approach to data fusion is conservative, Nettleton (2003) demonstrated its use for the initialization of decentralized filters when a single node previously in contact with a group of other nodes reestablishes contact. The common information between the nodes is unknown, and immediate use of the information filter update could potentially result in the double counting of this information, resulting in overconfidence. The CI algorithm makes it possible to make use of some of this information while still ensuring no double counting of information.

23.4.3.2 Pairwise Component Covariance Intersect

This variant of the CI algorithm involves a pairwise CI update between each of the Gaussian components in the two mixtures that are to be fused. The weight update for each component is given by

$$\pi_c = \alpha \pi_a \pi_b \quad (23.17)$$

where

$$\alpha = \frac{1}{(2\pi)^{D/2} |\Sigma_\omega|^{1/2}} e^{-1/2(\mu_a - \mu_b)^T \Sigma_\omega^{-1} (\mu_a - \mu_b)} \quad (23.18)$$

is the scaling constant resulting from the multiplication of two Gaussians, D is the dimension of the space, and $\Sigma_\omega = \Sigma_a/\omega + \Sigma_b/(1 - \omega)$.

The update has been found to remain non-divergent for all practical scenarios encountered and is always better than a straight multiplication in which the common information is not accounted for at all (Upcroft et al. 2005). Although this conservative behavior is not guaranteed, there is hope that future work will obtain convergence bounds for this method.

Recently, Julier (2006) has proposed a similar fusion update which behaves more consistently but again does not guarantee that consistency is maintained.

23.5 Experimental Hardware and Algorithms

In this chapter, the DDF algorithms are demonstrated through playback of data obtained from multiple UAVs and online between heterogeneous platforms including a ground vehicle, a UAV, and human operators. The following section describes the physical hardware used to gather the data, as well as some specific algorithm detail employed to process it.

23.5.1 Flight Platform

Data acquired during the ANSER project (University of Sydney) was gathered using the Brumby MKIII air vehicles as shown in Fig. 23.5. Figure 23.6 shows the vision sensors used in the experiments.

Both platforms were fitted with an INS/GPS subsystem that provides a position in a global coordinate frame as well as the corresponding Euler angles: roll ϕ ,

Fig. 23.5 Brumby Mk III flight vehicle

Fig. 23.6 Brumby sensors and payloads: the visual sensors used to gather data experiment

pitch θ , and yaw ψ . The GPS receiver was used to synchronize the local clocks of all onboard payloads, thus assuring accurate temporal registration of the data sets.

23.5.2 Sensor Model and Transforms

The camera was calibrated with well-established methods described in Heikkilä and Silvén (1997) with a readily available toolbox. The calibration procedure provides the principal point (u_0, v_0) and focal lengths f_u, f_v (in pixels) for each axis and the expected error in the pinhole model. Application of this model via the camera matrix (Hartley and Zisserman 2000) projects the feature coordinates (in the sensor reference frame) to homogenous coordinates:

$$\begin{bmatrix} u' \\ v' \\ s \end{bmatrix} = \begin{bmatrix} f_u & 0 & u_0 \\ 0 & f_v & v_0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} y \\ z \\ x \end{bmatrix} \quad (23.19)$$

From this, a direct mapping from sensor coordinates (x, y, z) to image coordinates (u, v) can be defined:

$$\begin{bmatrix} u \\ v \end{bmatrix} = \begin{bmatrix} \frac{y f_u}{x} + u_0 \\ \frac{z f_v}{x} + v_0 \end{bmatrix} \quad (23.20)$$

The inverse mapping cannot recover the loss of range information. However, a direction to the feature can be recovered. It may be more convenient to define this information in terms of the Euler angles ψ_f^s, θ_f^s , similar to the current vehicle state:

Fig. 23.7 Principal point, image, and sensor axes (*left*). Image, sensor, and body axes (*right*)

$$\psi_f^s = \arctan((u - u_0)/f_u) \quad (23.21)$$

$$\theta' = -\arctan((v - v_0)/f_v) \quad (23.22)$$

$$\theta_f^s = \arctan(\tan(\theta') \cos(\psi)) \quad (23.23)$$

Figure 23.7 provides a summary of the image, sensor, and platform geometry.

23.5.3 Extraction of Features

The flight test facility conveniently had artificial features placed under the vehicle flight path. The features were 0.9×0.9 m square plastic sheets that appeared as distinctive white points in the image. These features were able to be reliably extracted by a multi-pass algorithm progressively reducing possible candidates within the image. Objects that satisfied the criteria of intensity, size, and shape of the artificial features were reliably extracted.

Some range information can be recovered due to the fact that the features were of a known size. Utilizing the bearing equations and assuming the feature is parallel to the image plane, the height, width, and corresponding area (in pixels), A_i of an object can be defined, where A_f is the feature area in meters:

$$\begin{aligned} h_u &= \frac{h_y f_u}{x} \\ w_v &= \frac{h_z f_v}{x} \\ A_i &\approx \frac{f_u f_v A_f}{x^2} \end{aligned} \quad (23.24)$$

Rearranging Eq. 23.24 provides an expression for an estimate of the perpendicular height (x) above the feature. The area being expressed in terms of effective side length of the feature in pixels (p):

$$x = \sqrt{\frac{f_u f_v A_f}{p^2}} \quad (23.25)$$

The range estimate is then obtained by correcting the height estimate with the direction of the target:

$$r_f^s = \frac{x}{\cos(\theta) \cos(\psi)} \quad (23.26)$$

Differentiating x with respect to p provides an expression for the error in the range estimate, where Σ_p^2 is the variance in the pixels:

$$\begin{aligned} \Sigma_x &= \frac{f_u f_v A_f}{x p^3} \Sigma_p \\ \Sigma_r &= \frac{\Sigma_x}{\cos(\theta) \cos(\psi)} \end{aligned} \quad (23.27)$$

23.5.4 Observation Transformations

The previous sections only describe the extraction of a feature from an image, which provides an observation in the sensor coordinate frame. The sensor is mounted on a platform, with its own reference frame. The platform is localized within the global reference frame provided by the INS/GPS subsystem. This requires both rotation and translation of the observation multiple times to provide observation information in the global reference frame.

The cosine rotation matrix \mathbf{C}_i^j relating frame i to frame j with yaw ψ , pitch θ , and roll ϕ is used frequently when transforming between reference frames.

Three positions are required:

- \mathbf{X}_f^s : Position of feature relative to sensor coordinate frame
- \mathbf{X}_s^p : Position of sensor relative to platform coordinate frame
- \mathbf{X}_b^g : Position of body relative to global coordinate frame

Also, three different rotations are required:

- \mathbf{C}_f^s : Cosine matrix of feature relative to sensor coordinate frame
- \mathbf{C}_s^p : Cosine matrix of sensor relative to platform coordinate frame
- \mathbf{C}_b^g : Cosine matrix of body relative to global coordinate frame

The position of the feature relative to the sensor is

$$\mathbf{X}_f^s = \begin{bmatrix} r_f^s \cos \theta_f^s \cos \psi_f^s \\ r_f^s \cos \theta_f^s \sin \psi_f^s \\ r_f^s \sin \theta_f^s \end{bmatrix} \quad (23.28)$$

with covariance matrix

$$\mathbf{R}_f^s = \begin{bmatrix} \sigma_r^2 & 0 & 0 \\ 0 & r^2 \sigma_\psi^2 & 0 \\ 0 & 0 & r^2 \sigma_\theta^2 \end{bmatrix} \quad (23.29)$$

The full transformation of the feature position to the global coordinate frame is

$$\mathbf{X}_f^g = \mathbf{X}_b^g + \mathbf{C}_b^g \mathbf{X}_s^b + \mathbf{C}_b^g \mathbf{C}_s^b \mathbf{X}_f^s \quad (23.30)$$

The feature covariance in the global frame is

$$\mathbf{R}_f^p = [\mathbf{C}_p^g \mathbf{C}_s^p \mathbf{C}_f^s] \begin{bmatrix} \sigma_r^2 & 0 & 0 \\ 0 & r^2 \sigma_\psi^2 & 0 \\ 0 & 0 & r^2 \sigma_\theta^2 \end{bmatrix} [\mathbf{C}_p^g \mathbf{C}_s^p \mathbf{C}_f^s]^T \quad (23.31)$$

However, platform localization will normally contain uncertainties in roll, pitch, and yaw. To properly compensate for this, a more elaborate transformation is required. Either the angular uncertainties may be factored into the sensor observations, or the Jacobian of the observation function with respect to all platform states $\nabla g(\mathbf{P}_f^b, \psi_p^g, \theta_p^g, \phi_p^g)$ will have to be evaluated. The result being

$$\mathbf{R}_f^p = \nabla g(\mathbf{P}_f^b, \psi_p^g, \theta_p^g, \phi_p^g) \begin{bmatrix} \sigma_x^2 & 0 & 0 & 0 & 0 & 0 \\ 0 & \sigma_y^2 & 0 & 0 & 0 & 0 \\ 0 & 0 & \sigma_z^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & \sigma_\psi^2 & 0 & 0 \\ 0 & 0 & 0 & 0 & \sigma_\theta^2 & 0 \\ 0 & 0 & 0 & 0 & 0 & \sigma_\phi^2 \end{bmatrix} \nabla g(\mathbf{P}_f^b, \psi_p^g, \theta_p^g, \phi_p^g)^T \quad (23.32)$$

When using Gaussian mixtures, this method can be applied in turn to each component of the distribution. Alternatively, the unscented filter (Julier and Uhlmann 2001a) is an equally effective method to propagate the uncertainties associated with the platform localization system and can equally be applied in a Gaussian or Gaussian mixture-based system. The complexity in obtaining and evaluating the Jacobian may be bypassed.

23.5.5 Process Model

As the features are identical to that in the results obtained by Nettleton (2003) for the ANSER project, the process model remains unchanged as the integrated Ornstein-Uhlenbeck (IOU) process. This process has a bounded velocity by appropriate choice of the model parameter γ . The discrete-time system model is

$$\mathbf{x}(k) = \mathbf{F}_k \hat{\mathbf{x}}(k-1 | k-1) + \mathbf{w}_k \quad (23.33)$$

where the state vector is

$$\mathbf{x}(k) = [x, \dot{x}, y, \dot{y}, z]^T \quad (23.34)$$

The vertical dimension is modeled with position only, as the feature is assumed to remain on the ground at all times, and local flatness of the environment is assumed. The state transition matrix for this system is

$$\mathbf{F}_k = \begin{bmatrix} 1 & \Delta T & 0 & 0 & 0 \\ 0 & F_v & 0 & 0 & 0 \\ 0 & 0 & 1 & \Delta T & 0 \\ 0 & 0 & 0 & F_v & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (23.35)$$

where

$$F_v = e^{-\Delta T \gamma} \quad (23.36)$$

The process noise is $\mathbf{G}_k \mathbf{Q}_k \mathbf{G}_k^T$ where

$$\mathbf{Q}_{(k,k-1)} = \begin{bmatrix} q_x & 0 & 0 \\ 0 & q_y & 0 \\ 0 & 0 & q_z \end{bmatrix} \quad (23.37)$$

and

$$\mathbf{G}_k = \begin{bmatrix} \Delta T^2 & 0 & 0 \\ \frac{1}{\gamma}(1 - F_v) & 0 & 0 \\ 0 & \Delta T^2 & 0 \\ 0 & \frac{1}{\gamma}(1 - F_v) & 0 \\ 0 & 0 & \Delta T^2/2 \end{bmatrix} \quad (23.38)$$

While the features are stationary in this experiment, the model is appropriate for tracking moving features as well. The model is also an excellent choice for situations where features remain unobserved for large periods. A constant velocity model is inappropriate, as the target estimate will continue to drift in the last observed direction, until reobserved. This will make successful data association difficult to achieve. By bounding the velocity, the feature uncertainty will better encapsulate the variety of maneuvers a feature may make.

23.5.6 Feature Maintenance

The tracking of multiple targets suffers from data association problems caused by spurious observations and features that have too great an uncertainty. This implementation utilizes the Bhattacharyya coefficient as defined by Kailath (1967) for data association. It was chosen as its use for distributions other than Gaussian is straightforward and will allow for future comparisons. The feature was known to be well separated; thus, features that are associated with other features were culled.

Features with entropies greater than an empirical threshold were also culled. This kept the number of tracked features quite stable and ensured all features updated regularly due to reliable data association. More elaborate multi-hypothesis tracking management may be employed where the implementor deems necessary, but for the purposes of this experiment, this approach was sufficient.

23.6 Example Implementation with Gaussian and GMM

This section shows example results from a real-data simulation of two sets of two DDF nodes, one set operating with the Gaussian representation, the other with the Gaussian mixture representation.

The aim of this example is to show with actual data the feasibility of performing decentralized data fusion utilizing GMM density estimates. The quality and constancy of the solution will be compared at all nodes to a reference node that has a centralized solution.

Both simulations were run concurrently; both GMM and Gaussian likelihoods are generated from the same sensor observation. This makes a direct comparison more effective as each observation has the same time stamp, and both filters on each node run with the same time-base. This reduces any inconsistencies arising from variations between separate simulations.

23.6.1 Data Set

Data sets from two previous flights were used. Each set contains about 40,000 gray-scale video frames logged at 50 Hz at a resolution of 384×288 pixels, along with a corresponding GPS/INS navigation solution. These two data sets were played back concurrently to represent two flight vehicles searching an area at the same time. Figures 23.8 and 23.9 show the flight paths, artificial feature locations, and the raw observations allocated to each simulated platform. Sample video frames are shown in Fig. 23.10.

23.6.2 Platform and Component Topology

The component topology includes a parallel set of nodes operating with the same sensor components as shown in Fig. 23.11. There are two nodes operating with a DDF link and a separate node receiving all observations to provide a centralized solution with which to provide a comparison.

23.6.3 Comparison to Gaussian Representation

As both the Gaussian and GMM DDF nodes were run in parallel, it is straightforward to compare the difference in performance of the algorithms. Identical

Fig. 23.8 Flight path and raw observations of flight vehicle 0

camera observations were fed into two separate likelihood generators. The Gaussian likelihood generator makes use of a range estimate, whereas the GMM likelihood generator utilized 20 components numerically optimized off-line. A single feature was chosen to compare the different methods.

23.6.4 Sample Feature Results

Figure 23.12 shows the absolute errors for both Gaussian and GMM nodes. The different variants arrive at similar solutions. As would be expected, the GMM versions, not having range information, take longer to converge to their solution. The individual nodes are also less coherent, as the pairwise covariance intersect method is more conservative in its approach.

Figure 23.13 shows the entropy of the Gaussian and GMM variants. The entropy provides a measure of the certainty of a particular estimate. The GMM variants tend to have greater entropy. This would be expected as no explicit range information is used, and multimodal GMM distributions would always tend to have a greater entropy than that of a unimodal Gaussian (except in cases when the distribution collapses to a single Gaussian).

Fig. 23.9 Flight path and raw observations of flight vehicle 1

Fig. 23.10 Sample logged video data, showing features such as roads, dams, and artificial features (*bright white*)

23.6.5 Discussion

The error of the GMM solution is of similar magnitude to that of Gaussian version and is less variable. The Gaussian implementation was able to make use of the range estimate during image processing. However, this range estimate may be biased

Fig. 23.11 Communication topology of sensors and parallel nodes

Fig. 23.12 GMM and Gaussian DDF comparison. Absolute sample feature error at all nodes. Gaussian (*left*) and GMM (*right*)

due to variability in any given target. The GMM version is a more representative example of a true bearing-only sensor and made no use of no range information. It therefore had to depend on the accuracy of the fitted likelihood function and performed well.

The GMM DDF nodes tended to have differing solutions to each other; this is due to the heuristic applied to prevent a covariance intersect update from occurring when the information gain is minimal from channel data. Performing repeated update would only serve to increase overconfidence in the solution as the reduction process following the covariance intersect operation tends to cause a collapse of the distribution. Conversely the Gaussian nodes have more consistent

Fig. 23.13 GMM and Gaussian DDF comparison. Sample feature entropy of all nodes Gaussian (*left*), GMM (*Right*)

solutions; they only differ for the periods where information from new sensor observations have yet to propagate to the other node not directly connected to the sensor.

As expected, the entropy of the GMM solutions is equal to or greater than the Gaussian variants. This is to be expected due to the nature of multimodal distributions and the more conservative PCCI fusion algorithm.

23.7 Conclusion

The design of robust multi-platform UAV-based search and rescue or location/tracking systems would benefit from a decentralized approach due to the higher failure likelihood of UAV-based systems. The benefits of a decentralized data fusion approach for such a problem have been highlighted, as well as a high-level functional description of the system components.

The various options available to a systems designer for implementing a non-Gaussian UAV-based tracking/search and rescue system are numerous. This chapter has provided a summary of the available options and the benefits and difficulties that may arise from each option.

Kalman filter-based approaches to decentralized data fusion have been long established. More specific methods for the implementation of Gaussian mixture model-based DDF system have been outlined. Details are provided for the implementation of a system that employs a vision-based sensor to track an infrequently observed erratically moving object.

It has been shown, through example, that it is possible to implement a decentralized data fusion system using single Gaussian or mixtures of Gaussians. The use of Gaussian mixtures introduces many challenges, but none that are computationally intractable or otherwise infeasible to implement.

Kimón P. Valavanis and George J. Vachtsevanos

Propulsion is a critical and indispensable module of the UAV structure. Propulsion provides the necessary thrust to maintain a flight. The UAV performance, effectiveness, and utility depend strongly on the onboard propulsion capabilities. Jointly with other UAV design considerations, the propulsion system determines the endurance, size, weight, and application domain of all UAV classes.

► **Power Managements of a Hybrid Electric Propulsion System Powered by Solar Cells, Fuel Cells, and Batteries for UAVs** by Lee, Park, and Kim provides a very comprehensive description of the power management of a UAV hybrid electric propulsion system. It considers three electric propulsion systems with solar cells, fuel cells, and battery power sources, which are designed and constructed to share the same operation voltage range and connect to the power bus without the need for additional converters or controllers. MATLAB-/Simulink-based modeling is followed for each power source, and the component models are verified with published data from the manufacturers as well as flight test data. The component models are integrated into one power system model that is used to simulate the UAV electric propulsion system. For fuel cells and batteries, the simulation process is verified via comparison between simulation results and available UAV flight test results. Two types of power control logic are investigated, passive and active. The passive power management simulation shows that the behavior of each power source

Abstract

This chapter describes the power management of a UAV hybrid electric propulsion system. Three electric propulsion systems with different power sources, i.e., solar cells, fuel cells, and batteries, are considered. The power sources are designed and constructed to share the same operation voltage range and connect to the power bus without the need for additional converters or controllers. Each power source is modeled in MATLAB/Simulink, and the component models are verified with published data from the manufacturers as well as flight test data. Furthermore, the component models are integrated into one power system. The integrated power system model is used to simulate the

electric propulsion system. For fuel cells and batteries, the simulation process is verified via comparison between the simulation results and available UAV flight test results. Subsequently, two types of power control logic are investigated: passive and active. The passive power management simulation shows that the behavior of each power source and its integrated system are adequate for the overall UAV flight envelope. In addition, the active power management simulation demonstrates that active power management yields more efficient power distribution and better system safety than passive power management. Also, power simulation of a hybrid electric power system allows for estimation of the output behavior of the power source. Therefore, it can be a valuable tool for development of a power control logic that ensures efficient power distribution.

25.1 Introduction

The mainstay of aircraft propulsion is the internal combustion engine, which takes such forms as gas turbines and reciprocating engines. However, because of soaring fuel costs and tightened control on environmental issues such as carbon dioxide emissions and noise, the search for an environment-friendly propulsion device has been an imperative research topic. Thanks to advances in electric power sources such as fuel cells, solar cells, batteries, and associated components, which yield higher performance with lighter bodies, electric propulsion is very close to achieving practical application in vehicles and, thus, in UAVs.

UAVs that employ fuel cells as their primary power source are listed in Table 25.1 (Scheppat 2004; Kellogg 2005; Crumm 2006; Anon 2007; Herwerth et al. 2007; McConnell 2007; Velez 2007; Bradley et al. 2007, 2009). The Georgia Institute of Technology demonstrated the feasibility of a small fuel-cell-powered UAV through fabrication, flight testing, and ground testing of a 500 W PEM fuel-cell-powered aircraft (Bradley et al. 2007). KAIST investigated the current and voltage behaviors of a NaBH_4 fuel cell through a flight test of a UAV, which contained a 100 W fuel cell combined with a battery. Michigan State University and Adaptive Materials recorded 10 h of flight with a SOFC fuel cell that uses propane, a hydrocarbon fuel (Crumm 2006). Table 25.2 shows some representative UAVs that utilize solar cells as their primary power source (Boucher 1984; Herwitz et al. 2004; Noth 2006, 2008). Evidently, recent applications of solar cells in both manned and unmanned vehicles show remarkable progress in endurance. Solar Impulse, a manned aircraft, recorded 27 h of flight endurance, while Zephyr, a UAV from QinetiQ, recorded a flight time of 2 weeks in the air. To accomplish missions involving such long-endurance flights, the aircraft must be equipped with secondary high-capacity batteries for overnight operation.

This chapter describes the modeling of a hybrid system that employs all three major electric power sources, i.e., solar cell, fuel cell, and battery, and an associated power management system (PMS). The PMS is necessary to efficiently provide the UAV propulsion system with the required power from multiple power sources. A PMS can be passive or active. A passive PMS is the simplest form of power

Table 25.1 Fuel cell-powered UAV (Bradley et al. 2009)

management, and it only protects the power sources; the power output is manually controlled according to the behavior of the UAV propulsion system. On the other hand, an active PMS has the full authority to control both the power sources and output. In a passive management system, the efficiency of power usage and the safety of the power system are not as optimized as they can be in an active management system. However, as passive management does not require a power converter or a power controller, it makes the PMS simpler, yielding benefits in weight reduction. In addition, it can avoid the collateral power loss associated with the power conversion. Therefore, passive management is more widely used

in small UAVs, while active management is used in most hybrid electric vehicles (HEVs), which demand higher efficiency at the expense of weight reduction. The power simulation conducted in this chapter demonstrates both the passive and active managements.

Although the operational behavior and proper capacity of each power source in the hybrid propulsion system should be determined, it is too costly and time-consuming to evaluate it through tests of the onboard system. Therefore, it is necessary to formulate simulation models of the power sources and integrate the models to estimate the behavior of each power source in the prescribed flight profile before deployment of the system on the actual UAV. In cases involving hybrid and electric vehicles, there have been extensive studies in modeling and simulation (Powell et al. 1998; Butler et al. 1999; Rizzoni et al. 1999; Lin et al. 2001; He and Hodgson 2002a, b; Gao et al. 2005), and various mathematical models and simulators are available for HEV systems, e.g., ADvanced VehIcle SimulatOR (Wipke et al. 1999; Markel et al. 2002), Virtual Test Bed, and PSIM.

Each power source investigated in this chapter is modeled in MATLAB/Simulink, and the component models are verified with published data from the manufacturers as well as flight test data. The component models are integrated into one power system, and the integrated power system model is used in the simulation of the electric propulsion system. The target platform is the Electric Aerial Vehicle-2 (EAV-2), which was developed by Korea Aerospace Research Institute (KARI). Prior to implementing it in the target platform, the integrated system was constructed for EAV-1 to verify the simulation method. EAV-1, which was also developed by KARI, employs a fuel cell and batteries, making it an appropriate UAV to verify the system in terms of its functionality involving multiple power sources. The simulation results of EAV-1 are compared with flight test data, and the feasibility of the simulation method is verified. Using the verified simulation method, this chapter investigates the capacity determination and the behavior of the power output in terms of passive and active power managements.

25.2 Hybrid Electric Propulsion System

EAV-1 employs a fuel cell and batteries as its power sources, while EAV-2 has solar cells, fuel cells, and batteries. The main features and dimensions of these aircraft are shown in Table 25.3. The EAV-2 is a low-speed, long-endurance UAV with the potential to conduct ground observation and surveillance using its payload camera. Using its onboard flight control computer (FCC), it can perform autonomous flights according to mission commands transmitted from the Ground Control Station (GCS). Its maximum gross weight is 18.0 kg, and the wingspan reaches 6.9 m. It has a fuselage with a diameter of 0.19 m, which is equipped with 0.003 m² NACA intakes on both the left and right sides for supplying air to fuel cells. The heated air and fuel cell's exhaust are vented through air outlets on the top, left, and right sides at the rear of the fuselage. The cross-sectional shape of the

intake is adjusted in accordance with the fuselage cross section. The required cruise power determined by aerodynamic analysis is 400 W, with a maximum power rating of 1.3 kW. Taking into account the 25 W of additional power needed for avionics and payload, the total cruise power required is 425 W. This amount of power is generated by the hybrid electric propulsion system, as it combines the use of the three power sources: solar cells, fuel cells, and batteries. This chapter determines the optimized analytical capacity of each power source based on the performance requirements of the platform aircraft, the output behavior of the power sources, wing area, and specifications of available commercial components.

Each power source is summarized as follows: The solar cells generate electricity from light energy. Because they use an external energy source, their activity is not limited by the quantity of any onboard item, such as fuel. However, because their

energy source is external, their output is heavily dependent on external conditions such as solar irradiation. In addition, they require large areas to generate sufficient power for flight. In contrast, fuel cells provide stable electricity output and are minimally affected by external conditions. Their stacks also have relatively high power density. However, their operation is limited by the amount of onboard fuel, and, furthermore, the fuel influences the total weight of the aircraft. The fuel reservoir, generally hydrogen, is very heavy. Fuel cells also have limitations in their inherent characteristics, such as a long start-up time and poor responses to instantaneous power demands. Batteries, like fuel cells, have finite capacities. Although the energy density of a battery is low, the power density is very high. Therefore, the combination of batteries and fuel cells provides a hybrid power generation system with benefits of both the high power density of batteries and the high energy density of fuel cells (Jiang and Dougal 2004).

EAV-2's passive-controlled and active-controlled electric propulsion systems, each with their three power sources, are illustrated in Figs. 25.1 and 25.2, respectively. In the passive PMS, each power source is directly connected to the power bus without the use of a converter or controller. Therefore, the output terminal voltage range of every power source is the same as the bus voltage range. This leads to the fact that the operational voltage ranges of the solar cells, fuel cells, and batteries should be matched to the bus voltage range. Furthermore, the bus voltage is determined by the battery, which functions as a reservoir for the electric power. The battery used is a Li-Polymer battery with a nominal voltage of unit cell of 3.7 V. Seven unit cells are connected in series, yielding a nominal voltage of 25.9 V. The solar cells are constructed in the same method, with the proper number of cells, and the fuel cells are selected from commercially available items.

25.3 Electric Power Sources Modeling

The power sources are modeled in MATLAB/Simulink, and the models are verified using the manufacturer's data and test data.

25.3.1 Solar Cell

This study employs the empirical model that represents the equivalent electrical circuit of a solar cell as a single module or an array of units. The empirical model is a curve fit of the measured current-voltage (I-V) relationship and requires fewer parameters than the one-diode and the two-diode models. The parameters of this model are usually available from the manufacturer's data sheet. Therefore, an empirical model can be easily constructed with an acceptable accuracy that the manufacturer verifies. The empirical model for C60 cells from SunPower is used; C60 cells are the cells used by EAV-2.

Table 25.4 shows the manufacturer's data for 50 serial C60 cells under an ambient solar irradiation of $1,000 \text{ W/m}^2$ and a cell temperature of 25°C . Under the specified

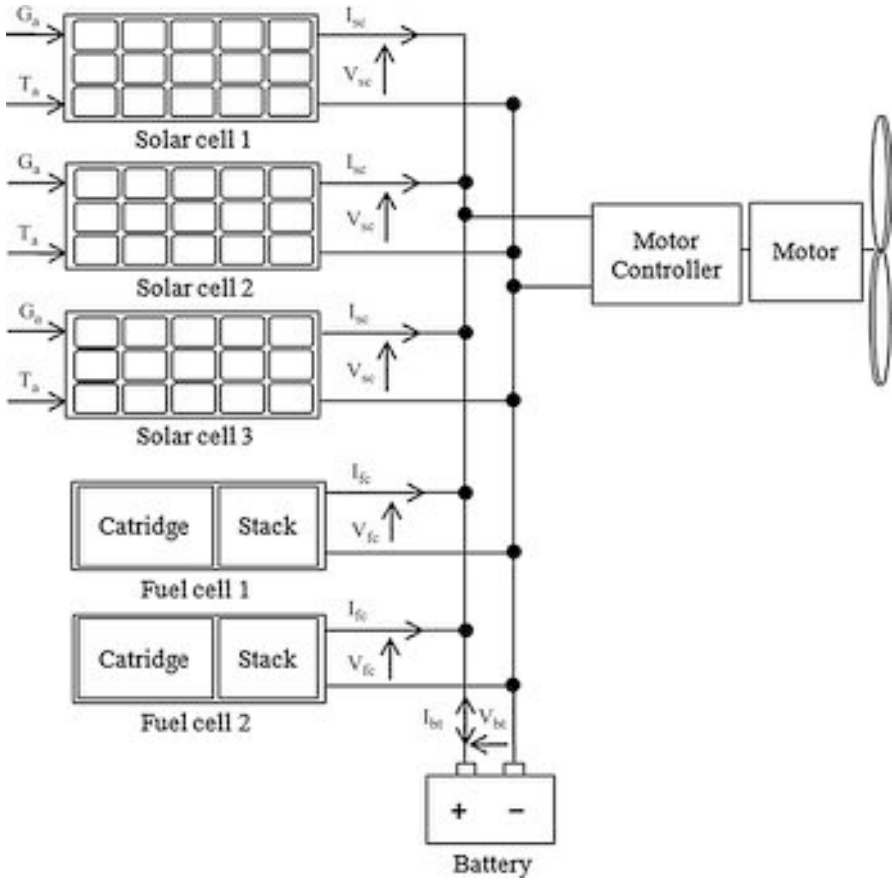

Fig. 25.1 EAV-2 passive electric control schematic

conditions, the net current from the solar cell module, which is the difference between photo current I_{ph} and diode current I_d , is given as

$$I = I_{ph} - I_d = I_{ph} - I_0 \left(\exp \frac{e(V + IR_s)}{akT_c} - 1 \right) \quad (25.1)$$

where I_0 is dark saturation current, R_s is serial resistance, k is Boltzmann's constant, and T_c is cell temperature. Idealizing factor a is applied.

Open-circuit voltage V_{oc} is the voltage when I is equal to 0, and it is related to thermal voltage V_t as follows:

$$V_{oc} = \frac{akT_c}{e} \ln \left(\frac{I_{ph}}{I_0} \right) = V_t \ln \left(\frac{I_{ph}}{I_0} \right) \quad (25.2)$$

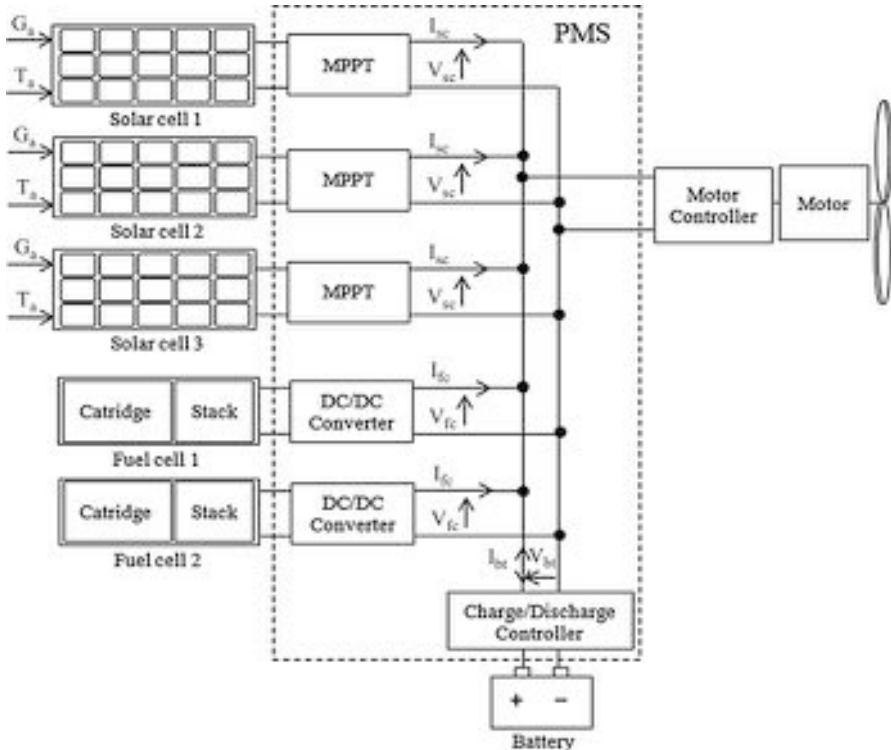

Fig. 25.2 EAV-2 active electric control schematic

Table 25.4 Solar cell data

| Parameter | Value |
|--------------------------|-------|
| Peak power, W | 238 |
| Rated voltage, V | 28.1 |
| Rated current, A | 5.88 |
| Open-circuit voltage, V | 33.7 |
| Short-circuit current, A | 6.25 |

Using the superscript C for a unit cell and M for a module of multiple cells, the electric current I^M under arbitrary operating conditions (V^M , ambient temperature T_a , solar irradiation G_a) can be calculated as shown in Eq. (25.3) (Hansen et al. 2000):

$$I^M = I_{sc}^M \left[1 - \exp \left(\frac{V^M - V_{oc}^M + R_s^M I^M}{N_{SM} V_t^C} \right) \right] \tag{25.3}$$

where N_{SM} is series module.

The simulated current-voltage (I-V) curves of the MATLAB/Simulink model for 50 serial solar cells are shown in Fig. 25.3 with the manufacturer’s data for

Fig. 25.3 Solar cell (one-cell 50 series) I-V curves

verification. The figure depicts the current behavior that is in accordance to the solar irradiation at the ambient temperature of 25 °C. The current remains constant until the output voltage reaches a threshold, and it drops if the voltage increases beyond the threshold. At this point, because power is the product of voltage and current, the power varies depending on the load voltage even under a constant light intensity. The point that generates maximum power is called the maximum power point (MPP). The power, according to the voltage under different sunlight intensities, is shown in Fig. 25.4. The MPP voltage decreases slightly as the light intensity decreases.

25.3.2 Fuel Cell

The estimation of the dynamic behavior of the fuel cell stack follows the mathematical models presented in Buasri and Salameh (2006) and Lee and Wang (2007). The theoretical optimum voltage of a unit cell is 1.2 V for any operational current. However, the actual voltage accounts for voltage lost due to activation V_{act} , voltage lost due to ohmic loss V_{ohmic} , and voltage lost due to concentration loss V_{con} as follows:

$$V_{fc} = E_{Nernst} - V_{act} - V_{ohmic} - V_{con} \quad (25.4)$$

where Nernst potential E_{Nernst} and the voltage losses are determined using Eqs. (25.5)–(25.8):

Fig. 25.4 Solar cell (one-cell 50 series) P-V curves

$$E_{\text{Nernst}} = 1.229 - 0.85 \times 10^{-3}(T - 298.15) + 4.3085 \times 10^{-5}T[\ln(P_{\text{H}_2}) + 0.5 \ln(P_{\text{O}_2})] \quad (25.5)$$

$$V_{\text{act}} = -[\xi_1 + \xi_2 T + \xi_3 T \ln(C_{\text{O}_2}) + \xi_4 T \ln(I_{\text{fc}})] \quad (25.6)$$

$$V_{\text{ohmic}} = I_{\text{fc}}(R_{\text{m}} + R_{\text{c}}) \quad (25.7)$$

$$V_{\text{con}} = -B_{\text{f}} \ln(1 - J/J_{\text{max}}) \quad (25.8)$$

where P_{H_2} and P_{O_2} are partial pressure of hydrogen and oxygen, respectively. $\xi_{1,2,3,4}$ is empirical coefficients of activation over voltage, and C_{O_2} is concentration of oxygen in the catalytic interface of the cathode. R_{m} and R_{c} are equivalent membrane resistance to proton conduction and equivalent contact resistance to electron conduction, respectively. B_{f} is constant dependent on the cell type and its operation state. J and J_{max} are actual cell current density and maximum cell current density, respectively.

A fuel cell stack voltage V_{stack} is a serial connection of unit cells, and its voltage is the unit voltage multiplied by the number of cells n , such that

$$V_{\text{stack}} = n \cdot V_{\text{fc}} \quad (25.9)$$

Fig. 25.5 Fuel cell I-V and P curves

The dynamic voltage of the fuel cell v_d is determined as follows:

$$\frac{dv_d}{dt} = \frac{1}{C} I_{fc} + \frac{1}{\tau} v_d \quad (25.10)$$

where fuel cell electrical time constant τ is given as

$$\tau = C \left(\frac{V_{act} + V_{con}}{I_{fc}} \right) \quad (25.11)$$

The dynamic behavior of the fuel cell voltage reflects the dynamic voltage as follows (Qingshan et al. 2008):

$$V_{fc} = E_{Nernst} - V_{ohmic} - v_d \quad (25.12)$$

A 200 W PEM-type fuel cell from Horizon Energy Systems is employed. It has a stack combined with a fuel cartridge that chemically generates hydrogen. The generated hydrogen is first stored in a small tank that maintains 4–6 bar, and then it is sent to the stack. Therefore, ideally, the generated hydrogen behaves identically to the hydrogen provided by a pressurized reservoir. The molar fractions of hydrogen and oxygen are assumed to be constant for all flight envelopes.

The fuel cell model is implemented in MATLAB/Simulink. The results of the simulation and the performance data from the manufacturer are shown together in Fig. 25.5.

Table 25.5 Battery data

| Parameter | Value |
|------------------------------|-------|
| Battery type | Li-Po |
| Nominal voltage, V | 25.9 |
| Rated capacity, Ah | 4.3 |
| Initial SOC, % | 100 |
| Nominal discharge current, A | 2.3 |

25.3.3 Battery

The dynamic model of a battery’s charge and discharge follows Tremblay and Dessaint (2009), as shown in Eqs. (25.13) and (25.14):

Charge: $V_{bt} = E_0 - R \cdot I - K \cdot \frac{Q}{it - 0.1 \cdot Q} \cdot i^* - K \cdot \frac{Q}{Q - it} \cdot it + A \cdot \exp(-B \cdot it)$

(25.13)

Discharge: $V_{bt} = E_0 - R \cdot I - K \cdot \frac{Q}{Q - it} \cdot (it + i^*) + A \cdot \exp(-B \cdot it)$

(25.14)

where A and B are exponential zone amplitude and exponential zone time constant inverse, respectively. E_0 is battery constant voltage; K is polarization constant. it and i^* are actual battery charge and filtered current, respectively. Q is battery capacity.

The parameters of this dynamic model are easily available from the manufacturer’s data sheet. Another advantage of this model is that it can be directly implemented in MATLAB/Simulink using library blocks. The battery model is verified with the battery block parameters shown in Table 25.5 for seven serially connected PQ4550XQ batteries from Enerland Co., Ltd. Figure 25.6 shows the simulation and test results of voltage and capacity of the battery pack in discharge at 2.3 A (0.5 C) and 4.5 A (1.0 C). The simulation generally agrees with the test results, with little deviation in capacity at roughly 1,000 mAh.

25.4 Simulation Modeling Verification with Flight Test Data

EAV-1 can fly in autonomous mode and path tracking for prescribed trajectories. In addition, it returns to the base and makes an emergency landing when it loses communication with the controller. It is equipped with an onboard camera and transmits video images and power source information to the ground station. EAV-1’s range reaches 3 km. The EAV-1 flight tests were conducted three times during October 18–19, 2010, at the Goheung Aerospace Center, Korea. The aircraft was programmed to loiter in autonomous flight mode, forming a specified trajectory within a radius of 500 m. It recorded an endurance of 4.5 h at an altitude of 450 m on the second day. The specifications of EAV-1’s fuel cell are determined according to the cruise condition so that it reaches a power output of 300 W and a capacity

Fig. 25.6 Battery voltage-capacity curves

of 950 Wh, while the capacity of the battery pack is determined to be 30 Wh considering its weight.

The simulation method is verified with a hybrid power system of a fuel cell and batteries applied to EAV-1, whose configuration is shown in Fig. 25.7. Before verification, the results of the flight test were investigated as follows: The average fuel cell voltage, given a 95 % confidence level, is shown in Fig. 25.8 as a function of current over a flight time of 4.5 h. It is noticeable that the fuel cell that was installed and tested in EAV-1 reaches higher operational current than indicated levels of the manufacturer's data shown in Fig. 25.5, yielding a maximum power of 300 W. The dispersion of the data is ± 1 V on average. The main factors that affect the dispersion are dynamic responses of the fuel cell due to the internal hardware, fluctuation in hydrogen supply pressure (insufficient hydrogen), and vapor purge control of the stack. The fuel cell simulation model is adjusted to reflect the I-V curve from the test data.

EAV-1's battery pack consists of six Li-Polymer batteries in series, which are grouped into two serial packs of three each. The individual batteries are Pro Lite V2s from Thunder Power RC. Output from the battery pack passes through a converter and combines with output from the fuel cell to provide the power required for EAV-1. The converter, which comes with the fuel cell, breaks the circuit for a current input of 230 mA or higher. The battery pack also supplies the additional power that cannot be provided by the fuel cell during takeoff and transient flights. Figure 25.9 shows the results of a simulation and the tests on the battery and converter while discharging at 700 mA (0.5 C based on the battery capacity) and charging at 230 mA.

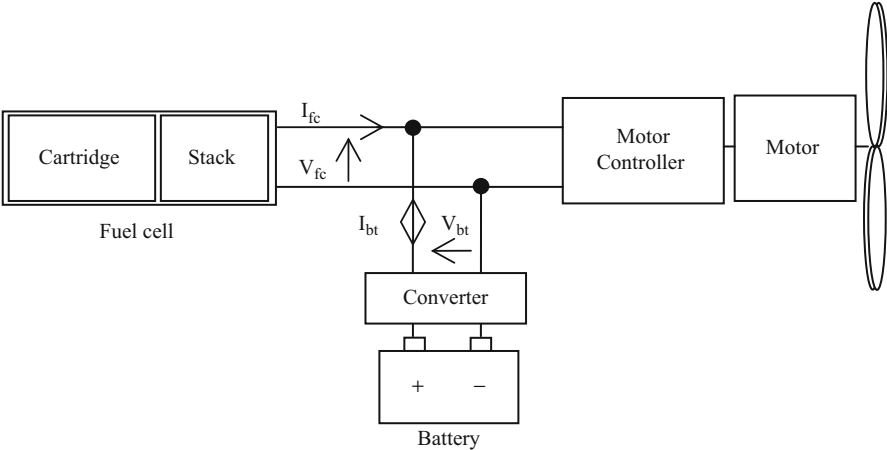

Fig. 25.7 EAV-I passive electric control schematic

Fig. 25.8 Fuel cell I-V and P curves

The discharge test indicates that the capacity of the Pro Lite V2 battery is 1.26 Ah, which is 93 % of the manufacturer’s data of 1.36 Ah.

When the fuel cell, the primary power source, provides the electricity to meet the power required of the system, the voltage temporarily drops along the I-V curve and the fuel cell takes several seconds to begin producing the required power. In the meantime, the fuel supply may not be sufficient and the electrocatalyst’s life may be reduced (Thounthong and Sethakul 2007). Therefore, the power sources should

Fig. 25.9 Battery and converter characteristic curves

be controlled so that the fuel cell is maintained at a steady state, as the battery compensates for the shortage of power. Once the battery's voltage is matched to the fuel cell's voltage, the current is adjusted along the I-V curve of the battery. This yields a power balance between the power required and the summation of outputs from the fuel cell and the battery.

The measured and simulated time histories of the voltage and residual current of the fuel cell in the fuel cell-battery-integrated system are shown in Fig. 25.10. The severe fluctuations in the flight test results before the 2.5-h mark result from the built-in system controller of the fuel cell, which maintains the hydrogen tank pressure at 4–5.5 bar and breaks the current to prevent further pressure drop if the pressure stays under 4 bar for 6 s or more. In this case, the voltage of the system becomes the open-circuit voltage. As the simulation assumes a steady supply of hydrogen, the results do not reflect the fluctuations that are caused by circuit breaks. However, the general trend of the simulated results closely resembles the test data, and good agreement is clearly seen after 2.5 h, at which point the controller no longer breaks the current.

Figures 25.11 and 25.12 indicate that the fuel cell is the primary power source in the regime that requires cruise power, and extra power is provided by the battery for takeoff and transient regimes. Meanwhile, the excess power from the fuel cell charges the battery. The simulation underestimates power output from the battery during the takeoff and transient flight because the fuel cell model provides power faster than the actual fuel cell. The response time of the model differs from that of the actual fuel cell because the fuel cell model employed by this study is

Fig. 25.10 Fuel cell current and voltage variation during the whole flight

Fig. 25.11 Current variations at takeoff

a simplified one, and it lacks dynamic response of detailed components for the particular Aeropak fuel cell. These detailed components include the anode model and cathode model, the stack controller that controls hydrogen pressure and vapor purge, and the associated balance of plant (BOP). However, these omissions are acceptable because the primary interests of this study are the overall behavior of the output during the flight and the remaining capacity of each power source of

Fig. 25.12 Power variations at takeoff

Fig. 25.13 Fuel cell voltage and current variations at landing

the hybrid power system. Figure 25.13 shows the time histories of the voltage and current of the fuel cell during landing, and Fig. 25.14 shows the power variation under the same conditions. In the simulation, because the aircraft manages flight conditions using the power available from the fuel cell, the battery output seldom varies. However, the actual battery is charged and discharged as the output of the fuel

Fig. 25.14 Power variations at landing

cell fluctuates. This fluctuation is caused by many reasons that are not reflected in the model, such as varying hydrogen pressure, vapor purge, and external disturbances.

The simulation results of the component models and the integrated model closely reflect the test results. This means that the simulation method provides a feasible estimation tool for the power behavior of an electric propulsion system that employs multiple power sources in types and classes. Based on this conclusion, the same simulation method is used for EAV-2, which employs solar cells as well.

25.5 EAV-2 Electric Propulsion System Simulation

25.5.1 Passive Simulation

It is necessary to yield a power balance between the power required and the summation of outputs from the solar cells, fuel cells, and batteries during the simulation. The current and voltage of each power source is determined by its characteristic curve for the supply of the required power. Because the integrated propulsion system model of EAV-2 consists of power sources directly connected to the power bus without a converter, the operational bus voltage range becomes the output voltage range of each power source. Once the solar cell's output voltage is determined by the real-time battery voltage, the current from the solar cell is determined via Eq. (25.3). It is apparent from the solar cell performance charts that for a moderate output voltage, the current is practically determined by the solar irradiation G_a and ambient temperature T_a . In the same way, the output voltage of the fuel cell stack is matched to the battery pack voltage range by adjusting its

current along the I-V curve. Consequently, the power of the fuel cell stack falls out. If the fuel cell deviates from the manufacturer's I-V curve, the load may not be evenly distributed in a passive power management system. The sum of the currents from each power source is supposed to be the same as the current that the motor consumes depending on the power required at the moment. Therefore, the current of the battery I_{bt} is determined as follows:

$$I_{bt} = I_{req} - I_{sc} - I_{fc} \quad (25.15)$$

If the available power varies, the required current I_{req} will also vary, resulting in a different real-time battery voltage along the I-V curve.

The simulation is conducted on a power-required profile of EAV-2, which is scaled from that of EAV-1. In order to evaluate the effects of sunlight conditions G_a and T_a on the solar cell's output P_{sc} , the simulation conditions are set to approximate the winter solstice and summer solstice. Assuming that EAV-2 maintains a level flight for the whole flight envelope, the solar irradiation projected onto a level plane at the end of the atmosphere is calculated in Eq. (25.16). On the Earth's surface, the clearness index, 0.6 for c is multiplied by Eq. (25.16), yielding the solar irradiation G_a as Eq. (25.17) (Pefititsis et al. 1994):

$$G_{ref} = G_{SC} \left[1 + 0.033 \cos \left(\frac{360n}{365} \right) \right] \cdot (\cos \phi \cos \delta \cos \omega + \sin \phi \sin \delta) \quad (25.16)$$

$$G_a = c \cdot G_{ref} \quad (25.17)$$

where ϕ of the simulation site is 36.18° , δ varies between -23.5° and $+23.5^\circ$, and ω varies from -180° to 180° in 15° increments. The variation of the solar irradiation at this site is shown in Fig. 25.15. The figure shows a difference of 400 W/m^2 between the summer and winter solstices at around noon. The temperature variation data from the National Weather Service is shown in Fig. 25.16.

The time histories of the simulation at the winter solstice are shown in Figs. 25.17 and 25.18. During periods that require high power, i.e., 10–30 s for takeoff and 200–210 s for transient flight, the high-power-density battery provides most of the power required, causing the SOC of the battery to drop. For the period spanning 12–200 s, which corresponds to the cruise, the solar cells and fuel cells take charge of the power required. During this period, the battery's output drops to under 100 W, as it recovers its voltage, and the SOC decrease slows down.

Figure 25.19 shows data for EAV-2 performing a cruise for 4.5 h, from 10:00 am to 2:30 pm. As demonstrated in the figure, the maximum output from the solar cells reaches only 86 W at the winter solstice. Therefore, more power output is demanded from the fuel cells and batteries. The maximum power of the fuel cell stack with the support of the batteries may be sufficient for the mission at the winter solstice. However, in the case of passive management, the fuel cells operate under a partial

Fig. 25.15 Solar irradiation

Fig. 25.16 Ambient temperature variations

Fig. 25.17 Power variations at the winter solstice

Fig. 25.18 Motor current and battery property variation at the winter solstice

Fig. 25.19 Simulation results at the winter solstice

load with continuous discharge of the batteries because the maximum power of the fuel cell occurs when the battery’s voltage, i.e., the bus voltage, is close to complete discharge. In the case of the summer solstice shown in Fig. 25.20, the solar cells generate up to 178 W. Therefore, with the output from the fuel cell stack added, the aircraft can charge the batteries while it cruises. During both the winter and summer solstices, the batteries are charged during the landing, which requires only 200 W.

The energy fractions at the winter solstice and summer solstice are shown in Table 25.6. The solar cells provide 46.9 % higher energy at the summer solstice than at the winter solstice.

25.5.2 Active Simulation

In an emergency situation in which the solar cells are not fully functional due to external factors, e.g., clouds, and at the same time the fuel cell stack undergoes a power outage, the aircraft should attempt to land only with the power left in the batteries. Therefore, a certain level of SOC of the battery pack should be maintained during the flight as a precaution against such cases. The aircraft consumes 33 Wh over 10 min during landing. Assuming that the descent requires 200 W, this corresponds to 30 % of the SOC. Table 25.6 indicates that in the case of passive power management, the remaining SOC of the battery pack after 4.5 h of flight is only 24.2 % at the winter solstice, meaning that the system

Fig. 25.20 Simulation results at the summer solstice

Table 25.6 Used energy portion from passive simulation

| Energy portion | Winter solstice | Summer solstice |
|----------------|-----------------|-----------------|
| Solar cell, % | 18.6 | 39.6 |
| Fuel cell, % | 76.4 | 59.9 |
| Capacity | 19.2 | 36.7 |
| Battery, % | 5.0 | 0.5 |
| Min. SOC | 16.0 | 86.4 |
| Final SOC | 24.2 | 93.0 |

requires adjustments to meet safety parameters. On the other hand, during the summer solstice, the remaining SOC reaches 93 %. This shows that the power is not efficiently distributed. To resolve this issue, the active power management takes control of the individual power sources. The active power management has a complex PMS and introduces more weight. However, it is beneficial to the safety because it actively handles any failure of power source and power distribution efficiency of the system because each power source can operate at its optimal condition.

Because the active power management system controls the output of individual power sources, the output voltage of each component is not necessarily the same as the system voltage. Therefore, DC/DC converters are required to match the output voltage of each component to the system voltage. A DC/DC is a passive element that matches input and output voltages, ideally without change in power. Therefore, it does not affect the results of the power simulations. This study does not account

for DC/DC converters in the power model and focuses primarily on the behavior of the power output with active management versus with passive simulations.

The active power management schemes widely used for the HEVs can be divided into the maximum SOC-of-PPS control strategy, the thermostat control strategy, and the constrained thermostat control strategy (Ehsani et al. 2009). The maximum SOC-of-PPS control strategy extracts power from each power source to supply the propulsion power required. At the same time, it charges the battery in real time to maintain a high SOC of the battery. For example, an automobile traveling in an urban area frequently makes quick starts and stops because of pedestrians and traffic signals. Therefore, the battery should be able to provide sufficient power for the entire duration. In such a case, the other power source must charge the battery to maintain a high SOC level. Therefore, the capacity of all the propulsion system, including the battery, has to be increased. However, for a UAV whose primary objective is long-endurance in the air, the weight of the system plays a crucial role in its mission capability. Furthermore, UAVs do not experience frequent high accelerations and transient flights. As a result, a power management to maintain a high SOC level is not a practical option for a UAV.

On the other hand, the thermostat control strategy turns off the fuel cell, the primary power source, and uses the other power sources for power supply when the power required is lower than 50 W preserving the fuel cell to be operated only at high efficiency conditions. It utilizes the fuel cell only when the power required is greater than 50 W. In this sense, automobiles usually employ this strategy to improve efficiency in highway operations. However, as the passive simulation in the previous section predicts that EAV-2's fuel cell stack operates under conditions with efficiency over 45 %, the on-off control for the fuel cell is unnecessary during the flight.

The constrained thermostat control strategy, which is employed in EAV-2, blends the two strategies above and controls output from each power source, maintaining a certain level of SOC of the battery. The active power management logic is illustrated in Fig. 25.21. The power from the solar cells is consumed with the highest priority because the solar cells do not consume the onboard fuel. Power from the solar cells that exceeds the power required is charged to the battery. Once the battery is fully charged, the controller reduces the output from the solar cells by increasing the system voltage and lowering the current from the solar cells. However, because of the high power demands made by an aircraft during the flight, the solar cells operate at their maximum capacity. For fuel cell control during the winter solstice, in order to maintain the battery's SOC at 30 %, the active power management controller assigns a higher output to the fuel cell stack than the passive management does. On the other hand, the controller assigns a lower output during the summer solstice to reduce the SOC. This logic is implemented using a constrained thermostat control strategy with an adding factor, as shown in Eq. (25.18):

$$P_{fc} = P_{req} - P_{sc} + P_{chg,m} \times (SOC_L - SOC) \quad (25.18)$$

where $P_{chg,m}$ is maximum charge power and SOC_L is low level of SOC.

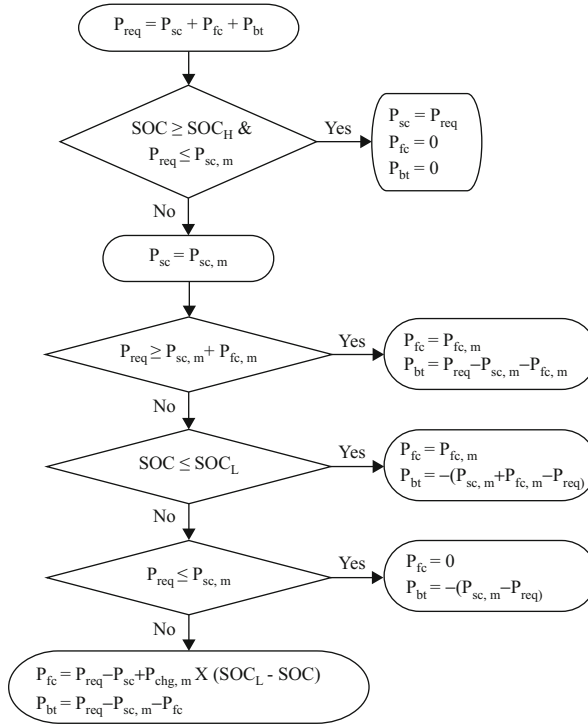

Fig. 25.21 Active power management logic

The controller demands its peak power from the battery for takeoff and transient flight. In addition, if the battery has a remaining capacity greater than SOC_L , the controller takes output from the battery to fill the power shortage of the solar cells and fuel cells. The results of the simulation that employs this management logic are shown in Figs. 25.22 and 25.23 for the winter and summer solstices, respectively. It is worth mentioning that the battery maintains an SOC of greater than 30 % after completion of 4.5 h of flight, as shown in Table 25.7.

25.6 Conclusion

In this chapter, the behavior of the power sources in a hybrid electric propulsion system for a UAV was simulated. The simulation was useful in confirming the feasibility of the capacities of the power sources and was helpful in predicting their characteristics in the UAV propulsion system. The propulsion system of the target UAV (EAV-2) consists of solar cells, fuel cells, and batteries. Each power source was modeled in MATLAB/Simulink and was verified with the manufacturer's data.

Fig. 25.22 Simulation results of applied active power management logic at the winter solstice

Fig. 25.23 Simulation results of applied active power management logic at the summer solstice

Table 25.7 Used energy portion from active simulation

| Energy portion | Winter solstice | Summer solstice |
|----------------|-----------------|-----------------|
| Solar cell, % | 18.5 | 39.6 |
| Fuel cell, % | 77.0 | 55.9 |
| Capacity | 18.7 | 42.6 |
| Battery, % | 4.5 | 4.5 |
| Final SOC | 31.6 | 31.6 |

In addition, the simulation of the power behavior of the system model was verified with the flight test data of EAV-1, which has a hybrid propulsion system consisting of a fuel cell and batteries.

The passive and active PMS were simulated and compared for the EAV-2 propulsion system. The simulation was conducted for duration of 4.5 h, from 10:00 am to 2:30 pm, at the winter and summer solstices. The components were selected for the operational conditions of passive management, in which the voltages of the components were matched. The simulation results of the passive management indicated that even without an active control applied to the system, the system operates reasonably and according to the characteristics of each power source: the solar cells and fuel cells operate as the primary power sources, and the batteries supplement them when peak power is required, e.g., during takeoff and transient flight. At the summer solstice, the solar cell generated 46.9 % more power than at the winter solstice, allowing the aircraft to fly only with the power from the solar cells and fuel cells, and as a result, it charged the batteries during the flight. The active management system, which controls the individual power sources, employed the constrained thermostat control strategy. The simulation results of active management indicated that it could maintain a minimum level of SOC for the battery pack, resulting in efficient power distribution and greater system safety.

In summary, the power simulation of a hybrid electric power system allows for prediction of the dynamic behavior of the system before the costly flight test, and it can be a useful tool in determining power distribution logic.

Nomenclature

A = exponential zone amplitude, V

a = idealizing factor

B = exponential zone time constant inverse, A/h

B_f = constant dependent on the cell type and its operation state, V

b = span, m

C = capacitance, F

C_F = capacity of fuel cell, %

C_{O_2} = concentration of oxygen in the catalytic interface of the cathode, mol/cm³

c = clearness index

E = energy, Wh

E_0 = battery constant voltage, V

E_{Nernst} = Nernst potential, V

e = electron charge, C

G_a = solar irradiation, W/m²

I = current, A

I_0 = dark saturation current, A

I_d = diode current, A

I_{ph} = photo current, A

it = actual battery charge, Ah

i^* = filtered current, A

J = actual cell current density, A/cm²

J_{max} = maximum cell current density, A/cm²

K = polarization constant, V/(Ah) or polarization resistance, Ω

k = Boltzmann's constant, J/K

N_{SM} = series module

n = number of cells

P = power, W

P_{H_2} = partial pressure of hydrogen, atm

P_{O_2} = partial pressure of oxygen, atm

Q = battery capacity, Ah

R = internal resistance, Ω

R_c = equivalent contact resistance to electron conduction, Ω

R_m = equivalent membrane resistance to proton conduction, Ω

R_s = serial resistance, Ω

s = wing area, m²

T = temperature, K

T_a = ambient temperature, °C

T_c = cell temperature, °C

V = voltage, V

V_{act} = voltage lost due to activation, V

V_{con} = Voltage lost concentration loss, V

V_{oc} = open-circuit voltage, V

V_{ohmic} = overvoltage due to ohmic loss, V

V_t = thermal voltage, V

W = weight, kg

v_d = dynamic voltage, V

τ = fuel cell electrical time constant

$\xi_1, \xi_2, \xi_3, \xi_4$ = empirical coefficients of activation over voltage

ϕ = latitude °

δ = solar declination °

ω = solar time, h

Subscripts

bt = battery
 chg = charge
 fc = fuel cell
 L = low limit
 m = maximum
 mtr = motor
 req = required
 sc = solar cell
 tot = total

UAV Control

Jonathan P. How

Kimon P. Valavanis and George J. Vachtsevanos

UAV Control presents a very comprehensive treatment of UAV control and related technologies. The inherently unstable nature of typical UAV configurations necessitates a rigorous approach to the analysis and design of UAV control technologies, as well as a thorough understanding of stability issues.

► **Linear Flight Control Techniques for Unmanned Aerial Vehicles** by How, Frazzoli, and Chowdhary presents an overview of linear flight control and guidance methods for UAVs, starting with a discussion of rotation matrices and UAV kinematic equations and followed by derivation of the 6 DOF UAV equations of motion. Equations of motion are then linearized, and several linear multi-loop closure techniques for UAV guidance and control are discussed.

► **Nonlinear Flight Control Techniques for Unmanned Aerial Vehicles** by Chowdhary, Frazzoli, How, and Liu discusses nonlinear and adaptive control techniques that are often used to improve UAV performance and reliability. Such techniques are actively being studied to handle nonlinear aerodynamic and kinematic effects, actuator saturations and rate limitations, modeling uncertainty, and time-varying dynamics. An overview of tools and techniques used for designing nonlinear flight controllers is presented along with a summary of Lyapunov stability theory. In detail, the nonlinear control techniques that are considered include gain scheduling, model predictive control, backstepping, dynamic inversion-based control, model reference adaptive control, and model-based fault-tolerant control.

► **Adaptive Control of Unmanned Aerial Vehicles: Theory and Flight Tests** by Kannan, Chowdhary, and Johnson focuses on adaptive control of unmanned aircraft that are underactuated systems. A 6 DOF flight control algorithm is derived that can track both position and attitude trajectories. Approximate inverse models for vehicle attitude and position dynamics are used for feedback linearization leading to an inner loop that tracks attitude and angular rate and an outer loop that tracks position and velocity commands. A single adaptive element is used to compensate for inversion errors (uncertainty) in both loops. A key challenge in realizing an adaptive control design on real aircraft is dealing with actuator magnitude and rate saturation. Such saturation elements cannot be easily captured in inverse models and lead to incorrect learning in the adaptive element during periods of saturation. A mechanism to exactly remove such incorrect learning is provided. Additionally, nonlinear reference models are introduced to mitigate the risks of the closed-loop system entering regions of the flight envelope that result in loss of controllability. The resulting adaptive controller accepts trajectory commands comprising of desired position, velocity, attitude, and angular velocity and produces normalized actuator signals required for flight control. A modification to the baseline adaptive control system is also provided that enables long-term retention of the uncertainty approximation within the adaptive element. This architecture is validated through flight tests on several fixed wing and rotorcraft UAVs.

► **Robust and Adaptive Control Methods for Aerial Vehicles** by Lavretsky includes a collection of reliable, efficient, robust, and adaptive control methods for aerial vehicles. It begins with a brief overview of flight dynamics models suitable for flight control design. The first control design method represents the well-understood and now classical linear quadratic regulator (LQR) command tracker, with proportional-integral (PI) feedback connections, serving as the backbone of all other subsequent methods. The main intent is to demonstrate the design of predictable, formally justified, yet numerically efficient flight controllers, with an LQR PI baseline and with a direct model reference adaptive control (MRAC), as an augmentation to the baseline. Through extensive simulation, analysis, and actual flight testing, it is shown that (LQR PI + adaptive) – controllers provide robust stability and maintain tracking performance, when operated in the presence of “unknown unknowns” in the vehicle dynamics and in often “unfriendly” operational environment. All presented control methods are flight tested and validated on a wide range of aerial vehicles.

In summary, this section presents a variety of classical and modern control techniques for unmanned aircraft, which have been successfully tested and implemented.

Linear Flight Control Techniques for Unmanned Aerial Vehicles

Abstract

This chapter presents an overview of linear flight control and guidance methods for unmanned aerial vehicles (UAVs). The chapter begins with a discussion of rotation matrices and kinematic equations of a UAV. The six degree of freedom UAV equations of motion are also derived using rigid-body dynamics principles. The equations of motion are then linearized, and several linear multi-loop closure techniques for UAV guidance and control are discussed.

27.1 Introduction

A flight control system is required to ensure that the UAV exhibits stable behavior and delivers desired performance such as following a desired trajectory with sufficient accuracy in the presence of external disturbances. Thus, a UAV flight control system is typically safety/mission critical, as an incorrect design, lack of robustness to model variations, or a component failure could result in poor performance (impacting, e.g., payload pointing capability) or even loss of the vehicle.

Figure 27.1 depicts a typical UAV control system. The goal of the control system is to track the desired reference command in presence of external disturbances. The control system achieves this by attempting to eliminate the tracking error between the reference commands and the measured response of the UAV. The control is typically achieved by using estimates of the UAV states, which include position, velocity, angular rate, and attitude of the UAV. These estimates are obtained by the navigation system that fuses noisy measurements from several sensors. The purpose of this chapter, and its companion chapter on nonlinear control (chapter [Nonlinear Flight Control Techniques for Unmanned Aerial Vehicles](#)), is to outline the various methods for designing the control system G_c (and some aspects of the navigation system) and in the process highlight the benefits and challenges of using each approach.

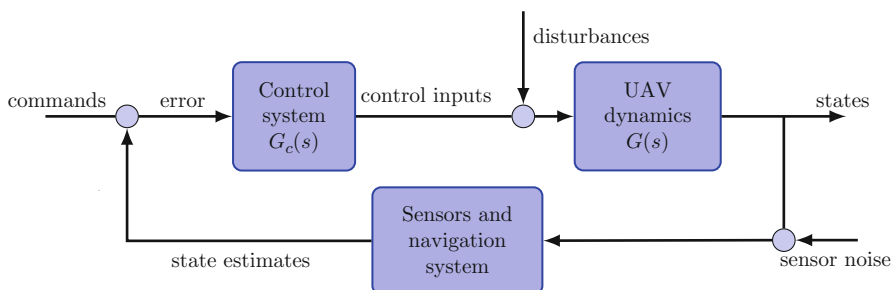

Fig. 27.1 A typical UAV control system architecture. A control system attempts to minimize the tracking error between the desired and estimated states in presence of disturbances. A navigation system provides estimates of the states by fusing together measurements from several complementary sensors

This chapter presents a detailed overview of linear techniques for UAV control. Linear control techniques for manned and unmanned aircraft are well understood and are widely utilized due to their simplicity, ease of implementation, and associated metrics of stability and performance. The chapter begins with a description of UAV dynamics in Sect. 27.2. Linear control techniques are then developed in Sect. 27.3. A brief discussion of path following guidance controllers is presented in Sect. 27.4.

27.2 Equations of Motion

For most problems of interest to UAVs, the Earth can be taken to be an inertial reference frame, and the aircraft can be modeled as a rigid body. In order to write equations of motions for an aircraft, it is customary to define a reference frame (often called a body frame) that is rigidly attached to it (see Fig. 27.2).

A standard choice (often referred to as NED) for the inertial reference frame (X, Y, Z) is to choose the X -axis pointing north, the Y -axis pointing east, and the Z -axis pointing down. Several choices of body frames are common, depending on the task at hand; examples include principal axes and stability axes, and will be discussed in the following. There are advantages to each choice, but the stability axes are very commonly used. In general though, the appropriate body frame (x, y, z) is chosen in such a way that the y -axis is orthogonal to the aircraft's plane of symmetry, pointing to the right. The x -axis is chosen pointing "forward" (the exact direction depends on the definition of the body frame), and the z -axis points "down," to complete the right-handed triad (see Fig. 27.3). Note that for this set, in different *flight equilibrium conditions*, the axes will be oriented differently with respect to the aircraft principal axes, so one must transform (rotate) the principal

Fig. 27.2 Aircraft body frame

Fig. 27.3 Various body frames used for aircraft analysis

inertia components between the frames. However, when vehicle undergoes motion with respect to the equilibrium, stability axes remain fixed to airplane as if *painted on* (see Fig. 27.3).

27.2.1 Dynamics

Newton's laws of mechanics imply that in a body frame whose origin coincides with the aircraft's center of mass,

$$F_B = m\dot{v}_B + \omega_B \times mv_B, \quad (27.1)$$

$$T_B = J_B\dot{\omega}_B + \omega_B \times J_B\omega_B. \quad (27.2)$$

In the above equations, the subscript $(\cdot)_B$ indicates vectors or tensors expressed in the body frame, the dot indicates differentiation with respect to time, v_B is the velocity of the aircraft's center of mass with respect to the inertial frame, ω_B is the angular velocity of the body frame with respect to the inertial frame, m is the aircraft's mass, and J_B is its inertia tensor, which is constant in the body frame. The operator \times denotes the cross product that arises due to the vector derivative transport theorem (see, e.g., Etkin 1982; Stevens and Lewis 2003; Nelson and Smith 1989). On the left-hand side, F_B denotes the sum of the forces acting on the vehicle (including aerodynamic, gravity, thrust, and buoyancy), and T_B denotes the sum of the moments of these forces about its center of mass.

In coordinates, Eqs. (27.1) and (27.2) are written as follows. Let $F_B = (X, Y, Z)$, $T_B = (\bar{L}, M, N)$, $v_B = (U, V, W)$, and $\omega_B = (P, Q, R)$. The inertia tensor is defined as

$$J_B = \int_{\text{Aircraft}} \rho(s) [(s \cdot s)I - s \otimes s] ds,$$

where $\rho(s)$ indicates the density of the aircraft at the point s in the body frame, I is the identity matrix, \cdot indicates the dot product, and \otimes is the Kronecker product, that is, if $u \in \mathbb{R}^m$, $v \in \mathbb{R}^n$, then $w = u \otimes v$ is an $m \times n$ matrix with entries $w_{ij} = u_i v_j$. In most cases of interest, aircraft has a plane of symmetry, typically separating the left and right halves. Assuming that the y -axis is orthogonal to the aircraft's plane of symmetry, the inertia tensor will have the following structure:

$$J_B = \begin{bmatrix} J_{xx} & 0 & -J_{xz} \\ 0 & J_{yy} & 0 \\ -J_{xz} & 0 & J_{zz} \end{bmatrix}.$$

(The cross moment of inertia $J_{xz} = \int_{\text{Aircraft}} \rho(x, y, z) xz dx dy dz$ will in general depend on the choice of the body axes and will be zero in case principal axes are chosen.) Substituting into Eqs. (27.1) and (27.2) (see Etkin and Reid 1996; Blakelock 1965; Etkin 1982; Stevens and Lewis 2003; Nelson and Smith 1989; Stengel 2004 for details),

$$\frac{1}{m} F_B \equiv \frac{1}{m} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} \dot{U} + QW - RV \\ \dot{V} + RU - PW \\ \dot{W} + PV - QU \end{bmatrix}, \quad (27.3)$$

$$T_B \equiv \begin{bmatrix} \bar{L} \\ M \\ N \end{bmatrix} = \begin{bmatrix} J_{xx}\dot{P} - J_{xz}\dot{R} + QR(J_{zz} - J_{yy}) - PQJ_{xz} \\ J_{yy}\dot{Q} + PR(J_{xx} - J_{zz}) + (P^2 - R^2)J_{xz} \\ J_{zz}\dot{R} - J_{xz}\dot{P} + PQ(J_{yy} - J_{xx}) + QRJ_{xz} \end{bmatrix}. \quad (27.4)$$

27.2.2 Kinematics

Equations (27.1) and (27.2) give the evolution over time of the velocity of the aircraft's center of mass and of the aircraft's angular velocity with respect to the inertial frame (expressed in body frame). In order to reconstruct the position and attitude (i.e., orientation) of the aircraft as a function of time, it is necessary to write equations for the aircraft's kinematics.

Let R_{IB} be the rotation matrix that maps vectors in the body frame to vectors in the inertial frame. Given a vector $u \in \mathbb{R}^3$, define a “hat” operator such that the matrix $(u)^\wedge = \hat{u}$ is the unique matrix satisfying $\hat{u}v = u \times v$, $\forall v \in \mathbb{R}^3$. In coordinates, given $u = (u_1, u_2, u_3)$, one gets

$$\hat{u} = \begin{bmatrix} 0 & -u_3 & u_1 \\ u_3 & 0 & -u_2 \\ -u_1 & u_2 & 0 \end{bmatrix}.$$

The aircraft kinematics can be written as

$$\dot{p} = R_{IB} v_B, \quad (27.5)$$

$$\dot{R}_{IB} = R_{IB} \hat{\omega}_B, \quad (27.6)$$

where p is the position of the aircraft's center of mass. Even though the position and attitude of the aircraft can be completely specified by (27.5) and (27.6), maintaining all components of the rotation matrix R_{IB} may be expensive from the computational point of view, since rotation matrices are not a minimal representation of aircraft attitude. In practice, several other methods to represent an aircraft's attitude are commonly used and will be discussed in the following sections. However, some additional properties of rotation matrices are discussed first.

A first point to note is that the spectrum of any matrix in $SO(3)$ has the form $\text{eig}(R) = \{1, \cos \bar{\theta} \pm i \sin \bar{\theta}\}$. Hence, any matrix R admits a unit eigenvector v such that $Rv = v$. Such an eigenvector identifies a fixed axis for the rotation R . The amplitude of the rotation is given by the angle $\bar{\theta}$. Since the trace of a matrix is the sum of its eigenvalues, it is the case that $\text{Tr}(R) = 1 + 2 \cos \bar{\theta}$. Conversely, given a rotation angle $\bar{\theta}$ and a fixed axis unit vector v , the corresponding rotation is computed through Rodriguez' formula:

$$\text{Rot}(\bar{\theta}, v) = I + \sin \bar{\theta} \hat{v} + (1 - \cos \bar{\theta}) \hat{v}^2. \quad (27.7)$$

The pair $(\bar{\theta}, v)$ is also referred to as the exponential coordinates of a rotation matrix $R = \text{Rot}(\bar{\theta}, v)$, since $\text{Rot}(\bar{\theta}, v) = \exp(\bar{\theta} \hat{v})$.

27.2.2.1 Quaternions

A widely used parametrization of rotations that requires fewer parameters than rotation matrices is based on unit quaternions, that is, unit vectors in \mathbb{R}^4 (Kuipers 2002). A quaternion $q = (\hat{q}, \vec{q})$ is typically written in terms of a scalar part $\hat{q} \in \mathbb{R}$ and a vector part $\vec{q} \in \mathbb{R}^3$. A unit quaternion is such that

$$q \cdot q = \hat{q}^2 + \vec{q} \cdot \vec{q} = 1.$$

The set of unit vectors in \mathbb{R}^4 is denoted as the sphere \mathbb{S}^3 . A unit quaternion $q = (\hat{q}, \vec{q}) \in \mathbb{S}^3$ defines a rotation

$$R = \text{Rot}(2 \arccos \hat{q}, \vec{q} / \|\vec{q}\|). \quad (27.8)$$

In other words, the vector part of a unit quaternion is parallel to the fixed axis of the rotation, and the scalar part determines the rotation angle. Conversely, a rotation matrix $R = \text{Rot}(\bar{\theta}, v)$ can be represented by the unit quaternion

$$q = (\cos(\bar{\theta}/2), \sin(\bar{\theta}/2) v). \quad (27.9)$$

Note that this representation is not unique, since for all $q \in \mathbb{S}^3$, q and $-q$ map to the same rotation matrix. (In other words, \mathbb{S}^3 is a double covering of $SO(3)$).

Quaternions are composed through a multiplication operation, indicated with \circ , defined as follows:

$$q_1 \circ q_2 = (\overset{\circ}{q}_1 \overset{\circ}{q}_2 - \vec{q}_1 \cdot \vec{q}_2, \quad \overset{\circ}{q}_1 \vec{q}_2 + \overset{\circ}{q}_2 \vec{q}_1 - \vec{q}_1 \times \vec{q}_2),$$

or in matrix form

$$q_1 \circ q_2 = \begin{bmatrix} \overset{\circ}{q}_1 & -\vec{q}_1^T \\ \vec{q}_1 & \hat{q} \end{bmatrix} q_2.$$

It can be verified that quaternion multiplication as defined above is consistent with matrix multiplication, in the sense that if R_1 and R_2 are rotation matrices corresponding (according to (27.8)) to the unit quaternions q_1 and q_2 , respectively, then $R_1 R_2$ corresponds to $q_1 \circ q_2$. Also, for any unit quaternion $q = (\overset{\circ}{q}, \vec{q})$, its conjugate quaternion $q^* = (\overset{\circ}{q}, -\vec{q})$ corresponds to the “inverse” rotation, in the sense that $q \circ q^* = q^* \circ q = (1, 0)$.

Finally, quaternion kinematics take the form

$$\dot{q}_{IB} = \frac{1}{2}(0, \omega_I) \circ q_{IB} = \frac{1}{2}q_{IB} \circ (0, \omega_B). \quad (27.10)$$

This equation can be written in matrix form as follows:

$$\dot{q} = -\frac{1}{2}\Omega(\omega_B)q, \quad (27.11)$$

where

$$\Omega(\omega) \equiv \begin{bmatrix} 0 & P & Q & R \\ -P & 0 & -R & Q \\ -Q & R & 0 & -P \\ -R & -Q & P & 0 \end{bmatrix}. \quad (27.12)$$

Quaternions are often the preferred method to model aircraft kinematics, since storing and multiplying quaternions require less memory and computation time than storing and multiplying rotation matrices. On the other hand, the fact that the set of unit quaternions is a double covering of the set of rotation matrices can cause stability and robustness issues (Chaturvedi et al. 2011). Numerical errors in quaternion propagation can result in the quaternion losing its normalization constraint. It is common practice therefore to normalize a quaternion to ensure $\|q\|_2 = 1$ if it is numerically integrated for control or navigation purposes.

27.2.2.2 Euler Angles

A rotation can also be parameterized through a sequence of three elementary rotations about coordinated axes. While many choices are possible, in the field of

Fig. 27.4 Definition of the three Euler angles used and the associated sequence of rotations

aircraft flight dynamics and control, it is customary to use the “roll,” “pitch,” and “yaw” Euler angles, defined as follows.

Let (X, Y, Z) be unit vectors defining the inertial frame, and let e_1, e_2, e_3 be the columns of the identity matrix. Starting with a body frame coinciding with the inertial frame, rotate it by an angle ψ (yaw) about the Z -axis (coinciding with the third body axis), obtaining a first intermediate body frame given by $R_{IB'} = \text{Rot}(\psi, e_3) = [x', y', z']$ (with $z' = Z$, see Fig. 27.4). Then, rotate this body frame by an angle θ (pitch) about the y' -axis, obtaining a second intermediate body frame given by $R_{IB''} = R_{IB'} \text{Rot}(\theta, e_2) = [x'', y'', z'']$ (with $y'' = y'$). Finally, rotate this body frame by an angle ϕ (roll) about the x'' -axis, obtaining the final body frame $R_{IB} = R_{IB''} \text{Rot}(\phi, e_1) = [x, y, z]$, with $x = x''$. In summary, the rotation matrix R_{IB} is computed as a function of the roll, pitch, and yaw Euler angles (ϕ, θ, ψ) as

$$\begin{aligned}
 R_{IB} &= \text{Rot}(\psi, e_3) \text{Rot}(\theta, e_2) \text{Rot}(\phi, e_1) \\
 &= \begin{bmatrix} \cos \psi \cos \theta & \cos \psi \sin \phi \sin \theta - \cos \phi \sin \psi & \sin \phi \sin \psi + \cos \phi \cos \psi \sin \theta \\ \cos \theta \sin \psi & \cos \phi \cos \psi + \sin \phi \sin \psi \sin \theta & \cos \phi \sin \psi \sin \theta - \cos \psi \sin \phi \\ -\sin \theta & \cos \theta \sin \phi & \cos \phi \cos \theta \end{bmatrix}.
 \end{aligned} \tag{27.13}$$

Conversely, given a rotation matrix R , Euler angles can be obtained as

$$\theta = \arcsin R_{31}, \quad \phi = \arctan \frac{R_{32}}{R_{33}}, \quad \psi = \arctan \frac{R_{21}}{R_{11}},$$

where the 4-quadrant arctangent should be taken for ϕ and ψ .

A direct relationship can also be given between Euler angles and quaternions. Let the components of a quaternion be given by $q = [\overset{\circ}{q}, q_x, q_y, q_z]$; then

$$\begin{aligned}
 \theta &= -\arcsin 2(q_x q_z - \overset{\circ}{q} q_y), \\
 \phi &= \arctan 2 \left[2(q_y q_z + \overset{\circ}{q} q_x), 1 - 2(q_x^2 + q_y^2) \right], \\
 \psi &= \arctan 2 \left[2(\vec{q}_x q_y + \overset{\circ}{q} q_z), 1 - 2(q_y^2 + q_z^2) \right],
 \end{aligned} \tag{27.14}$$

and

$$\overset{\circ}{q} = \pm (\cos(\phi/2) \cos(\theta/2) \cos(\psi/2) + \sin(\phi/2) \sin(\theta/2) \sin(\psi/2)), \tag{27.15}$$

$$q_x = \pm (\sin(\phi/2) \cos(\theta/2) \cos(\psi/2) - \cos(\phi/2) \sin(\theta/2) \sin(\psi/2)), \tag{27.16}$$

$$q_y = \pm (\cos(\phi/2) \sin(\theta/2) \cos(\psi/2) + \sin(\phi/2) \cos(\theta/2) \sin(\psi/2)), \tag{27.17}$$

$$q_z = \pm (\cos(\phi/2) \cos(\theta/2) \sin(\psi/2) - \sin(\phi/2) \sin(\theta/2) \cos(\psi/2)), \tag{27.18}$$

where the sign is arbitrary but must be consistent.

The kinematics of the Euler angles can be obtained by differentiating (27.13) with respect to time and recalling (27.6). After simplification, one obtains

$$\begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} = \begin{bmatrix} 1 & \sin \phi \tan \theta & \cos \phi \tan \theta \\ 0 & \cos \phi & -\sin \phi \\ 0 & \frac{\sin \phi}{\cos \theta} & \frac{\cos \phi}{\cos \theta} \end{bmatrix} \begin{bmatrix} P \\ Q \\ R \end{bmatrix}. \tag{27.19}$$

Singularities are a potential problem for an Euler angle representation of the attitude kinematics. In the case of roll, pitch, and yaw Euler angles, the singularities at $\theta = \pm 90^\circ$ can cause computational difficulties. Hence, the recommended practice, especially for agile vehicles, such as fighter aircraft or small UAVs, that perform large-angle attitude maneuvers, is to use quaternions (or rotation matrices) to model the aircraft's kinematics. On the other hand, since Euler angles may be

more intuitive to work with, it is common practice to use them as a front end for humans, for example, to specify initial conditions and to present simulation or flight test results.

Equations (27.3)–(27.5) and (27.11)–(27.14) can be combined to form the nonlinear rigid-body equations of motion for a UAV. The next logical step is to discuss how the forces and moments acting on the UAV are generated. The full equations of motion will then be linearized to develop models for the linear control design.

27.2.3 Forces

Forces and torques acting on a UAV are from a variety of sources, including aerodynamic, gravity, and thrust. In general, forces and torques will depend on the aircraft's position, attitude, on its linear and angular speed with respect to the surrounding air, and on the control settings.

The aerodynamic forces are typically resolved into two components, lift (L) and drag (D) (see Fig. 27.5). The aerodynamic lift force is perpendicular to the relative wind vector, while the drag force resists the vehicle motion along the relative wind. The direction of the aircraft's velocity relative to the wind with respect to the body frame is expressed by two angles, which can be thought of as spherical coordinates. The sideslip angle β is the angle formed by the aircraft's velocity with the aircraft's symmetry plane. The angle of attack α is the angle formed by the projection of the aircraft velocity on the aircraft's symmetry plane with the x body axis.

Aerodynamic forces primarily depend on the angle of attack α , on the sideslip β , and on the dynamic pressure $\bar{Q} = \frac{1}{2}\rho V_T^2$, where ρ is the air density, which depends

Fig. 27.5 Lift and drag acting on the aircraft

on the altitude, and V_T is the free-stream airspeed of the aircraft. The lift and drag forces on the body will be in the plane of the x - and z -axes of the wind axis system shown in Fig. 27.5. These can be rotated into the body frame using a rotation matrix that is a function of the angles α and β :

$$R_{BW} = \begin{bmatrix} \cos \alpha \cos \beta & -\cos \alpha \sin \beta & -\sin \alpha \\ \sin \beta & \cos \beta & 0 \\ \sin \alpha \cos \beta & -\sin \alpha \sin \beta & \cos \alpha \end{bmatrix}. \quad (27.20)$$

In this case, the aerodynamic forces in the body frame can be written in terms of lift and drag (assuming no side forces):

$$(F_{\text{aero}})_B = \begin{bmatrix} X_a \\ Y_a \\ Z_a \end{bmatrix} = R_{BW} \begin{bmatrix} -D \\ 0 \\ -L \end{bmatrix}. \quad (27.21)$$

Propulsive forces are typically contained within the aircraft's symmetry plane, possibly with a small angular offset α_T with respect to the x body axis, yielding

$$(F_{\text{prop}})_B = \begin{bmatrix} X_p \\ Y_p \\ Z_p \end{bmatrix} = \|F_{\text{prop}}\| \begin{bmatrix} \cos \alpha_T \\ 0 \\ -\sin \alpha_T \end{bmatrix}. \quad (27.22)$$

Given the usual (NED) choice of inertial axis, wherein the z inertial axis points “down,” the forces due to gravity can be written as

$$(F_{\text{gravity}})_B = \begin{bmatrix} X_g \\ Y_g \\ Z_g \end{bmatrix} = mg R_{IB}^T \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} = mg \begin{bmatrix} -\sin \theta \\ \cos \theta \sin \phi \\ \cos \theta \cos \phi \end{bmatrix}, \quad (27.23)$$

where g is the gravity acceleration.

27.2.4 Linearization of the Equations of Motion

The right-hand side of Eqs. (27.3) and (27.4) are nonlinear and typically far more complicated than can be addressed by standard control techniques and are more complicated than necessary for most flight regimes. Furthermore, the left-hand side, which specify the total forces and moments acting on the vehicle are even more complicated. Thus, numerous simplifications have been developed.

27.2.4.1 Relative Equilibria

The standard approach is to assume that the vehicle is flying in a *relative equilibrium condition* and then linearize the equations of motion about this nominal

flight condition. In the case of aircraft dynamics, a relative equilibrium is defined as a “steady-state” trajectory along which $\dot{\omega}_B = 0$ and $\dot{v}_B = 0$, and the control inputs are maintained fixed or “trimmed” to some value δ_0 . Clearly, such a trajectory will be such that the linear and angular velocities in body frame are constant. These nominal values of the linear and angular velocities will be denoted by v_0 and ω_0 , respectively.

At equilibrium conditions, after writing out explicitly the dependency of the forces and moments, Eqs. (27.1) and (27.2) take the form

$$F_B(p, R_{IB}, v_0, \omega_0, \delta_0) = \omega_0 \times m v_0, \quad (27.24)$$

$$T_B(p, R_{IB}, v_0, \omega_0, \delta_0) = \omega_0 \times J_B \omega_0. \quad (27.25)$$

Note that the position p and attitude R change along the trajectory, according to the kinematics equations $\dot{p} = R_{IB} v_0$ and $\dot{R} = R_{IB} \hat{\omega}_0$. For Eqs. (27.24) and (27.25) to hold over time, it is necessary that the left-hand sides do not change along the trajectory, even though the aircraft’s position and attitude change. In the case of aircraft dynamics, and over small vertical excursions (i.e., neglecting the dependency of the air density on altitude), it can be safely assumed that the body forces and moments are invariant to translations and to rotations about a vertical (inertial) axis, that is,

$$F_B(p, R_{IB}, v_0, \omega_0, \delta_0) = F_B(p + \Delta p, \text{Rot}(\Delta\psi, e_3) R_{IB}, v_0, \omega_0, \delta_0),$$

$$T_B(p, R_{IB}, v_0, \omega_0, \delta_0) = T_B(p + \Delta p, \text{Rot}(\Delta\psi, e_3) R_{IB}, v_0, \omega_0, \delta_0),$$

for any translation Δp and for any heading rotation $\Delta\psi$.

In order for Eqs. (27.24) and (27.25) to hold throughout the trajectory and hence for the trim condition $(v_0, \omega_0, \delta_0)$ to be a valid relative equilibrium, it is necessary that $R_{IB} \hat{\omega}_0 = [0, 0, \dot{\psi}_0]^T$ for some constant heading rate $\dot{\psi}_0$. In other words, in the inertial frame, trajectories corresponding to relative equilibria take the form of circular helices with a vertical axis, flown at constant speed, angle of attack, and sideslip angle. In the special case in which $\dot{\psi}_0 = 0$, that is, on relative equilibria corresponding to straight-line motion, the total forces and moments are zero – but this is not true for the general case.

When analyzing the dynamics of an aircraft near a relative equilibrium, it is convenient to choose the body frame in such a way that the angle of attack is zero at equilibrium. In other words, the x body axis is chosen in such a way that the relative wind direction is in the (x, y) body plane at equilibrium. Such a body frame is called the stability frame, due to its importance in the aircraft stability analysis. Notice that the stability frame depends on the particular relative equilibrium under consideration; for different flight conditions, stability frames will in general be different.

In the following, a class of “symmetric” relative equilibria are considered, along which the sideslip, roll, and yaw angle are zero. To proceed with the linearization of the dynamics for various flight conditions, define the perturbed velocity and accelerations in terms of the nominal values, as given in Table 27.1. The assumption

Table 27.1 Definition of the perturbation variables about the equilibrium condition

| | Nominal velocity | Perturbed velocity | Perturbed acceleration |
|---------------|------------------|------------------------------|-------------------------------|
| Velocities | U_0 | $U = U_0 + u$ | $\dot{U} = \dot{u}$ |
| | $W_0 = 0$ | $W = w$ | $\dot{W} = \dot{w}$ |
| | $V_0 = 0$ | $V = v$ | $\dot{V} = \dot{v}$ |
| Angular rates | $P_0 = 0$ | $P = p$ | $\dot{P} = \dot{p}$ |
| | $Q_0 = 0$ | $Q = q$ | $\dot{Q} = \dot{q}$ |
| | $R_0 = 0$ | $R = r$ | $\dot{R} = \dot{r}$ |
| Angles | Θ_0 | $\Theta = \Theta_0 + \theta$ | $\dot{\Theta} = \dot{\theta}$ |
| | $\Phi_0 = 0$ | $\Phi = \phi$ | $\dot{\Phi} = \dot{\phi}$ |
| | $\Psi_0 = 0$ | $\Psi = \psi$ | $\dot{\Psi} = \dot{\psi}$ |

herein is that the perturbations to the nominal are much smaller in magnitude than the nominal (i.e., $|u| \ll |U_0|$).

A key element of the complexity here is that typically the aerodynamic, thrust, and gravity forces and moments will also be perturbed by the perturbed motion of the vehicle, which are denoted in the following as $\Delta X, \dots, \Delta N$:

$$\begin{bmatrix} \Delta X \\ \Delta Y \\ \Delta Z \end{bmatrix} = m \begin{bmatrix} \dot{u} \\ \dot{v} + rU_0 \\ \dot{w} - qU_0 \end{bmatrix} \quad (27.26)$$

$$\begin{bmatrix} \Delta \bar{L} \\ \Delta M \\ \Delta N \end{bmatrix} = \begin{bmatrix} J_{xx}\dot{p} - J_{xz}\dot{r} \\ J_{yy}\dot{q} \\ J_{zz}\dot{r} - J_{xz}\dot{p} \end{bmatrix} \quad (27.27)$$

where we use the $\overline{(\cdot)}$ to distinguish between the lift L and the moment \bar{L} . The key aerodynamic parameters are also perturbed:

$$\text{Total velocity} \quad V_T = ((U_0 + u)^2 + v^2 + w^2)^{1/2} \approx U_0 + u \quad (27.28)$$

$$\text{Perturbed sideslip angle} \quad \beta = \sin^{-1}(v/V_T) \approx v/U_0 \quad (27.29)$$

$$\text{Perturbed angle of attack} \quad \alpha_x = \tan^{-1}(w/U) \approx w/U_0 \quad (27.30)$$

27.2.4.2 Stability Derivatives

To develop the equations of motion further, the terms $\Delta X \dots \Delta N$ must be investigated. Recall that at equilibrium, the net forces and moments must be zero. But since the aerodynamic and gravity forces are a function of equilibrium condition and the perturbations about this equilibrium, in general, it is very difficult to determine the exact nature of these aerodynamic perturbations. Thus, the standard approach (see detailed discussions in Etkin (1982), Etkin and Reid (1996), and Nelson and Smith (1989)) is to try to predict the changes in the aerodynamic forces and moments using a first-order expansion in the key flight parameters:

$$\Delta X = \frac{\partial X}{\partial U} \Delta U + \frac{\partial X}{\partial W} \Delta W + \frac{\partial X}{\partial \dot{W}} \Delta \dot{W} + \frac{\partial X}{\partial \Theta} \Delta \Theta + \dots + \frac{\partial X_g}{\partial \Theta} \Delta \Theta + \Delta X^c \quad (27.31)$$

$$= \frac{\partial X}{\partial U} u + \frac{\partial X}{\partial W} w + \frac{\partial X}{\partial \dot{W}} \dot{w} + \frac{\partial X}{\partial \Theta} \theta + \dots + \frac{\partial X_g}{\partial \Theta} \theta + \Delta X^c, \quad (27.32)$$

where $\frac{\partial X}{\partial U}$ is called a stability derivative, which is evaluated at the equilibrium condition. Note that both dimensional and nondimensional forms are used. Clearly, this is an approximation since it ignores any time lags in aerodynamics forces (assumes that forces are only functions of instantaneous values).

As before, X_g in Eq. (27.32) corresponds to the X body force component due to gravity and the perturbation gravity and thrust forces and moments. Assuming $\Phi_0 = 0$, then

$$\left. \frac{\partial X_g}{\partial \Theta} \right|_0 = -mg \cos \Theta_0 \quad \left. \frac{\partial Z_g}{\partial \Theta} \right|_0 = -mg \sin \Theta_0.$$

Also ΔX^c denotes the perturbations due to the control actuators (e.g., rudder, ailerons, elevators, thrust).

While Eq. (27.32) leads to simplified force (and moment) perturbations, it is still clear that the linearized expansion can involve many terms $u, \dot{u}, \ddot{u}, \dots, w, \dot{w}, \ddot{w}, \dots$. Thus, it is typical to only retain a few terms to capture the dominant effects. For symmetric aircraft, this dominant behavior is most easily discussed in terms of the *symmetric* variables U, W, Q and forces/torques X, Z , and M , and the *asymmetric* variables V, P, R , and forces/torques Y, \bar{L} , and N (Table 27.2).

Furthermore, for most flight conditions, further simplifications can often be made. For example, for truly symmetric flight, Y, \bar{L} , and N will be exactly *zero* for any value of U, W, Q . So the derivatives of asymmetric forces/torques with respect to the symmetric motion variables are *zero*. Also, the derivatives of symmetric forces/torques with respect to the asymmetric motion variables are small and can often be neglected. Often derivatives with respect to the derivatives of the motion variables can also be neglected, but $\partial Z / \partial \dot{w}$ and $M_{\dot{w}} \equiv \partial M / \partial \dot{w}$ (aerodynamic lag involved in forming new pressure distribution on the wing in response to the perturbed angle of attack) should not be neglected. Also, $\partial X / \partial q$ is often negligibly small. A summary of the effects of the aerodynamic perturbations is as follows:

- (1) $\Delta X = \left(\frac{\partial X}{\partial U} \right)_0 u + \left(\frac{\partial X}{\partial W} \right)_0 w \Rightarrow \Delta X \sim u, \alpha_x \approx w / U_0$
- (2) $\Delta Y \sim \beta \approx v / U_0, p, r$
- (3) $\Delta Z \sim u, \alpha_x \approx w / U_0, \dot{\alpha}_x \approx \dot{w} / U_0, q$
- (4) $\Delta \bar{L} \sim \beta \approx v / U_0, p, r$
- (5) $\Delta M \sim u, \alpha_x \approx w / U_0, \dot{\alpha}_x \approx \dot{w} / U_0, q$
- (6) $\Delta N \sim \beta \approx v / U_0, p, r$

The result is that, with these force and torque approximations, Eqs. (27.1), (27.3), and (27.5) decouple from (27.2), (27.4), and (27.6). In particular, Eqs. (27.1), (27.3),

Table 27.2 Standard stability derivatives for a typical aircraft planform showing that numerous terms are 0 or small. The other nonzero terms, denoted as •, must be computed using the methods described in Etkin and Reid (1996) and Nelson and Smith (1989)

| $\partial()/\partial()$ | X | Y | Z | \bar{L} | M | N |
|-------------------------|-------------|-----|-----|-----------|-----|-----|
| u | • | 0 | • | 0 | • | 0 |
| v | 0 | • | 0 | • | 0 | • |
| w | • | 0 | • | 0 | • | 0 |
| p | 0 | • | 0 | • | 0 | • |
| q | ≈ 0 | 0 | • | 0 | • | 0 |
| r | 0 | • | 0 | • | 0 | • |

and (27.5) are the longitudinal dynamics in u , w , and q :

$$\begin{bmatrix} \Delta X \\ \Delta Z \\ \Delta M \end{bmatrix} = \begin{bmatrix} m\dot{u} \\ m(\dot{w} - qU_0) \\ J_{yy}\dot{q} \end{bmatrix} \quad (27.33)$$

$$\approx \begin{bmatrix} \left(\frac{\partial X}{\partial U}\right)_0 u + \left(\frac{\partial X}{\partial W}\right)_0 w + \left(\frac{\partial X_g}{\partial \Theta}\right)_0 \theta + \Delta X^c \\ \left(\frac{\partial Z}{\partial U}\right)_0 u + \left(\frac{\partial Z}{\partial W}\right)_0 w + \left(\frac{\partial Z}{\partial \dot{W}}\right)_0 \dot{w} + \left(\frac{\partial Z}{\partial Q}\right)_0 q + \left(\frac{\partial Z_g}{\partial \Theta}\right)_0 \theta + \Delta Z^c \\ \left(\frac{\partial M}{\partial U}\right)_0 u + \left(\frac{\partial M}{\partial W}\right)_0 w + \left(\frac{\partial M}{\partial \dot{W}}\right)_0 \dot{w} + \left(\frac{\partial M}{\partial Q}\right)_0 q + \Delta M^c \end{bmatrix}, \quad (27.34)$$

and Eqs. (27.2), (27.4), and (27.6) are the lateral dynamics in v , p , and r :

$$\begin{bmatrix} \Delta Y \\ \Delta \bar{L} \\ \Delta N \end{bmatrix} = \begin{bmatrix} m(\dot{v} + rU_0) \\ J_{xx}\dot{p} - J_{xz}\dot{r} \\ J_{zz}\dot{r} - J_{xz}\dot{p} \end{bmatrix} \quad (27.35)$$

$$\approx \begin{bmatrix} \left(\frac{\partial Y}{\partial V}\right)_0 v + \left(\frac{\partial Y}{\partial P}\right)_0 p + \left(\frac{\partial Y}{\partial R}\right)_0 r + \Delta Y^c \\ \left(\frac{\partial \bar{L}}{\partial V}\right)_0 v + \left(\frac{\partial \bar{L}}{\partial P}\right)_0 p + \left(\frac{\partial \bar{L}}{\partial R}\right)_0 r + \Delta \bar{L}^c \\ \left(\frac{\partial N}{\partial V}\right)_0 v + \left(\frac{\partial N}{\partial P}\right)_0 p + \left(\frac{\partial N}{\partial R}\right)_0 r + \Delta N^c \end{bmatrix}. \quad (27.36)$$

27.2.4.3 Actuators

The primary actuators in the longitudinal direction are the elevators and thrust. Clearly the thrusters and elevators play a key role in defining the steady-state and equilibrium flight condition. The focus now is on determining how they also influence the aircraft motion about this equilibrium condition. For example, if the elevator is deflected, a perturbation in the vehicle motion would be expected, as captured by $u(t)$, $w(t)$, $q(t)$.

Recall that ΔX^c is the perturbation in the total force in the X direction as a result of the actuator commands, that is, a force change due to an actuator deflection

from trim. As before, one can approximate these aerodynamic terms using the same perturbation approach:

$$\Delta X^c = X_{\delta_{th}} \delta_{th} + X_{\delta_e} \delta_e, \quad (27.37)$$

where δ_e is the deflection of the elevator from trim (down positive), δ_{th} is the change in thrust, and X_{δ_e} and $X_{\delta_{th}}$ are the control stability derivatives. This results in

$$\begin{bmatrix} \Delta X^c \\ \Delta Z^c \\ \Delta M^c \end{bmatrix} = \begin{bmatrix} X_{\delta_{th}} & X_{\delta_e} \\ Z_{\delta_{th}} & Z_{\delta_e} \\ M_{\delta_{th}} & M_{\delta_e} \end{bmatrix} \begin{bmatrix} \delta_{th} \\ \delta_e \end{bmatrix}. \quad (27.38)$$

A similar process can be performed in the lateral direction for the rudder and ailerons.

Equations of Motion

Combining the results of the previous sections for the longitudinal dynamics yields the equations of motion:

$$m\dot{u} = X_u u + X_w w - mg \cos \Theta_0 \theta + \Delta X^c \quad (27.39)$$

$$m(\dot{w} - qU_0) = Z_u u + Z_w w + Z_{\dot{w}} \dot{w} + Z_q q - mg \sin \Theta_0 \theta + \Delta Z^c \quad (27.40)$$

$$J_{yy} \dot{q} = M_u u + M_w w + M_{\dot{w}} \dot{w} + M_q q + \Delta M^c. \quad (27.41)$$

If there is no roll/yaw motion so that $q = \dot{\theta}$ and $M_{\dot{w}}$ and $Z_{\dot{w}}$ are assumed to be small, these can be rewritten in state space form using $\alpha = w/U_0$ as

$$\begin{bmatrix} m\dot{u} \\ m\dot{\alpha} \\ J_{yy}\dot{q} \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} X_u & X_\alpha & 0 & -mg \cos \Theta_0 \\ Z_u/U_0 & Z_\alpha/U_0 & Z_q/U_0 + m & -mg/U_0 \sin \Theta_0 \\ M_u & M_\alpha & M_q & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} u \\ \alpha \\ q \\ \theta \end{bmatrix} + \begin{bmatrix} \Delta X^c \\ \Delta Z^c \\ \Delta M^c \\ 0 \end{bmatrix} \quad (27.42)$$

or equivalently as $\dot{x} = Ax + Bu$ where

$$A = \begin{bmatrix} \frac{X_u}{m} & \frac{X_\alpha}{m} & 0 & -g \cos \Theta_0 \\ \frac{Z_u}{mU_0} & \frac{Z_\alpha}{mU_0} & \frac{Z_q}{mU_0} + \frac{g}{U_0} \sin \Theta_0 & \\ \frac{M_u}{J_{yy}} & \frac{M_\alpha}{J_{yy}} & \frac{M_q}{J_{yy}} & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} \frac{X_{\delta_{th}}}{m} & \frac{X_{\delta_e}}{m} \\ \frac{Z_{\delta_{th}}}{mU_0} & \frac{Z_{\delta_e}}{mU_0} \\ \frac{M_{\delta_{th}}}{J_{yy}} & \frac{M_{\delta_e}}{J_{yy}} \\ 0 & 0 \end{bmatrix}. \quad (27.43)$$

Note there are significant notational simplifications if the stability derivatives are defined to include m and J_{yy} .

Using a procedure similar to the longitudinal case, the equations of motion for the lateral dynamics can be developed using the state vector:

$$x = \begin{bmatrix} \phi \\ \beta \\ p \\ r \end{bmatrix} \quad \text{with inputs} \quad u = \begin{bmatrix} \delta_a \\ \delta_r \end{bmatrix},$$

where $\dot{\psi} = r \sec \Theta_0$

$$A = \begin{bmatrix} 0 & 0 & 1 & \tan \theta_0 \\ \frac{g}{U_0} \cos \theta_0 & \frac{Y_\beta}{mU_0} & \frac{Y_p}{mU_0} & \frac{Y_r}{mU_0} - 1 \\ 0 & \left(\frac{\bar{L}_\beta}{J'_{xx}} + J'_{zx} N_\beta \right) & \left(\frac{\bar{L}_p}{J'_{xx}} + J'_{zx} N_p \right) & \left(\frac{\bar{L}_r}{J'_{xx}} + J'_{zx} N_r \right) \\ 0 & \left(J'_{zx} \bar{L}_\beta + \frac{N_\beta}{J'_{zz}} \right) & \left(J'_{zx} \bar{L}_p + \frac{N_p}{J'_{zz}} \right) & \left(J'_{zx} \bar{L}_r + \frac{N_r}{J'_{zz}} \right) \end{bmatrix} \quad (27.44)$$

$$B = \begin{bmatrix} 0 & 0 & 0 \\ (mU_0)^{-1} & 0 & 0 \\ 0 & (J'_{xx})^{-1} & J'_{zx} \\ 0 & J'_{zx} & (J'_{zz})^{-1} \end{bmatrix} \begin{bmatrix} Y_{\delta_a} & Y_{\delta_r} \\ \bar{L}_{\delta_a} & \bar{L}_{\delta_r} \\ N_{\delta_a} & N_{\delta_r} \end{bmatrix} \quad (27.45)$$

and

$$\begin{aligned} J'_{xx} &= (J_{xx}J_{zz} - J_{zx}^2)/J_{zz} \\ J'_{zz} &= (J_{xx}J_{zz} - J_{zx}^2)/J_{xx} \\ J'_{zx} &= J_{zx}/(J_{xx}J_{zz} - J_{zx}^2). \end{aligned} \quad (27.46)$$

Thus, in either case, the aircraft equations of motion can be written as

$$\dot{x} = Ax + Bu \quad (27.47)$$

$$y = Cx + Du, \quad (27.48)$$

where typically $D = 0$, but this depends on the sensor and actuator selection. One can also convert the dynamics into transfer function form (for each sensor/actuator pair) $y_i = G_{ij}(s)u_j$, $G_{ij}(s) = C_i(sI - A)^{-1}B_j + D_{ij}$ that can be used in the classical control design process.

27.2.5 Wind Disturbances

In the presence of wind, the atmosphere is moving relative to the Earth frame (Nelson and Smith 1989; Stevens and Lewis 2003). Therefore, the equations of motion must be modified to account for the fact that the aerodynamic force and moments are functions of the relative motion between the aircraft and the atmosphere and not the inertial velocities. Thus, we must differentiate between the inertial velocity of the vehicle v_i and the velocity of the vehicle with respect to the air mass v_a resulting from wind effects W_g

$$v_a = v_i - R_{BI} W_g. \quad (27.49)$$

In this case, v_a should be used to calculate the aerodynamic forces and moments rather than v_i , and this quantity can be reliably estimated using an airspeed measurement device. More specifically, in the X direction, let u be the aircraft perturbation speed and u_g be the gust speed in that direction, then the aircraft speed with respect to the atmosphere is $u_a = u - u_g$. In this case, the linearization of the aerodynamic forces and moments in Eq. (27.32) should be rewritten in terms of the perturbations relative to the atmosphere:

$$\begin{aligned} \Delta X = & \frac{\partial X}{\partial U}(u - u_g) + \frac{\partial X}{\partial W}(w - w_g) + \frac{\partial X}{\partial \dot{W}}(\dot{w} - \dot{w}_g) + \frac{\partial X}{\partial Q}(q - q_g) \\ & + \dots + \frac{\partial X}{\partial \Theta}\theta + \dots + \frac{\partial X_g}{\partial \Theta}\theta + \Delta X^c \end{aligned} \quad (27.50)$$

but note that the gravity and control input terms remain the same. The rotational aspects of the gusts are caused by spatial variations in the gust components, so that $p_g = \frac{\partial w_g}{\partial y}$ and $q_g = \frac{\partial w_g}{\partial x}$. Repeating the linearization process outlined before leads to a new input term

$$\dot{x} = Ax + Bu + B_w w, \quad (27.51)$$

where, for example, in the longitudinal case,

$$B_w = \begin{bmatrix} -\frac{X_u}{m} & -\frac{X_\alpha}{m} & 0 \\ -\frac{Z_u}{mU_0} & -\frac{Z_\alpha}{mU_0} & -\frac{Z_q}{mU_0} \\ -\frac{M_u}{J_{yy}} & -\frac{M_\alpha}{J_{yy}} & -\frac{M_q}{J_{yy}} \\ 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad w = \begin{bmatrix} u_g \\ \alpha_g \\ q_g \end{bmatrix}, \quad (27.52)$$

and a similar operation can be performed for the lateral dynamics in terms of the disturbance inputs β_g , p_g , and r_g .

The input w can now be used to model the effects of various steady and stochastic wind models, as well as wind shear. Numerous stochastic models have been developed for studying the effect of winds on the aircraft dynamics and performance (Moorhouse and Woodcock 1982; Tatom and Smith 1981; Stevens and Lewis 2003), but these must be used with care when applied to the low altitude operations expected for most small-scale UAV flights.

27.2.6 Simplified Aircraft Equations of Motion for Path Planning

A simplified set of aircraft equations of motion can be derived for path planning purposes. In deriving these equations, the aircraft roll rate, pitch rate, and yaw rate dynamics are ignored and are replaced using kinematic approximations. The resulting model describes the motion of a rigid point mass with kinematic path constraints. For the purpose of this model, the position of the aircraft in an inertial frame whose x -axis is parallel to the local horizon is denoted by x_e, y_e, z_e .

The flight path angle γ denotes the angle between the local horizon and the velocity vector of the aircraft V_T (see Fig. 27.6). The heading angle ψ is the angle between V_T and the z -axis of the local inertial frame. The bank angle ϕ is the angle that the aircraft is banked about the velocity vector V_T . The forces acting on the aircraft consist of the weight mg , thrust T , lift L , and drag D . The equations for a point mass model of a fixed wing aircraft can then be formulated by assuming small γ and ψ (Zhao and Tsiotras 2010; Etkin and Reid 1996):

$$\dot{x}_e = V_T \cos \gamma \cos \psi, \quad (27.53)$$

$$\dot{y}_e = V_T \cos \gamma \sin \psi, \quad (27.54)$$

$$\dot{z}_e = -V_T \sin \gamma, \quad (27.55)$$

$$\dot{V}_T = \frac{1}{m} [T - D - mg \sin \gamma], \quad (27.56)$$

$$\dot{\gamma} = \frac{1}{m V_T} [L \cos \phi - mg \cos \gamma], \quad (27.57)$$

Fig. 27.6 Definition of the flight path angle

$$\dot{\psi} = \frac{L \sin \phi}{m V_T \cos \gamma}, \quad (27.58)$$

and the lift and drag of the aircraft can be approximated as

$$L = \overline{Q} S C_L \quad \text{and} \quad D = \overline{Q} S (C_{D_0} + K C_L^2), \quad (27.59)$$

where S is the wing surface area, C_L is the lift coefficient, C_{D_0} is the parasitic drag coefficient, and K is a constant dependent on the aircraft wing geometry.

27.3 Flight Vehicle Control Using Linear Techniques

As presented above, even in the simplest case of decoupled linearized dynamics, the equations of motion of an aircraft are quite complicated, with both the longitudinal and lateral dynamics being described by a fourth-order system with multiple actuator inputs and sensor outputs y . Furthermore, the speed of the natural response of the system associated with the pole locations of the open-loop dynamics are typically inconsistent with fast and/or stable response to commands, such as waypoint, trajectory tracking, and agile maneuvers. Finally, the dynamics of several UAVs can be inherently unstable, typical examples include rotorcraft such as helicopters, quadrotors, and ducted fans (see, e.g., Mettler 2003; Chowdhary and Jategaonkar 2009). Thus, feedback control is required to stabilize and/or speed up the response.

Given the complexity of the dynamics, there are two basic strategies for the control design. The first is to continue the decomposition in the previous section to identify components of the dynamics that are well controlled by specific choices of the actuators and then perform *successive loop closure* (see, e.g., Lawrence et al. 2008; Johnson and Kannan 2005). In this case, the loops are nested by arranging that the reference commands for the inner loop are provided by the outer-loop controller. An example of this is shown in Fig. 27.13 in which the outermost position control loop provides desired velocity commands using path following guidance discussed in Sect. 27.4. The outer velocity control loop provides a reference (in this case, a desired quaternion value) for the inner attitude control loop. One key advantage of this approach is that it leads to a natural mechanism of handling limits on flights variables (e.g., such as bank or pitch angles) and actuator inputs because the reference commands can be saturated before being passed to the inner loop. Each step of the control design process is simpler, but the nesting of the control loops leads to some challenges. The general rule of thumb is to ensure that the inner control loops result in “fast” dynamics, and then each successive loop added is “slower than the previous one.” The primary difficulties here are to determine what is meant by fast and slow and how to determine if there is too much interaction between the inner/outer loops being closed (e.g., closing the outer loop might reduce the performance of the inner loop, requiring a redesign).

The second approach is to design a controller for the full dynamics – either linear or nonlinear. The advantage of this approach is that it employs the power of state space control approaches to handle the fully coupled dynamics. However, it is difficult to handle actuator saturation and very hard to include state constraints. Furthermore, unless done with extreme care, these controllers, especially in high performance flight, can be very sensitive to modeling errors and omissions.

Having determined the architecture, the next step in any control design is to determine the dynamics of the system of interest (i.e., the full set of dynamics or the approximate inner loop dynamics). Having identified this, one should then determine the requirements and the extent to which the dynamics meet these goals. For example, there may be requirements on certain frequency (to ensure the dynamics are “fast”) and damping (to ensure that the oscillations die out quickly) specifications on the pole locations. There may also be requirements on the maximum steady tracking error to a step command input. Since the open-loop dynamics of the vehicle rarely satisfy these requirements, the typical approach is to use linear feedback control to modify the pole locations and loop gains.

27.3.1 Standard Performance Specifications

Figure 27.7 shows a standard feedback control loop, where a typical performance metric, the tracking error, can be written as

$$e = r - (y + v) = S(r - d_o - v) - SGd_i$$

yielding $y = T(r - v) + Sd_o + SGd_i$ with $L = GG_c$, $S = (I + L)^{-1}$, $T = L(I + L)^{-1}$. So good tracking performance of $r(t)$ (signal typically has low-frequency content) requires e be small, which translates to $\|S(j\omega)\|$ being small at low frequencies, that is, $0 \leq \omega \leq \omega_l$. Furthermore, to reduce the impact of sensor noise v (which typically has high-frequency content) requires $\|T(j\omega)\|$ be small for all $\omega \geq \omega_h$. Since $T(s) + S(s) = I \forall s$, one cannot make both

Fig. 27.7 Classical control feedback loop

Fig. 27.8 Standard loop shaping goals for the indirect design approach

$\|S(j\omega)\|$ and $\|T(j\omega)\|$ small at the same frequencies, which represents a fundamental design constraint.

There are two basic approaches to design: the indirect approach that works on L and the *loop transfer function*, rather than S and T . Much of classical control design takes this approach. The direct approach, which works with S and T , is discussed in Sect. 27.3.4.4.

For the indirect approach, note that if $|L(j\omega)| \gg 1$, $S = (1 + L)^{-1} \approx L^{-1}$, so $|S| \ll 1$ and $|T| \approx 1$. Furthermore, if $|L(j\omega)| \ll 1$, $S = (1 + L)^{-1} \approx 1$, and $T \approx L$, so $|T| \ll 1$. So this converts the performance requirements on S , T into specifications on L , with the two regions in Fig. 27.8: (A) high loop gain which leads to good command following and disturbance rejection and (B) low loop gain leads to attenuation of any sensor noise. One must be careful at crossover, when $|L(j\omega_c)| \approx 1$, which requires that $\arg L(j\omega_c) \neq \pm 180^\circ$ to maintain stability (Levine 1996; Franklin et al. 1994; Kuo 1991; Dorf and Bishop 1995; Skogestad and Postlethwaite 2005). In summary, the typical control design challenges are to achieve high enough gain at low frequency to obtain good performance, low enough gain at high frequency to attenuate sensor noise effects, and sufficient stability margins in the transition range.

27.3.2 Classical Techniques

27.3.2.1 Classical and PID Controllers

There are three standard forms of the classical controller, which in the form of Fig. 27.7 can be written as $u = G_c(s)e = \frac{N_c(s)}{D_c(s)}e$, where e is the *error signal*, typically the difference between the actual variable, for example, θ and the commanded value θ_c ($e = \theta_c - \theta$).

The simplest is proportional feedback, which uses $G_c \equiv K_g$ a gain, so that $N_c = D_c = 1$. This is adequate for some systems but is typically constrained in what gains can be applied before at least some of the dynamics of the vehicle are destabilized. Integral feedback uses $u(t) = K_i \int_0^t e(\tau) d\tau$ which means that $G_c(s) = \frac{K_i}{s}$. This is typically used to reduce/eliminate steady-state error since, if $e(\tau)$ is approximately constant, then the magnitude of $u(t)$ will grow and thus hopefully correct the error.

Example 1. Consider the error response of $G_p(s) = \frac{1}{(s+a)(s+b)}$ ($a > 0, b > 0$) to a step $r(t) = \mathbf{1}(t) \rightarrow r(s) = 1/s$ where

$$\frac{e}{r} = \frac{1}{1 + G_c G_p} = S(s) \rightarrow e(s) = \frac{r(s)}{(1 + G_c G_p)}$$

and $S(s)$ is the *sensitivity transfer function* for the closed-loop system. The final value theorem ($\lim_{t \rightarrow \infty} e(t) = \lim_{s \rightarrow 0} s e(s)$) can be used to analyze the error. So with proportional control,

$$e_{ss} = \lim_{t \rightarrow \infty} e(t) = \lim_{s \rightarrow 0} \left(\frac{s}{s} \right) \frac{1}{1 + K_g G_p(s)} = \frac{1}{1 + \frac{K_g}{ab}}$$

indicating that e_{ss} can be made small but only with a very large K_g . Note, however, that with integral control, $\lim_{s \rightarrow 0} G_c(s) = \infty$, so $e_{ss} \rightarrow 0$. To summarize, integral control improves the steady state, but this is at the expense of the transient response, which typically gets worse because the system is less well damped.

Example 2. $G_p(s) = \frac{1}{(s+a)(s+b)}$, add integral feedback to improve the steady-state response. Increasing K_i to increase the speed of the response pushes the poles toward the imaginary axis leading to a more oscillatory response (compare the possible locus of roots of the closed-loop system shown in Figs. 27.9 and 27.10 using the two control approaches).

If the proportional and integral (PI) feedback are combined, then $G_c(s) = K_1 + \frac{K_2}{s} = \frac{K_1 s + K_2}{s}$ which introduces a pole at the origin and zero at $s = -K_2/K_1$. The zero has the effect of reducing the tendency of the closed-loop poles to move into the

Fig. 27.9 Root locus for $G(s)$ in Example 2 using proportional feedback

right-half plane as the gain is increased, and thus, this PI combination solves some of the problems with using just integral control (compare Figs. 27.10 and 27.11).

The third approach is derivative feedback which uses $u = K_d \dot{e}$ so that $G_c(s) = K_d s$. Note that this will not help with the steady-state response since, if stable, at steady state one should have $\dot{e} \approx 0$. However, it does provide feedback on the rate of change of $e(t)$ so that the control can anticipate future errors.

Example 3. $G(s) = \frac{1}{(s-a)(s-b)}$, ($a > 0$, $b > 0$) with $G_c(s) = K_d s$. As shown in Fig. 27.12, derivative feedback is very useful for pulling the root locus into the left-hand plane or increasing the damping leading to a more stable response. It is typically used in combination with proportional feedback to form proportional-derivative feedback PD $G_c(s) = K_1 + K_2 s$ which moves the zero in Fig. 27.12 away from the origin.

The three approaches discussed above can be combined into the standard PID controller:

$$G_c(s) = \left(K_p + \frac{K_I}{s} + K_D s \right). \quad (27.60)$$

Fig. 27.10 Root locus for $G(s)$ in Example 2 with integral feedback

Typical difficulties in this case are that numerical differentiation of a noisy measured signal can result in noisy or lagged estimates in practice. Furthermore, long-term integration of a signal that has an unknown bias can lead to large control commands. Thus, one would typically use band-limited differentiation/integration instead, by rolling off the PD control with a high-frequency pole (or two) and only integrating signals above a certain frequency (high pass filter) in the PI controller. This leads to a slightly different primary building block for the controller components that is of the form

$$G_B(s) = K_c \frac{(s + z)}{(s + p)} \quad (27.61)$$

which, depending on how the gains are selected, can be morphed into various types of controllers. For example, if one picks $z > p$, with p small, then $G_B(s) \approx K_c \frac{(s+z)}{s}$ which is essentially a PI compensator. In this form, the compensator is known as a *lag*. If instead p is chosen such that $p \gg z$, then at low frequency, the impact of $\frac{p}{(s+p)}$ is small, so $G_B(s) = \frac{K_c}{p}(s + z) \frac{p}{(s+p)} \approx K_c'(s + z)$ which is essentially a PD compensator. In this form, the compensator is called a *lead*.

Various algorithms exist for selecting the components of $G_B(s)$. One basic procedure is to first use a lead controller to augment the phase margin of the loop transfer function $L = G_c(s)G(s)$ at the crossover frequency ω_c to meet

Fig. 27.11 Root locus for $G(s)$ using proportional and integral feedback

the requirements (e.g., desired phase margin). The phase margin is a standard stability margin for a system that measures the amount that the phase of the loop transfer function $L(s)$ differs from -180° when $|L(j\omega)| = 1$. Typically one wants a phase margin of greater than 30° , but other important performance metrics include the gain margin, the peak of the allowable transient, rise, and settling times, and time-delay margin (Dorf and Bishop 1995; Özbay 2000).

1. Find ϕ_{required} required from the performance specifications. Note that $\phi_{\text{required}} = PM - (180^\circ + \angle G(j\omega_c))$.
2. Arrange to put ϕ_{max} at the crossover frequency. Note that the maximum phase added by a lead is $\sin \phi_{\text{max}} = \frac{1-\alpha}{1+\alpha}$ where $\alpha = \frac{|z|}{|p|}$, which implies that $\alpha = \frac{1-\sin \phi_{\text{max}}}{1+\sin \phi_{\text{max}}}$. Further, since the frequency of the maximum phase addition is $\omega_{\text{max}} = \sqrt{|z| \cdot |p|}$, set $\omega_c^2 = |p| \cdot |z|$.
3. Select K_c so that the crossover frequency is at ω_c .

To increase the low-frequency gain to improve the steady-state response, one could use an integrator or use a lag to increase the loop gain. This is done by picking k_c to yield the desired low-frequency gain increase for the loop transfer function (which now includes the vehicle dynamics and the lead controller if added). It is also important to include the constraint that $\lim_{|s| \rightarrow \infty} |G_{\text{lag}}(s)| = 1$, so $k_c = |z|/|p|$

Fig. 27.12 Root locus for $G(s)$ using derivative feedback

to avoid impacting the higher-frequency dynamics. A rule of thumb is to limit the frequency of the zero of the lag compensator so that there is a minimal impact of the phase lag at ω_c . Thus, with $z \approx \omega_c/10$ and k_c both specified, one can solve for the pole location using $|p| = |z|/k_c$.

27.3.3 Successive Loop-Closure Examples

As an example of the successive loop-closure process in Fig. 27.13, the following considers the combination of the velocity and attitude control loops, wherein the attitude reference command is created by the velocity controller. Note that for small angles, the attitude controller could be based on independent PD control of each Euler angle, but the following presents a more general attitude control approach that is based on the quaternion representation of the vehicle attitude. A second example of the successive loop-closure approach is provided in Sect. 27.4.

27.3.3.1 Quaternion-Based Attitude Control

The sequential rotation properties of quaternions can be used to devise a generalized attitude controller for flight vehicles (Wie and Barba 1985; Knoebel 2007; Hall et al. 2008; Michini 2009). Consider some desired aircraft attitude that is

Fig. 27.13 Example of a possible successive loop-closure control architecture where the measured quantities $(x_a, v_a, \vec{q}_a, \omega_a)$ are fed back to specific control loops. Each outer loop generates a reference command that is used to create error signals for the inner loop. Saturation on these reference commands can easily be incorporated (not shown). As shown in the text, the particular architecture required depends on the vehicle and control objectives

specified as a quaternion rotation from the global frame \vec{q}_d . This desired rotation can be constructed intuitively with an axis and an angle as in Eq. (27.9). The actual *measured* attitude of the aircraft can also be represented as a quaternion rotation from the global frame \vec{q}_a . Now consider that the desired attitude \vec{q}_d can be constructed as the measured attitude \vec{q}_a sequentially rotated by some error quaternion \vec{q}_e . Since quaternion rotations are sequential, the error quaternion represents a rotation from the *body frame*:

$$\underbrace{q_d}_{\text{global frame}} = \underbrace{q_e}_{\text{body frame}} \circ \underbrace{q_a}_{\text{global frame}} \quad (27.62)$$

The error quaternion can then be solved for explicitly using the conjugate of the measured attitude quaternion:

$$\underbrace{q_e}_{\text{body frame}} = \underbrace{q_d}_{\text{global frame}} \circ \underbrace{q_a^*}_{\text{global frame}} \quad (27.63)$$

The error quaternion q_e represents the rotation required to get from the measured attitude to the desired attitude. Since the rotation is from the body frame, the x , y , and z components of q_e correspond to the rotations needed about the x , y , and z body axes of the aircraft. Thus, the three components correspond directly to the required aileron, elevator, and rudder commands (or roll cyclic, pitch cyclic, and pedal commands for a helicopter UAV) without any transformation. The scalar part of q_e , \hat{q}_e represents the angle through which the aircraft must be rotated and is thus proportional to the amount of control effort required. As in Sect. 27.2.2.1, let \vec{q}_e denote the vector part of q_e .

The quaternion representation suggests a simple control law of the form $u = -K_p \vec{q}_e - K_d \omega$, where $u = [\delta_a, \delta_e, \delta_r]^T$ is the vector containing the aileron, elevator, and rudder deflections, and K_p and K_d are positive definite proportional and derivative gain matrices. However, this control law suffers from the unwinding phenomena (see, e.g., Mayhew et al. 2011) characterized by the aircraft undergoing

a larger full rotation in order to achieve the desired attitude instead of a more efficient smaller rotation. One reason this happens is because the unit quaternions $[1, 0, 0, 0]$ and $[-1, 0, 0, 0]$ both represent the unique zero attitude and are the equilibria of the quaternion dynamics given in Eq. (27.10). Hence, if a naïve control law was used for regulation to zero attitude represented by $q_d = [-1, 0, 0, 0]$, an undesirable rotation, possibly leading to instability, could occur. On the other hand, the control law $u = K_p \vec{q}_e - K_d \omega$ would stabilize $q_d = [-1, 0, 0, 0]$ but result in an undesirable rotation if $q_d = [1, 0, 0, 0]$. This indicates that the sign of the error quaternion determines the sign of the gain K_p . Therefore, a *consistent* control law that satisfies $u(\overset{\circ}{q}_e, \vec{q}, \omega) = u(-\overset{\circ}{q}_e, \vec{q}, \omega)$ is desirable (Mayhew et al. 2011). Several such consistent asymptotically stabilizing quaternion control laws can be formulated (see, e.g., Mayhew et al. 2011; Wie and Barba 1985), with two examples being

$$u = -\text{sgn}(\overset{\circ}{q}_e) K_p \vec{q}_e - K_d \omega, \quad (27.64)$$

or

$$u = -\frac{\overset{\circ}{q}_e}{2} K_p \vec{q}_e - K_d \omega. \quad (27.65)$$

Another way to implement a consistent control law is to simply monitor the sign of $\overset{\circ}{q}_e$ online and enforce that the right error quaternion representation is chosen. With this constraint, the following control law with time-varying gains has yielded good attitude control performance (Sobolic 2009; Michini 2009; Cutler and How 2012)

$$u = -\frac{\bar{\theta}_e}{\sin(\bar{\theta}_e/2)} K_p \vec{q}_e - K_d \omega, \quad (27.66)$$

where $\bar{\theta}_e = 2 \arccos(\overset{\circ}{q}_e)$.

While denoted above as aileron, elevator, and rudder, the control commands are given in the body frame and thus easily generalizable to any actuator set (e.g., a three-wing tailsitter or quadrotor helicopter) as long as the commands can be mapped to the appropriate actuators. Another key advantage of this attitude controller over Euler angle methods is the lack of singularities, that is, the output of the controller is the direct rotation needed (from the body frame) to get from the measured attitude to the desired attitude (Hall et al. 2008; Knoebel 2007; Michini 2009; Cutler and How 2012). Computationally, no trigonometric functions or rotation matrices are needed, making the controller amenable to onboard or embedded implementation.

27.3.3.2 Outer-Loop Horizontal Velocity Controller

The outer-loop velocity controller can be designed to command a desired attitude based on the desired velocity. For airplanes, this means that in order to achieve a desired velocity in the body y direction, the aircraft must rotate (bank) about

its body x -axis and/or rotate (yaw) about its body z -axis. Furthermore, in order to achieve a desired flight path angle γ , it must rotate (pitch) about its y -axis.

Velocity error and desired attitudes are also tightly coupled for rotorcraft UAVs, where horizontal velocity is achieved by tilting the thrust vector. For a rotorcraft with non-hinged blades such as typical quadrotors, this is often achieved by tilting the body itself. Tilting the vehicle in any direction will generate a horizontal component of velocity.

With the attitude controller in place, a simple outer-loop horizontal velocity controller can be added to generate the desired attitude q_d . To calculate the desired quaternion given the desired x , y , and z velocities $[v_{d_x}, v_{d_y}, v_{d_z}]$ and the actual measured x , y , and z velocities $[v_{a_x}, v_{a_y}, v_{a_z}]$, the velocity errors are calculated:

$$\begin{aligned} v_{e_x} &= v_{d_x} - v_{a_x} \\ v_{e_y} &= v_{d_y} - v_{a_y} \\ v_{e_z} &= v_{d_z} - v_{a_z}. \end{aligned} \quad (27.67)$$

The errors are then used to determine the desired quaternion rotation q_d in the form

$$q_d = [1.0, q_{d_x}(\vec{v}_e), q_{d_y}(\vec{v}_e), q_{d_z}(\vec{v}_e)]. \quad (27.68)$$

A simple control law that works particularly well for rotorcraft by generating the elements of the desired rotation in Eq. (27.68) based on the velocity error is

$$\begin{aligned} q_{d_x} &= K_{p_{v_y}} v_{e_y} + K_{i_{v_y}} \int v_{e_y} dt, \\ q_{d_y} &= -K_{p_{v_x}} v_{e_x} - K_{i_{v_x}} \int v_{e_x} dt, \\ q_{d_z} &= 0, \end{aligned} \quad (27.69)$$

where K_p are the proportional gains and K_i are the integral gains. In this control law, lateral motion is achieved by a rotation about the x -axis, and longitudinal motion is achieved by a rotation about the y -axis. For a rotorcraft, such a controller is based around the hover configuration, where thrust is being generated vertically to counteract the acceleration of gravity.

For airplanes, an outer-loop controller that commands the desired attitude is based around the level forward flight configuration. For airplanes, it is also desirable to command a yaw rotation in the direction that reduces lateral velocity error and a pitch rotation to help achieve the desired flight path angle. This can be achieved by the following control law:

$$q_{d_x} = K_{p_{v_y}} v_{e_y} + K_{i_{v_y}} \int v_{e_y} dt,$$

$$q_{d_y} = -K_{p_{v_z}} v_{e_z} - K_{i_{v_z}} \int v_{e_z} dt, \quad (27.70)$$

$$q_{d_z} = K_{p_{v_r}} v_{e_y} + K_{i_{v_r}} \int v_{e_y} dt.$$

Finally, the desired quaternion is normalized to ensure that $\|q_d\|_2 = 1$. The result is a combined proportional-integral (PI) horizontal velocity controller and quaternion attitude controller.

Care must be taken in commanding q_{d_y} for airplanes in order to avoid stall due to high angle of attacks. If airspeed measurements are available, this can be achieved by limiting commanded pitch attitude to keep the estimated angle of attack within limits (Chowdhary et al. 2011). Care must also be taken in order to ensure that the commanded attitude does not result in an undesired loss of altitude. For airplanes, this can be partially achieved by ensuring that the airplane pitches to maintain vertical speed as in Eq. (27.70). More generally, this can be achieved by limiting the magnitude of the desired attitudes in Eq. (27.68). In order to achieve this, define the inertial altitude error as $z_e = z_d - z_a$, where z_d is the desired altitude and z_a is the actual altitude, and redefine the authority limited quaternion attitude controller as

$$q_d = [1.0, q_{d_x}(\vec{v}_e) - \kappa_x, q_{d_y}(\vec{v}_e) - \kappa_y, q_{d_z}(\vec{v}_e)]. \quad (27.71)$$

An effective control authority limiting term is Sobolic (2009)

$$\begin{aligned} \kappa_x &= K_{p_z} \text{sgn}(v_{a_y}) z_e + K_{v_z} \text{sgn}(v_{a_y}) v_{d_z} \\ \kappa_y &= K_{p_z} \text{sgn}(v_{a_x}) z_e + K_{v_z} \text{sgn}(v_{a_x}) v_{d_z}. \end{aligned} \quad (27.72)$$

This controller is typically implemented in combination with a forward speed (or airspeed) controller and an altitude controller.

27.3.4 Multi-input–Multi-output Control

While PID and classical control are very effective ways of closing single-input–single-output (SISO) loops, it is often challenging to use those techniques to design controllers for systems with multiple sensors and actuators (MIMO). State space techniques can handle that additional complexity very easily.

27.3.4.1 Full-State Feedback Controller

The decoupled system dynamics were given in state space form in Eqs. (27.47) and (27.48), where it is assumed that $D = 0$. The time response of this linear state space system is determined by the eigenvalues of the matrix A , which are the same as the poles of a transfer function representation (Chen 1984; Franklin et al. 1994; Stengel 1994). As before, if the eigenvalues (poles) are unstable or in the wrong location for the desired response, the goal is to use the inputs $u(t)$ to modify

the eigenvalues of A to change the system dynamics. The first approach is to assume a full-state feedback of the form

$$u(t) = r(t) - Kx(t), \quad (27.73)$$

where $r(t) \in \mathcal{R}^m$ is a reference input and $K \in \mathcal{R}^{m \times n}$ is the controller gain.

This gives the closed-loop dynamics:

$$\begin{aligned} \dot{x}(t) &= Ax(t) + B(r(t) - Kx(t)) = (A - BK)x(t) + Br(t) \\ &= A_{cl}x(t) + Br(t) \end{aligned} \quad (27.74)$$

$$y(t) = Cx(t). \quad (27.75)$$

Note that for a system with one input, there are n parameters in K that have to be selected to attempt to place the n eigenvalues in A . For a system with n states, a necessary and sufficient condition for controllability (see, e.g., Dorf and Bishop 1995) is that

$$\text{rank } \mathcal{M}_c \triangleq \text{rank } [B \ AB \ A^2B \ \dots \ A^{n-1}B] = n.$$

Ackermann's Formula

This gives us a method of doing this entire design process in one step. For single-input system, the gains are

$$K = [0 \ \dots \ 0 \ 1] \mathcal{M}_c^{-1} \Phi_c(A),$$

where the roots of the polynomial $\Phi_c(s)$ give the desired pole locations.

Linear Quadratic Regulator (LQR)

It may be difficult to relate the desired performance criteria to desired pole locations. In such cases, an alternative approach is to automatically select pole locations so that the closed-loop system optimizes the cost function

$$J_{\text{LQR}} = \int_0^\infty [x(t)^T R_{xx} x(t) + u(t)^T R_{uu} u(t)] dt, \quad (27.76)$$

where $x^T R_{xx} x$ is the state cost with weight $R_{xx} = R_{xx}^T \geq 0$ and $u^T R_{uu} u$ is called the control cost with weight $R_{uu} = R_{uu}^T > 0$. It is well known that the solution to this infinite horizon optimal control problem is a linear time-invariant state feedback of the form (see, e.g., Bryson and Ho 1969)

$$u(t) = -K_{\text{lqr}} x(t), \quad (27.77)$$

where $K_{\text{lqr}} = R^{-1} B^T P_r$ and P_r is found by solving the algebraic Riccati equation (ARE) for the positive semidefinite symmetric solution P_r

$$0 = A^T P_r + P_r A + R_{xx} - P_r B R_{uu}^{-1} B^T P_r. \quad (27.78)$$

Equation (27.78) can be easily solved numerically, for example, by using the commands `are` or `lqr` in MATLAB.

The design freedom in this case is to select the R_{xx} and R_{uu} matrices. A good rule of thumb, typically called the Bryson's rule (Bryson and Ho 1969), when selecting the weighting matrices R_{xx} and R_{uu} is to normalize the signals: $R_{xx} = \text{diag} \left(\frac{\alpha_1^2}{(x_1)_{\max}^2}, \dots, \frac{\alpha_n^2}{(x_n)_{\max}^2} \right)$ and $R_{uu} = \rho \text{diag} \left(\frac{\beta_1^2}{(u_1)_{\max}^2}, \dots, \frac{\beta_m^2}{(u_m)_{\max}^2} \right)$. The $(x_i)_{\max}$ and $(u_i)_{\max}$ represent the largest desired response or control input for that component of the state/actuator signal. $\sum_i \alpha_i^2 = 1$ and $\sum_i \beta_i^2 = 1$ are used to add an additional relative weighting on the various components of the state/control. The ρ is used as the last relative weighting between the control and state penalties – it effectively sets the controller bandwidth. This gives a relatively concrete way to discuss the relative size of R_{xx} and R_{uu} and their ratio R_{xx}/R_{uu} .

LQR is a very attractive control approach because it easily handles multiple actuators and complex system dynamics. Furthermore, it offers very large stability margins to errors in the loop gain (gain margin of infinity, gain reduction margin of 1/2, and a minimum phase margin of 60° in each control input channel) (Stengel 1994). However, LQR assumes access to the full state, which is rarely available. This assumption is removed in Sect. 27.3.4.2.

Reference Inputs

The proceeding showed how to pick K to change the dynamics to achieve some desired properties (i.e., stabilize A). The question remains as to how well this controller allows the system to track a reference command, which is a performance issue rather than just stability. For good tracking performance the goal is to have $y(t) \approx r(t)$ as $t \rightarrow \infty$. To consider this performance issue in the frequency domain, the final value theorem can be used. This indicates that for good performance, $sY(s) \approx sR(s)$ as $s \rightarrow 0$, which gives $\left. \frac{Y(s)}{R(s)} \right|_{s=0} = 1$. So, for good performance, the transfer function from $R(s)$ to $Y(s)$ should be approximately 1 at low frequency (DC).

One approach is to scale a constant reference input r so that $u = \bar{N}r - Kx(t)$ where \bar{N} is an extra gain used to scale the closed-loop transfer function.

The closed-loop equations are now $y = Cx(t)$ and

$$\dot{x}(t) = (A - BK)x(t) + B\bar{N}r \quad (27.79)$$

so that

$$\frac{Y(s)}{R(s)} = C(sI - (A - BK))^{-1} B\bar{N} = G_{cl}(s)\bar{N}.$$

Given the goal at DC, one can compute

$$\bar{N} = G_{cl}(0)^{-1} = -(C(A - BK)^{-1}B)^{-1}. \quad (27.80)$$

Note that this development assumed that r was constant, but it could also be used if r is a slowly time-varying command. This approach is simple to implement but is typically not robust to errors in the choice of \bar{N} .

An alternative strategy within the LQR framework is to embed an integrator into the feedback control to obtain an *LQR servo*. If the relevant system output is $y(t) = C_y x(t)$ and reference $r(t)$, add extra states $x_I(t)$, where $\dot{x}_I(t) = e(t)$. In this case, if the state of the original system is $x(t)$, then the dynamics are modified to be

$$\begin{bmatrix} \dot{x}(t) \\ \dot{x}_I(t) \end{bmatrix} = \begin{bmatrix} A & 0 \\ -C_y & 0 \end{bmatrix} \begin{bmatrix} x(t) \\ x_I(t) \end{bmatrix} + \begin{bmatrix} B_u \\ 0 \end{bmatrix} u(t) + \begin{bmatrix} 0 \\ I \end{bmatrix} r(t) \quad (27.81)$$

or

$$\dot{\bar{x}}(t) = \bar{A}\bar{x}(t) + \bar{B}u(t) + \bar{B}_r r(t), \quad (27.82)$$

where $\bar{x}(t) = [x^T(t) \ x_I^T(t)]^T$. The modified optimal control problem is to obtain the feedback controller that minimizes the cost:

$$J_{\text{LQR servo}} = \int_0^\infty [\bar{x}^T \bar{R}_{xx} \bar{x} + u^T R_{uu} u] dt$$

which is found by solving the Riccati equation (27.78) using the augmented dynamics \bar{A} and \bar{B} to obtain

$$u(t) = -\bar{K}\bar{x}(t) = -[K \ K_I] \begin{bmatrix} x \\ x_I \end{bmatrix}.$$

Note that the implementation of this LQR servo requires that the integrator states x_I be implemented in software. While slightly more complicated to implement, the advantage of this approach is the additional robustness of ensuring a sufficiently high low-frequency gain in the loop transfer function that the steady-state tracking error to a step reference input will be zero. As such, the LQR-servo form is highly recommended.

27.3.4.2 Estimation

The preceding assumed access to the full state for the feedback control. If that information is available, the control given is very effective, but typically only the output of a few sensors are available. In this case, consider the n -th order system model of the form in Eqs. (27.47) and (27.48) (again with $D = 0$), $x(0)$ unknown, and C such that $x(t)$ cannot be directly determined. One could try direct (static) output feedback of the form $u(t) = K_y y(t)$, but finding K_y is very difficult, and this approach will be fundamentally limited in what it can achieve.

The alternative typically used is to create a dynamic output feedback (DOFB) controller, which uses an *observer* or *estimator* to estimate the system state as $\hat{x}(t)$, and then employs full-state feedback on the estimated state (so $u(t) = -K\hat{x}(t)$) to control the system. This approach, called the *separation principle*, separates the design of the DOFB compensator into the regulator problem (picking K) and the design of the estimator (Stengel 1994; Franklin et al. 1994; Bryson and Ho 1969).

The estimator design starts with a simulation of the system dynamics, which are assumed known, but then adds a feedback term on the measurement error – the difference between what was measured and what was expected based on the estimator, $\tilde{y}(t) = y(t) - C\hat{x}(t)$. The feedback gain is called L_e , and it yields the closed-loop estimator:

$$\begin{aligned}\dot{\hat{x}}(t) &= A\hat{x}(t) + Bu(t) + L_e\tilde{y}(t) \\ &= (A - L_eC)\hat{x}(t) + Bu(t) + L_e y(t)\end{aligned}\quad (27.83)$$

which is a dynamic system with poles given by $\lambda_i(A - L_eC)$ and which takes the measured plant outputs as an input and generates an estimate of $x(t)$. Note that if the pair A, C is observable, then the eigenvalues of $A - L_eC$ can be placed arbitrarily, leading to a similar (actually the *dual*) design problem as the regulator. A necessary and sufficient condition for observability (see, e.g., Dorf and Bishop 1995; Özbay 2000) is that

$$\text{rank } \mathcal{M}_o \triangleq \text{rank} \begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{bmatrix} = n. \quad (27.84)$$

L_e can be determined using pole placement, with the typical strategy of choosing the real part of the poles to be approximately a factor of 2 larger in magnitude than the associated regulator poles. Given the desired estimator pole locations specified as the roots of the polynomial $\Phi_e(s)$, the estimator equivalent of Ackermann's formula is

$$L_e = \Phi_e(A)\mathcal{M}_o^{-1} [0 \dots 0 \ 1]^T. \quad (27.85)$$

Optimal Estimation

Similar to Eq. (27.52), noise in the system is typically modeled as

$$\dot{x}(t) = Ax(t) + Bu(t) + B_w w(t) \quad (27.86)$$

$$y(t) = C_y x(t) + v(t) \quad (27.87)$$

where w is the *process noise* that models the uncertainty in the system model and v is the *sensor noise* that models uncertainty in the measurements. It is typically assumed that $w(t)$ and $v(t)$ are zero mean ($E[w(t)] = 0$, $E[v(t)] = 0$) and uncorrelated Gaussian white random noises so that

$$E[w(t_1)w(t_2)^T] = R_{ww}(t_1)\delta(t_1 - t_2) \Rightarrow w(t) \sim \mathcal{N}(0, R_{ww}),$$

$$E[v(t_1)v(t_2)^T] = R_{vv}(t_1)\delta(t_1 - t_2) \Rightarrow v(t) \sim \mathcal{N}(0, R_{vv}),$$

$$E[w(t_1)v(t_2)^T] = 0.$$

Given this noise, one can develop an optimal estimator, where the key step in the design is to balance the effect of the various types of random noise in the system on the estimation error. With noise in the system, the dynamics of the estimation error $\tilde{x}(t)$ for the closed-loop estimator are

$$\begin{aligned} \dot{\tilde{x}} &= \dot{x} - \dot{\hat{x}} = [Ax + Bu + B_w w] - [A\hat{x} + Bu + L_e(y - \hat{y})] \\ &= (A - L_e C_y)\tilde{x} + B_w w - L_e v. \end{aligned} \quad (27.88)$$

Equation (27.88) explicitly shows the conflict in the estimator design process because one must achieve a balance between the speed of the estimator decay rate, which is governed by $\mathcal{R}[\lambda_i(A - L_e C_y)]$, and the impact of the sensing noise v through the gain L_e . Fast state reconstruction requires rapid decay rate, which typically requires a large L_e , but that tends to magnify the effect of v on the estimation process. The effect of the process noise cannot be modified, but the choice of L_e will tend to mitigate/accentuate the effect of v on $\tilde{x}(t)$.

An optimal filter can be designed that minimizes $J = \text{trace}(Q_e(t))$ with (see Bryson and Ho 1969; Kwakernaak and Sivan 1972; Lewis 1986; Gelb 1974; Crassidis and Junkins 2004; Stengel 1994; Simon 2006 for details)

$$Q_e(t) = E[\{x(t) - \hat{x}(t)\}\{x(t) - \hat{x}(t)\}^T]$$

which is the covariance matrix for the estimation error. The result is a closed-loop estimator with $L_e(t) = Q_e(t)C_y^T R_{vv}^{-1}$ and $Q_e(t) \geq 0$ solves

$$\dot{Q}_e(t) = A Q_e(t) + Q_e(t) A^T + B_w R_{ww} B_w^T - Q_e(t) C_y^T R_{vv}^{-1} C_y Q_e(t)$$

where $\hat{x}(0)$ and $Q_e(0)$ are known. It is standard to assume that $R_{vv} > 0$, $R_{ww} > 0$, all plant dynamics are constant in time, $[A, C_y]$ is detectable, and $[A, B_w]$ is stabilizable. A system is said to be stabilizable if all unstable modes are controllable and is detectable if all unstable modes are observable. In this case, the forward propagation of the covariance $Q_e(t)$ settles down to a constant Q_{ss} independent of $Q_e(0)$, as $t \rightarrow \infty$ where

$$AQ_{ss} + Q_{ss}A^T + B_w R_{ww} B_w^T - Q_{ss} C_y^T R_{vv}^{-1} C_y Q_{ss} = 0$$

and $L_{ss} = Q_{ss} C_y^T R_{vv}^{-1}$. Note that the stabilizable/detectable assumptions give a unique $Q_{ss} \geq 0$. Also, if Q_{ss} exists, the steady-state filter

$$\dot{\hat{x}}(t) = (A - L_{ss} C_y) \hat{x}(t) + L_{ss} y(t) \quad (27.89)$$

is asymptotically stable given these assumption, and thus, L_{ss} can be used as the estimator gains L_e for the system.

27.3.4.3 Dynamic Output Feedback Control System

Given a closed-loop estimator with gain L_e ,

$$\dot{\hat{x}}(t) = (A - L_e C) \hat{x}(t) + B u(t) + L_e y(t). \quad (27.90)$$

Then if L_e is chosen as outlined in the previous sections, it is known that $\hat{x}(t) \rightarrow x(t)$ as $t \rightarrow \infty$, but in general, $\hat{x}(t) \neq x(t) \forall t$. Even so, the approach taken in the output feedback control case is to implement $u(t) = -K \hat{x}(t)$, leading to the closed-loop system dynamics

$$\begin{bmatrix} \dot{x}(t) \\ \dot{\hat{x}}(t) \end{bmatrix} = \begin{bmatrix} A & -BK \\ L_e C & A - BK - L_e C \end{bmatrix} \begin{bmatrix} x(t) \\ \hat{x}(t) \end{bmatrix} \quad (27.91)$$

or

$$\dot{x}_{cl}(t) = A_{cl} x_{cl}(t). \quad (27.92)$$

The stability of this closed-loop system can be analyzed using the *similarity transformation* matrix $T = \begin{bmatrix} I & 0 \\ I & -I \end{bmatrix}$ that preserves the location of the eigenvalues.

In fact it is easy to show that the dynamics matrix of the transformed system is given by

$$\bar{A}_{cl} \triangleq T A_{cl} T^{-1} = \begin{bmatrix} A - BK & BK \\ 0 & A - L_e C \end{bmatrix}.$$

Thus, the closed-loop pole locations are given by the roots of the polynomial

$$\det(sI - \bar{A}_{cl}) \triangleq \det(sI - (A - BK)) \cdot \det(sI - (A - L_e C)) = 0$$

which consist of the union of the regulator poles and estimator poles. The significance of this result is that it implies that one can design the estimator and regulator separately and combine them at the end, and the closed-loop system will be stable. This is called the *separation principle*, and when it holds, it greatly simplifies the control design process.

The resulting *dynamic output feedback compensator* is the combination of the regulator and closed-loop estimator written using the new state $x_c(t) \equiv \hat{x}(t)$ as

$$\dot{x}_c(t) = A_c x_c(t) + B_c y(t) \quad (27.93)$$

$$u(t) = -C_c x_c(t), \quad (27.94)$$

where the compensator dynamics are $A_c \triangleq A - BK - L_e C$, $B_c \triangleq L_e$, and $C_c \triangleq K$. Note that, as expected, the compensator maps *sensor measurements* to *actuator commands*.

The DOFB solution provided in this section is called the (infinite horizon) linear quadratic Gaussian (LQG), and it is the controller that optimizes the expected time-averaged value of the cost in Eq. (27.76) for the stochastic system in Eqs. (27.86) and (27.87) (Bryson and Ho 1969; Stengel 1994; Franklin et al. 1994; Skogestad and Postlethwaite 2005). While LQG has proven to be very effective design algorithm for many MIMO systems, it does not have the same robustness properties guaranteed for the LQR design (Doyle 1978). Furthermore, LQG designs can exhibit high sensitivity to modeling errors. Thus, it is prudent to be cautious and check the peak magnitude of the sensitivity $S(s)$, which provides a measure of the closeness of the loop transfer function to the critical point at $s = -1$. High sensitivities (above 20–50) are indicative of designs that could be susceptible to modeling errors, so further testing and simulation using perturbed dynamics should be considered.

27.3.4.4 Robust Control Techniques

The alternative approach to control design mentioned in Sect. 27.3.1 works with the $S(s)$ and $T(s)$ functions to shape them directly (McFarlane and Glover 1992). For example, consider the following design problem in Fig. 27.14 where

$$G(s) = \frac{200}{(0.05s + 1)^2(10s + 1)}.$$

Fig. 27.14 Direct design problem

Note that there is one input (r) and two performance outputs – one that penalizes the sensitivity $S(s)$ of the system and the other that penalizes the control effort used with the weight functions $W_s(s)$ and $W_u(s)$ to be defined later. With

$$z_1 = W_s(s)(r - Gu) \quad (27.95)$$

$$z_2 = W_u(s)u \quad (27.96)$$

$$e = r - Gu, \quad (27.97)$$

then closing the loop with $u = G_c(s)e$ yields

$$P_{CL}(s) = \begin{bmatrix} W_s \\ 0 \end{bmatrix} + \begin{bmatrix} -W_s G \\ W_u \end{bmatrix} G_c(I + G G_c)^{-1} \quad (27.98)$$

$$= \begin{bmatrix} W_s - W_s G G_c S \\ W_u G_c S \end{bmatrix} = \begin{bmatrix} W_s S \\ W_u G_c S \end{bmatrix} \quad (27.99)$$

so that

$$\begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} W_s S \\ W_u G_c S \end{bmatrix} r, \quad (27.100)$$

and thus, the closed-loop transfer function from the reference input to the performance variable z_1 is the weighted sensitivity function.

This setup gives us direct access to the sensitivity function in the analysis. It is now possible to embed tests such as whether $|S(s)|$ satisfies a desired bound such as

$$|S(j\omega)| < \frac{1}{|W_s(j\omega)|} \quad \forall \omega$$

or equivalently, whether $|W_s(j\omega)S(j\omega)| < 1$, $\forall \omega$. To make this bound useful, one can select the weight $W_s(s)$ to emphasize different frequency regions. For example, to achieve good low-frequency tracking and a crossover frequency of about 10 rad/s, pick

$$W_s = \frac{s/1.5 + 10}{s + (10) \cdot (0.0001)} \quad W_u = 1.$$

Once the architecture of the problem is determined, the structure of $P_{CL}(s)$ is set. The design choice is in the selection of the weights $W_s(s)$ and $W_u(s)$ which then “shape” the closed-loop $S(s)$. The output z_2 participates by providing access to a measure of the amount of control authority being used.

The overall objective then is to bound the size of the closed-loop transfer function $P_{CL}(s)$, which in most cases will be a matrix. The bound used is based on the singular values of the transfer function matrix evaluated over all frequencies. For a complex transfer function matrix $G(j\omega)$, the singular values are the positive square roots of the eigenvalues of $G^H G$. The largest of these is called the maximum singular value, so that $\bar{\sigma}[G(j\omega)] = \max_i \sqrt{\lambda_i(G^H G)}$. Thus, for a stable system,

define

$$\|P_{CL}(s)\|_{\infty} = \sup_{\omega} \bar{\sigma}[P_{CL}(\mathbf{j}\omega)]. \quad (27.101)$$

One interpretation of this \mathcal{H}_{∞} norm, $\|P_{CL}(s)\|_{\infty}$, of the system is that it is the energy gain from the input to output. This maximum gain is achieved using a “worst case” input signal that is essentially a sinusoid at frequency ω^* with (appropriate input direction) that yields $\bar{\sigma}[P_{CL}(\mathbf{j}\omega^*)]$ as the amplification. This interpretation is consistent with the graphical test which finds the peaks of $\bar{\sigma}$ plotted versus frequency. Note that the difference here is that the performance test in the \mathcal{H}_{∞} case is concerned with the maximum amplification of the input signals at any one frequency (worst case). This is contrast to the LQG design, which is concerned with minimizing the sum of the square of all singular values over all frequencies (average case).

The \mathcal{H}_{∞} norm can also be evaluated using a state space test based on the Hamiltonian matrix \mathcal{H} (Zhou et al. 1996), and the following result, which states that the gain of a generic stable system $G(s)$ with state space representation

$$\dot{x}_n(t) = A_n x_n(t) + B_n u(t) \quad (27.102)$$

$$y(t) = C_n x_n(t) + D_n u(t), \quad (27.103)$$

is bounded in the sense that $G_{\max} = \|G(s)\|_{\infty} < \gamma$ if and only if

1. $|D| < \gamma$.
2. The Hamiltonian matrix

$$\mathcal{H} = \left[\begin{array}{c|c} A_n + B_n(\gamma^2 I - D_n^T D_n)^{-1} D_n^T C_n & B_n(\gamma^2 I - D_n^T D_n)^{-1} B_n^T \\ \hline -C_n^T (I + D_n(\gamma^2 I - D_n^T D_n)^{-1} D_n^T) C_n & -A_n^T - C_n^T D_n(\gamma^2 I - D_n^T D_n)^{-1} B_n^T \end{array} \right]$$

has no eigenvalues on the imaginary axis.

Thus, finding the \mathcal{H}_{∞} norm of a system requires to find the smallest γ for which no imaginary eigenvalues of \mathcal{H} exist. This is an iterative process, typically done using a bisection search called the γ -iteration (Skogestad and Postlethwaite 2005; Zhou et al. 1996). Given these analysis tools, the synthesis problem can now be defined.

Robust Control Synthesis

The synthesis problem using the analysis techniques in the previous section is to design a controller that, to the extent possible, ensures that the loop-shaping objectives are satisfied. The approach works with the generalized plant that has all weighting functions embedded. As depicted in Fig. 27.15, the input/output signals of the generalized plant $P(s)$ are defined as z performance output, w disturbance/reference inputs, y sensor outputs, and u actuator inputs. With the loop closed ($u = G_c(s)y$), one can show that

$$P_{CL}(s) \equiv F_l(P, G_c) = P_{zw} + P_{zu} G_c (I - P_{yu} G_c)^{-1} P_{yw} \quad (27.104)$$

Fig. 27.15 Generalized plant for \mathcal{H}_∞ synthesis

which is called a (lower) linear fractional transformation (LFT). The design objective is to find $G_c(s)$ to stabilize the closed-loop system and minimize $\|F_l(P, G_c)\|_\infty$. As noted previously, even finding the \mathcal{H}_∞ norm is challenging, so the approach taken to this synthesis problem is to consider a suboptimal problem:

1. Find $G_c(s)$ to satisfy $\|F_l(P, G_c)\|_\infty < \gamma$.
2. Then use the γ -iteration to find the smallest value (γ_{opt}) for which $\|F_l(P, G_c)\|_\infty < \gamma_{\text{opt}}$.

Thus, the suboptimal \mathcal{H}_∞ synthesis problem (Maciejowski 1989; Skogestad and Postlethwaite 2005; Zhou et al. 1996) is to find $G_c(s)$ to satisfy $\|F_l(P, G_c)\|_\infty < \gamma$:

$$P(s) = \begin{bmatrix} P_{zw}(s) & P_{zu}(s) \\ P_{yw}(s) & P_{yu}(s) \end{bmatrix} := \left[\begin{array}{c|cc} A & B_w & B_u \\ \hline C_z & 0 & D_{zu} \\ \hline C_y & D_{yw} & 0 \end{array} \right]$$

where it is assumed that

1. (A, B_u, C_y) are stabilizable/detectable (essential).
2. (A, B_w, C_z) are stabilizable/detectable (essential).
3. $D_{zu}^T [C_z \ D_{zu}] = [0 \ I]$ (simplifying, essential).
4. $\begin{bmatrix} B_w \\ D_{yw} \end{bmatrix} D_{yw}^T = \begin{bmatrix} 0 \\ I \end{bmatrix}$ (simplifying, essential).

Skogestad and Postlethwaite (2005) and Zhou et al. (1996) derive the controller for this case, and to summarize, there exists a stabilizing $G_c(s)$ such that $\|F_l(P, G_c)\|_\infty < \gamma$ if and only if

- (1) $\exists X \geq 0$ that solves

$$A^T X + XA + C_z^T C_z + X(\gamma^{-2} B_w B_w^T - B_u B_u^T) X = 0 \quad (27.105)$$

$$\text{and } \mathcal{R}\lambda_i [A + (\gamma^{-2} B_w B_w^T - B_u B_u^T) X] < 0 \quad \forall i$$

- (2) $\exists Y \geq 0$ that solves

$$AY + YA^T + B_w^T B_w + Y(\gamma^{-2} C_z^T C_z - C_y^T C_y) Y = 0 \quad (27.106)$$

$$\text{and } \mathcal{R}\lambda_i [A + Y(\gamma^{-2} C_z^T C_z - C_y^T C_y)] < 0 \quad \forall i$$

- (3) $\rho(XY) < \gamma^2$ (27.107)

where ρ is the spectral radius ($\rho(A) = \max_i |\lambda_i(A)|$). Given these solutions, the central \mathcal{H}_∞ controller is written as

$$G_c(s) := \left[\begin{array}{c|c} A + (\gamma^{-2} B_w B_w^T - B_u B_u^T) X - Z Y C_y^T C_y & Z Y C_y^T \\ \hline -B_u^T X & 0 \end{array} \right],$$

where $Z = (I - \gamma^{-2} Y X)^{-1}$. Note that the central controller has as many states as the generalized plant. Also, this design does not decouple as well as the regulator/estimator for LQG, though it can be shown that a separation principle does exist (Green and Limbeer 1995; Zhou et al. 1996). More general forms of the \mathcal{H}_∞ synthesis problem are available that relax some of the assumptions given above (Zhou et al. 1996; Skogestad and Postlethwaite 2005).

The standard design approach is to define an architecture such as Fig. 27.14 that captures the key transfer functions that must be shaped in $P_{CL}(s)$. The functional form of the weighting functions $W_s(s)$ and $W_u(s)$ must then be selected, written in state space form and then embedded into the generalized plant leading to a state space representation of $P(s)$. One can then use the various MATLAB toolboxes (e.g., μ -tools or the robust control toolbox (Balas et al. 1995; Chiang and Safonov 1997; Gahinet et al. 1994)) to solve for the controller $G_c(s)$. The parameters of the weighting functions can then be adjusted to tune the resulting closed-loop transfer functions. Numerous examples of using these approaches for aircraft flight control exist in the literature, see, for example, Hyde (1995), Hu et al. (2000), Sadraey and Colgren (2005), Balas et al. (1998), Reiner et al. (1993), Gadewadikar et al. (2009), and Chao et al. (2007).

One appealing aspect of this design process is that, in contrast to the LQG controller framework, there are direct extensions of the \mathcal{H}_∞ control design process to account for model uncertainty (Balas et al. 1995; Chiang and Safonov 1997; Gahinet et al. 1994). However, a challenge in this case is finding an appropriate *error model* for the model uncertainty that fit into the required assumptions. Also note that the dimension of the resulting controller can increase dramatically as the various weighting functions required to capture this model uncertainty are included. Controller order reduction is possible, but it is often unclear what impact this has on the performance and robustness of the closed-loop system.

27.4 Path Following

Once the controllers for the inner-loop dynamics (e.g., attitude and velocity) have been designed, it is then possible to consider tracking a desired flight path. This flight path might be in the form of interpolated waypoints or a continuous smooth curve. In either case, this path represents the desired location of the vehicle in 3D (possibly 4D if it is time-parametrized), and the goal of the outer-loop controller is to generate reference commands for the inner loops which ensure that the path is tracked.

Fig. 27.16 Pure pursuit guidance logic (Park et al. 2004, 2007)

One way to track the trajectory is a UAV implementation of the “pure pursuit” (Amidi and Thorpe 1990; Ollero and Heredia 1995). The resulting guidance logic in Park et al. (2004, 2007) selects a reference point on the desired trajectory and uses it to generate a lateral acceleration command. This reference point is on the desired path at a distance (L_1) forward of the vehicle, as shown in Fig. 27.16. The algorithm then generates a lateral acceleration command that is determined by

$$a_{scmd} = 2 \frac{V^2}{L_1} \sin \eta. \quad (27.108)$$

The direction of acceleration depends on the sign of the angle between the L_1 line segment and the vehicle velocity vector. If the selected reference point is to the right of the vehicle velocity vector, then the vehicle will be commanded to accelerate to the right (see Fig. 27.16), which means that the vehicle will tend to align its velocity direction with the direction of the L_1 line segment.

Asymptotic Lyapunov stability of the nonlinear guidance method is demonstrated when the UAV is following circular paths (for details, see Park et al. 2004, 2007). This stability analysis is also extended to show robust stability of the guidance logic in the presence of saturated lateral acceleration, which typically occur when there are limitations on the vehicle bank angle.

Further insights on the approach can be obtained through linearization. If d is the cross-track error and V is the vehicle nominal speed, then, assuming η is small,

$$a_{scmd} = 2 \frac{V^2}{L_1} \sin \eta \approx 2 \frac{V}{L_1} \left(\dot{d} + \frac{V}{L_1} d \right). \quad (27.109)$$

Thus, linearization yields a PD controller for the cross-track error. The result also shows that the vehicle speed V and look-ahead distance L_1 determine the proportional and derivative gains. Note that the nonlinear form in Eq. 27.108 works for all η and thus is more powerful than a simple PD implementation.

Several other nonlinear approaches have been proposed for UAV trajectory tracking. For example, Nelson et al. (2006) describes an approach using vector fields to represent desired ground track headings so as to direct the vehicle onto the desired path. In Lawrence (2003), a Lyapunov approach is used to control the vehicle velocity vector to ensure convergence to a limit cycle. The method is well suited to guiding a vehicle from any initial position to a circular orbit above a target location. In Niculescu (2001), an approach that can accommodate large cross-track or heading deviations from a straight line path between way points is presented.

In contrast to the complexity of these approaches, the guidance law in Eq. 27.108 is very simple and easy to implement. In particular, some key properties of this algorithm are as follows (Park et al. 2007). It can naturally follow any circular path of radius greater than a specific limit imposed by the dynamics of the vehicle. It has an element of anticipation of the desired flight path, enabling tight tracking of curved flight trajectories. By incorporating the instantaneous vehicle speed, it adds an adaptive feature with respect to changes in vehicle ground speed caused by external disturbances, such as wind. The approach is proven to be asymptotically stable, for all velocities, in the entire state space of useful initial conditions and in the presence of saturation limits on lateral acceleration.

The implementation typically follows the successive loop-closure ideas discussed in Sect. 27.3. For example, one can implement this command by assuming that vehicle maintains sufficient lift to balance weight, even though banked at angle ϕ . This requires that the vehicle speed up and/or change to a larger α . Assume that $L \sin \phi = ma_s$ to achieve the desired lateral acceleration and that $L \cos \phi = mg$, then $\tan \phi = a_s/g$. The requisite lift increment is

$$\Delta C_L = \frac{L - mg}{QS} \equiv (n - 1) \frac{mg}{QS}, \quad (27.110)$$

where $n \equiv L/(mg)$ is the *load factor*. The expression $\tan \phi = a_s/g$ can be used to develop the required bank angle command ϕ_d that must be applied to the roll controller in the successive loop approach (similar to the architecture in Fig. 27.13). Depending on the vehicle, the command ϕ_d is typically saturated at $\pm 15^\circ$.

Note that this algorithm is designed to follow a given path. It can be used to fly between waypoints simply by connecting the waypoints with either straight lines or arcs, but additional algorithms are needed to generate the paths and/or waypoints. For example, Richards and How (2002) and Richards and How (2004) develop a waypoint optimization approach using mixed-integer linear programming that was demonstrated using UAVs (King et al. 2006). Cowlagi and Tsiotras (2009), Zhao and Tsiotras (2010), and Cowlagi and Tsiotras (2012) develop an alternative

approach based on optimal control theory. In Zhao and Tsiotras (2010) the authors use the kinematic model described in Sect. 27.2.6 along with state and control constraints to formulate and solve an optimal control problem to create time-optimal trajectories.

27.5 Conclusion and Future Directions

Linear control provides a very powerful set of procedures for controller, a vehicle near trim conditions. As shown in this chapter, there are numerous choices to be made, with the primary being classical/PID versus state space. Classical techniques are useful for relatively simple systems (low-state dimension). This is often the case for most airplanes in that the full dynamics decouple into the longitudinal and lateral dynamics and then can be further decomposed into even simpler models associated with the primary dynamic modes (e.g., phugoid, short period, spiral, dutch roll (Nelson and Smith 1989)). UAVs, with rotorcraft or other less traditional planforms, might not exhibit equivalent decompositions, but this option should be considered. If there remains significant coupling in the dynamics, then the large number of modes (poles) can greatly complicate a classical design, and a state space approach should be considered. Two state space options were presented: LQG and \mathcal{H}_∞ , both of which consider different performance objectives. The particular challenge with the LQG (and to some extent LQR) and \mathcal{H}_∞ control systems is determining the system dynamics with sufficient accuracy to ensure that the controllers are robust and work well in practice. This can often require extensive modeling, wind tunnel testing, and system identification. Robust control approaches exist if necessary, but the design procedures are quite complicated compared to those shown here.

With all of the design approaches, the fundamental challenge is to determine what are the design objectives (i.e., the pole locations in classical design, the R_{xx} and R_{uu} matrices in LQR, and the $W_s(s)$ and $W_u(s)$ in \mathcal{H}_∞ control). It should be noted that well-studied guidance and control strategies for manned aircraft may be overly conservative for unmanned vehicles. Choosing these performance specifications can be an iterative process requiring many tests to achieve good/robust overall vehicle performance, especially for a controller with many nested loops. Typically, the tendency with many control designs is to push the performance as high as possible. This is certainly true for the inner loops of the successive loop architecture in Fig. 27.13. Actuator magnitude (and rate) saturation are then natural limits on the achievable performance and should be modeled accurately to test the stability of the system. Excessive feedback of sensor noise and bias can then often be a problem, as can fatigue of the vehicle actuators if the control gains are very high.

As seen in Sect. 27.2, UAV dynamics are inherently nonlinear. Therefore, any linear control approach can only be guaranteed to be locally stable. Hence, it may be difficult to extract the desired performance or even guarantee stability when agile maneuvers are performed. For traditional fixed wing configurations executing way-point flight, this is usually not a significant problem due to vehicle symmetry and inherent stability. However, for rotorcraft platform and other non-

traditional configurations, it may be difficult to guarantee satisfactory performance with a single linear controller. Nonlinear and adaptive control techniques must also be evoked when the linear models of the UAV are not exactly known or are time varying. The problem of design and analysis of nonlinear controllers is studied in the companion chapter on nonlinear flight control techniques for UAVs (chapter ► [Nonlinear Flight Control Techniques for Unmanned Aerial Vehicles](#)).

Abstract

In order to meet increasing demands on performance and reliability of unmanned aerial vehicles, nonlinear and adaptive control techniques are often utilized. These techniques are actively being studied to handle nonlinear aerodynamic and kinematic effects, actuator saturations and rate limitations, modeling uncertainty, and time-varying dynamics. This chapter presents an overview of some tools and techniques used for designing nonlinear flight controllers for UAVs. A brief overview of Lyapunov stability theory is provided. Nonlinear control techniques covered include gain scheduling, model predictive control, backstepping, dynamic inversion-based control, model reference adaptive control, and model-based fault-tolerant control.

28.1 Introduction

UAV flight control systems provide enabling technology for the aerial vehicles to fulfill their flight missions, especially when these missions are often planned to perform risky or tedious tasks under extreme flight conditions that are not suitable for piloted operation. Not surprisingly, UAV flight control systems are often considered safety/mission critical, as a flight control system failure could result in loss of the UAV or an unsuccessful mission. The purpose of this chapter, and its companion chapter on linear control (chapter ►[Linear Flight Control Techniques for Unmanned Aerial Vehicles](#)), is to outline some well-studied linear control methods and their applications on different types of UAVs as well as their customized missions.

The federal inventory of UAVs grew over 40 times in the last decade (Gertler 2012). Most UAVs in operation today are used for surveillance and reconnaissance (S&R) purposes (U.S. Army UAS Center of Excellence 2010) and in very few cases for payload delivery. In these cases a significant portion of the UAVs in operation remains remotely piloted, with autonomous flight control restricted to attitude hold, non-agile waypoint flight, or loiter maneuvers. Linear or gain-scheduled linear controllers are typically adequate for these maneuvers. But in many future scenarios, collaborating UAVs will be expected to perform agile maneuvers in the presence of significant model and environmental uncertainties (Office of the Secretary of Defense 2005, 2007; Gertler 2012). As seen in the companion chapter on linear flight control (chapter ►[Linear Flight Control Techniques for Unmanned Aerial Vehicles](#)), UAV dynamics are inherently nonlinear. Thus, any linear control approach can only be guaranteed to be locally stable, and it may be difficult to extract the desired performance or even guarantee stability when agile maneuvers are performed or when operating in the presence of significant nonlinear effects. This is particularly true for rotorcraft and other nontraditional

fixed-wing planform configurations that might be developed to improve sensor field of view, or for agile flight. In these cases, nonlinear and adaptive control techniques must be utilized to account for erroneous linear models (e.g., incorrect representation of the dynamics or time-varying/state-varying dynamics), nonlinear aerodynamic and kinematic effects, and actuator saturations and rate limitations.

The chapter begins with an overview of Lyapunov stability theory in Sect. 28.2. An overview of Lyapunov-based control techniques including gain scheduling, backstepping, and model predictive control is presented in Sect. 28.3. Dynamic inversion-based techniques are introduced in Sect. 28.3.4. A brief overview of model reference adaptive control is presented in Sect. 28.3.5. The intent of this chapter is to provide an overview of some of the more common methods used for nonlinear UAV control. There are several methods and active research direction beyond those discussed here for UAV nonlinear control; two examples are sliding mode control (see, e.g., Levant et al. 2000; Shkolnikov and Shtessel 2001; Koyuncu et al. 2010) and reinforcement learning-based methods (Abbeel et al. 2010).

28.2 An Overview of Nonlinear Stability Theory

This section presents a brief overview of Lyapunov theory-based mathematical tools used in nonlinear stability analysis and control. A detailed treatment of Lyapunov-based methods can be found in Khalil (2002), Haddad and Chellaboina (2008), Slotine and Li (1991), and Krstić et al. (1995). A state space representation of UAV dynamics will be used. Let $t \in \mathbb{R}^+$ denote the time; then the state $x(t) \in D \subset \mathbb{R}^n$ is defined as the minimal set of variable required to describe a system. Therefore, the choice of state variables is different for each problem. For a typical UAV control design problem, the state consists of the position of the UAV, its velocity, its angular rate, and its attitude. The admissible control inputs are defined by $u(t) \in U \subset \mathbb{R}^m$ and typically consist of actuator inputs provided by elevator, aileron, rudder, and throttle for a fixed wing UAV. Detailed derivation of UAV dynamics can be found in chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book. For the purpose of this chapter, it is sufficient to represent the UAV dynamics in the following generic form:

$$\dot{x}(t) = f(x(t), u(t)). \quad (28.1)$$

The initial condition for the above system is $x(0) = x_0$, with $t = 0$ being the initial time. Note that if the dynamics are time varying, then time itself can be considered as a state of the system (see, e.g., Chap. 4 of Haddad and Chellaboina (2008)). In a state-feedback framework, the control input u is often a function of the states x . Therefore, for stability analysis, it is sufficient to consider the following unforced dynamical system:

$$\dot{x}(t) = f(x(t)). \quad (28.2)$$

The set of all states $x_e \in \mathbb{R}^n$ that satisfy the equation $f(x_e) = 0$ is termed as the set of equilibrium points. Equilibrium points are of great interest in study of nonlinear dynamical systems as they are a set of states in which the system can stay indefinitely if not disturbed. A general nonlinear system may have several equilibrium points or may have none at all. The rigid-body equations of motion of a UAV as studied in chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) have several equilibrium points. Since a simple linear transformation can move an equilibrium point to the origin in the state space, it is assumed in the following that the nonlinear dynamical system of Eq. 28.2 has an equilibrium at the origin, that is, $f(0) = 0$. The solution $x(t)$ to Eq. 28.2 is

$$x(t) = x(0) + \int_0^t f(x(t))dt, \quad x(0) = x_0. \quad (28.3)$$

A unique solution is guaranteed to exist over D if $f(x)$ is Lipschitz continuous over D , that is, for all x and all y within a bounded distance of x , $\|f(x) - f(y)\| \leq c\|x - y\|$ for some constant c (Khalil 2002; Haddad and Chellaboina 2008). Most UAVs also satisfy some condition on controllability (Nijmeijer and van der Schaft 1990) that guarantees the existence of an admissible control u that drives the state close to any point in D in finite time.

28.2.1 Stability of a Nonlinear Dynamical System

The stability of a dynamical system is closely related with the predictability or well-behavedness of its solution. Particularly, the study of stability of a dynamical system answers the question: How far the solution of a dynamical system would stray from the origin if it started away from the origin? The most widely studied concept of stability are those of Lyapunov stability (Haddad and Chellaboina 2008; Khalil 2002; Slotine and Li 1991; Isidori 1995).

Definition 28.1. The origin of the dynamical system of Eq. 28.2 is said to be Lyapunov stable if for every $\epsilon > 0$ there exists a $\delta(\epsilon) > 0$ such that if $\|x(0)\| \leq \delta$ then $\|x(t)\| \leq \epsilon$.

Definition 28.2. The origin of the dynamical system of Eq. 28.2 is said to be asymptotically stable if it is Lyapunov stable and if $\|x(t)\| \leq \delta$ then $\lim_{t \rightarrow \infty} x(t) = 0$.

Definition 28.3. The origin of the dynamical system of Eq. 28.2 is said to be exponentially stable if there exist positive constants α and β such that the solution $x(t)$ satisfies $\|x(t)\| \leq \alpha\|x(0)\|e^{-\beta t}$.

If the above definitions hold for all initial conditions $x(0) \in \mathbb{R}^n$, then the stability definitions are said to be global (assuming a unique solution exists everywhere on \mathbb{R}^n). If a dynamical system is not Lyapunov stable, then it is called unstable.

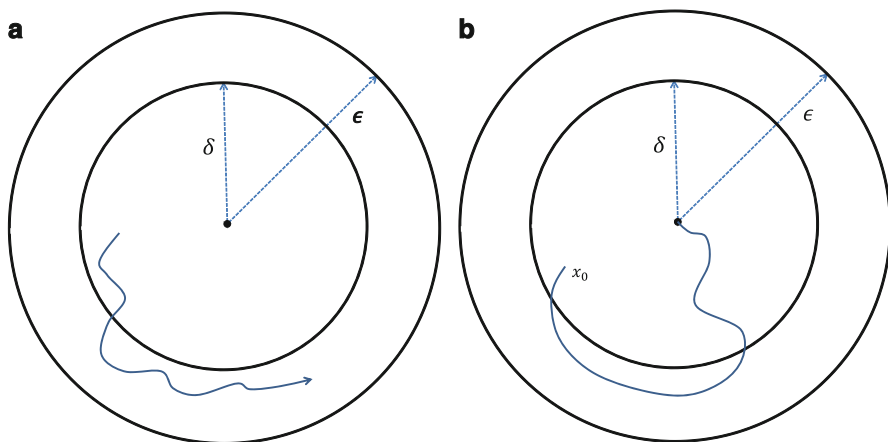

Fig. 28.1 A geometric depiction of Lyapunov stability concepts. (a) Depiction of a Lyapunov stable system. (b) Depiction of an asymptotically stable system

It follows from the above definitions that the stronger notion of stability is that of exponential stability, which requires that the solution goes to the origin at an exponential rate. This is different than the notion of asymptotic stability, which requires the solution to go to the origin eventually. The notion of exponential stability encompasses asymptotic stability, and the notion of asymptotic stability encompasses Lyapunov stability. A geometric depiction of Lyapunov stability is presented in Fig. 28.1.

Lyapunov's direct method, often referred to as Lyapunov's second method, is a powerful technique that provides sufficient conditions to determine the stability of a nonlinear system.

Theorem 28.1. (Khalil 2002; Haddad and Chellaboina 2008; Slotine and Li 1991) Consider the nonlinear dynamical system of Equation 28.2, and assume that there exists a continuously differentiable real-valued positive-definite function $V(x): D \rightarrow \mathbb{R}^+$ such that for $x \in D$

$$\begin{aligned} V(0) &= 0, \\ V(x) &> 0 \quad x \neq 0, \\ \frac{\partial V(x)}{\partial x} f(x) &\leq 0, \end{aligned} \tag{28.4}$$

then the origin is Lyapunov stable. If in addition

$$\frac{\partial V(x)}{\partial x} f(x) < 0, \tag{28.5}$$

the origin is asymptotically stable. Furthermore, if there exist positive constants $\alpha, \beta, \epsilon \in \mathbb{R}^+$ such that

$$\begin{aligned}\alpha \|x\|^2 &\leq V(x) \leq \beta \|x\|^2, \\ \frac{\partial V(x)}{\partial x} f(x) &\leq -\epsilon V(x),\end{aligned}\tag{28.6}$$

then the origin is exponentially stable.

The function $V(x)$ is said to be a Lyapunov function of the dynamical system in Eq. 28.2 if it satisfies these conditions. Therefore, the problem of establishing stability of a dynamical system can be reduced to that of finding a Lyapunov function for the system. If a system is stable, a Lyapunov function is guaranteed to exist (Slotine and Li 1991; Khalil 2002; Haddad and Chellaboina 2008), although finding one may not be always straightforward. It should be noted that the inability to find a Lyapunov function for a system does not imply its instability. A Lyapunov function is said to be radially unbounded if as $x \rightarrow \infty$, $V(x) \rightarrow \infty$. If a radially unbounded Lyapunov function exists for a dynamical system whose solution exists globally, then the stability of that system can be established globally. In the following, $\dot{V}(x(t))$ and $\frac{\partial V(x(t))}{\partial x(t)} f(x(t))$ are used interchangeably.

It is possible to relax the strict negative definiteness condition on the Lyapunov derivative in Eq. 28.5 if it can be shown that the Lyapunov function is nonincreasing everywhere, and the only trajectories where $\dot{V}(x) = 0$ indefinitely are the origin of the system. This result is captured by the Barbashin-Krasovskii-LaSalle invariance principle (see, e.g., Khalil 2002; Haddad and Chellaboina 2008; Slotine and Li 1991), which provides sufficient conditions for convergence of the solution of nonlinear dynamical system to its largest invariant set (described shortly). A point x_p is said to be a positive limit point of the solution $x(t)$ to the nonlinear dynamical system of Eq. 28.2 if there exists an infinite sequence $\{t_i\}$ such that $t_i \rightarrow +\infty$ and $x(t_i) \rightarrow x_p$, as $i \rightarrow \infty$. The positive limit set (also referred to as ω -limit set) is the set of all positive limit points. A set \mathcal{M} is said to be positively invariant if $x(0) \in \mathcal{M}$ then $x(t) \in \mathcal{M}$ for all $t \geq 0$. That is, a positively invariant set is the set of all initial conditions for which the solution of Eq. 28.2 does not leave the set. The set of all equilibria of a nonlinear dynamical system, for example, is a positively invariant set. The Barbashin-Krasovskii-LaSalle theorem can be stated as follows:

Theorem 28.2. (Haddad and Chellaboina 2008; Khalil 2002; Slotine and Li 1991) Consider the dynamical system of Equation 28.2, and assume that \bar{D} is a compact positively invariant set. Furthermore, assume that there exists a continuously differentiable function $V(x) : D \rightarrow \mathbb{R}$ such that $\frac{\partial V(x)}{\partial x} f(x) \leq 0$ in \bar{D} , and let \mathcal{M} be the largest invariant set contained in the set $S = \{x \in D | \dot{V}(x) = 0\}$. Then, if $x(0)$ in \bar{D} , the solution $x(t)$ of the dynamical system approaches \mathcal{M} as $t \rightarrow \infty$.

A corollary to this theorem states that if $V(x)$ is also positive definite over \bar{D} and no solution except the solution $x(t) = 0$ can stay in the set S , then the origin is asymptotically stable (Khalil 2002; Haddad and Chellaboina 2008).

In the following the quaternion attitude controller discussed in chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) is used to illustrate the application of Lyapunov stability analysis. A unit quaternion

$$q = (\overset{\circ}{q}, \vec{q}), \quad \overset{\circ}{q}^2 + \vec{q} \cdot \vec{q} = 1,$$

can be interpreted as a representation of a rotation of an angle $\theta = 2 \arccos(\overset{\circ}{q})$, around an axis parallel to \vec{q} . The attitude dynamics of an airplane modeled as a rigid body with quaternion attitude representation can be given by

$$\begin{aligned} J_B \dot{\omega}_B &= -\omega_B \times J_B \omega_B + u, \\ \dot{q} &= \frac{1}{2} q \circ (0, \omega_B), \end{aligned} \quad (28.7)$$

where J_B is the inertia tensor expressed in the body frame, $\omega_B = [\omega_1, \omega_2, \omega_3]^T \in \mathbb{R}^3$ is the angular velocity of the body frame with respect to the inertial frame, and u is the control input. The operator \circ denotes the quaternion composition operator, using which the quaternion kinematics Eq. 28.7 can be expanded as

$$q_1 \circ (0, \omega_B) = (-\vec{q}_1 \cdot \omega_B, \quad \overset{\circ}{q}_1 \omega_B + \overset{\circ}{q}_1 \vec{q}_1 + \vec{q}_1 \times \omega_B).$$

The goal is to design a control law u such that the system achieves the unique zero attitude represented by the unit quaternions $[1, 0, 0, 0]$ and $[-1, 0, 0, 0]$. It is shown that a control law of the form

$$u = -\frac{\overset{\circ}{q}}{2} K_p \vec{q} - K_d \omega_B, \quad (28.8)$$

where K_p and K_d are positive-definite gain matrices, guarantees that the system achieves zero attitude using Lyapunov analysis. Consider the Lyapunov candidate

$$V(q, \omega) = \frac{1}{2} \vec{q} \cdot K_p \vec{q} + \frac{1}{2} \omega \cdot J \omega.$$

Note that $V(q, \omega) \geq 0$ and is zero only at $q = (\pm 1, \vec{0})$, $\omega = 0$; both points correspond to the rigid body at rest at the identity rotation. The time derivative of the Lyapunov candidate along the trajectories of system Eq. 28.7 under the feedback Eq. 28.8 is computed as

$$\dot{V}(q, \omega) = \vec{q} \cdot K_p \dot{\vec{q}} + \omega \cdot J \dot{\omega}.$$

Note that from the kinematics of unit quaternions, $\dot{\vec{q}} = 1/2 (\dot{\vec{q}}\omega + \vec{q} \times \omega)$. Then,

$$\dot{V}(q, \omega) = \frac{1}{2} \vec{q} \cdot K_p (\dot{\vec{q}}\omega + \vec{q} \times \omega) - \omega \cdot \left(\omega \times J\omega + \frac{\dot{\vec{q}}}{2} K_p \vec{q} + K_d \omega \right) = -\omega \cdot K_d \omega \leq 0.$$

Therefore, $V(q, \omega) \leq 0$; furthermore, the set $S = \{x \in D \mid \dot{V}(x) = 0\}$ consists of only $q = (\pm 1, \vec{0})$, $\omega = 0$. Therefore, Theorem 28.2 guarantees asymptotic convergence to this set.

28.3 Lyapunov-Based Control

28.3.1 Gain Scheduling

In the companion chapter (chapter ►[Linear Flight Control Techniques for Unmanned Aerial Vehicles](#)), it was shown that aircraft dynamics can be linearized around equilibrium points (or trim conditions). A commonly used approach in aircraft control leverages this fact by designing a finite number of linear controllers, each corresponding to a linear model of the aircraft dynamics near a design trim condition. The key motivation in this approach is to leverage well-understood tools in linear systems design. Let A_i, B_i , $i \in \{1, \dots, N\}$ denote the matrices containing the aerodynamic and control effectiveness derivatives around the i th trimmed condition \bar{x}_i . Let X_1, \dots, X_N be a partition of the state space, that is, $\cup_{i=1}^N X_i = \mathbb{R}^n$, $X_i \cap X_j = \emptyset$ for $i \neq j$, into regions that are “near” the design trim conditions; in other words, whenever the state x is in the region X_i , the aircraft dynamics are approximated by the linearization at $\bar{x}_i \in X_i$. Then, the dynamics of the aircraft can be approximated as a state-dependent switching linear system as follows:

$$\dot{x} = A_i x + B_i u \quad \text{when } x \in X_i. \quad (28.9)$$

The idea in gain scheduling-based control is to create a set of gains K_i corresponding to each of the switched model and apply the linear control $u = K_i x$, this is depicted in Fig. 28.2. Contrary to intuition, however, simply ensuring that the i th system is rendered stable (i.e., the real parts of the eigenvalues of $A_i - B_i K_i$ are negative) is not sufficient to guarantee the closed-loop stability of Eq. 28.9 (Branicky 1998; Liberzon 2003, 2005). A Lyapunov-based approach can be used to guarantee the stability of the closed loop when using gain scheduling controller.

Consider the following Lyapunov candidate:

$$V(x(t)) = x(t)^T P x(t), \quad (28.10)$$

where P is a positive-definite matrix, that is, for all $x \neq 0$, $x^T P x > 0$. Therefore, $V(0) = 0$, and $V(x) > 0$ for all $x \neq 0$ making V a valid Lyapunov candidate. The derivative of the Lyapunov candidate is

$$\dot{V}(x) = \dot{x}^T P x + x^T P \dot{x}. \quad (28.11)$$

For the i th system, Eq. 28.11 can be written as

$$\dot{V}(x) = (A_i x - B_i K_i x)^T P x + x^T P (A_i x - B_i K_i x). \quad (28.12)$$

Let $\bar{A}_i = (A_i - B_i K_i)$; then from Lyapunov theory, it follows that for a positive-definite matrix Q if for all i

$$\bar{A}_i^T P + P \bar{A}_i < -Q, \quad (28.13)$$

$\frac{\partial V(x)}{\partial x} f(x) < -x^T Q x$. In this case, $V(x)$ is a common Lyapunov function for the switched closed-loop system (see, e.g., Liberzon 2003) establishing the (globally uniformly exponential) stability of the equilibrium at the origin. Therefore, the control design task is to select the gains K_i such that Eq. 28.13 is satisfied. One way to tackle this problem is through the framework of linear matrix inequalities (LMI) (Boyd et al. 1994; Gahinet et al. 1994). It should be noted that the condition in Eq. 28.13 allows switching between the linear models to occur infinitely fast; this can be a fairly conservative assumption for most UAV control applications. This condition can be relaxed to $\bar{A}_i^T P_i + P_i \bar{A}_i < -Q_i$ for $Q_i > 0$ to guarantee the stability of the system if the system does not switch arbitrarily fast. A rigorous condition for proving asymptotic stability of a system of the form (Eq. 28.9) was introduced in Branicky (1998). Let $V_i, i \in \{1, \dots, N\}$ be Lyapunov-like functions, that is, positive-definite functions such that $V_i(x) < 0$ whenever $x \in X_i \setminus \{0\}$. Define $V_i[k]$ as the infimum of all the values taken by V_i during the k -th time interval over which $x \in X_i$. Then, if the system satisfies the *sequence nonincreasing condition* $V_i[k+1] < V_i[k]$, for all $k \in \mathbb{N}$, asymptotic stability is guaranteed (Branicky 1998; Liberzon 2003).

The above example illustrates the use of Lyapunov techniques in synthesizing controllers. In general, given the system of Eq. 28.2, and a positive-definite Lyapunov candidate, the Lyapunov synthesis approach to create robust exponentially stable controllers can be summarized as follows: Let $\dot{V}(x) = g(x, u)$, and find a control function $u(x)$ such that $\dot{V}(x) < -\epsilon V(x)$ for some positive constant ϵ . Robust methods for Lyapunov-based control synthesis are discussed in Haddad and Chellaboina (2008). Furthermore, Rodrigues and How (2003) provides an output feedback control algorithms for system with switching dynamics.

The framework of linear parameter-varying (LPV) systems lends naturally to design and analysis of controllers based on a UAV dynamics representation via linearization across multiple equilibria. Gain scheduling-based LPV control synthesis techniques have been studied for flight control, and conditions for stability have been established (see, e.g., Lee et al. 2001; He and Zhao 2012; Balas et al. 2003; Shamma and Michael Athans 1991; Masubuchi et al. 2004).

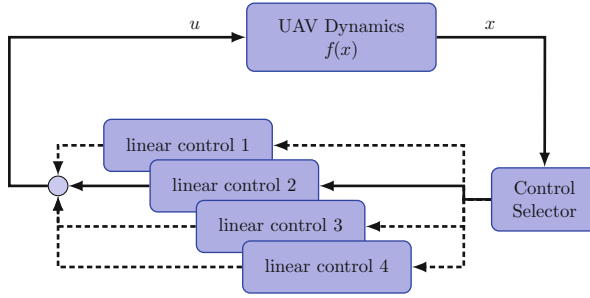

Fig. 28.2 Schematic of a gain-scheduled scheme for UAV control. The controller selector box decides which linear controller is to be used based on measured system states. In the depicted situation, controller 2 is active

28.3.2 Backstepping Control

Backstepping is an example of a Lyapunov-based technique, providing a powerful recursive approach for stabilizing systems that can be represented in nested loops (Kokotović 1992; Krstić et al. 1995).

28.3.2.1 Systems in Strict-Feedback Form

As a basic example, consider a system of the (strict-feedback) form

$$\begin{aligned}\dot{x} &= f_0(x) + g_0(x)z, \\ \dot{z} &= f_1(x, z) + g_1(x, z)u,\end{aligned}\tag{28.14}$$

where $x \in \mathbb{R}^n$, z is a scalar, and u is a scalar input. Assume that the “inner” system,

$$\dot{x} = f_0(x) + g_0(x)z,$$

has an equilibrium point for $x = 0$ and $z = 0$ and admits a known stabilizing feedback control law $x \mapsto u_0(x)$ with Lyapunov function $V_0 : \mathbb{R}^n \rightarrow \mathbb{R}_{\geq 0}$, $V_0(0) = 0$. In other words, if $z = u_0(x)$, then

$$\frac{d}{dt}V_0(x) = \frac{\partial V_0(x)}{\partial x} (f_0(x) + g_0(x)u_0(x)) = -W(x) < 0, \quad \forall x \neq 0.$$

Now consider the system in Eq. 28.14; the idea is to design a control input u such that the state z tracks the control law u_0 , which is known to be stabilizing for the inner system. However, in general z will not match exactly $u_0(x)$; thus, stability for the whole closed-loop system must be established. Defining $e = z - u_0(x)$, Eq. 28.14 can be rewritten as

$$\begin{aligned}
\dot{x} &= f_0(x) + g_0(x)u_0(x) + g_0(x)e, \\
\dot{e} &= f_1(x, z) + g_1(x, z)u - \frac{\partial u_0(x)}{\partial x} (f_0(x) + g_0(x)z) = v.
\end{aligned} \tag{28.15}$$

Now consider the Lyapunov function candidate

$$V_1(x, e) = V_0(x) + \frac{1}{2}e^2;$$

its time derivative along the system's trajectories is

$$\frac{d}{dt} V_1(x, e) = \frac{\partial V_0(x)}{\partial x} (f_0(x) + g_0(x)u_0(x) + g_0(x)e) + ev.$$

If one picks $v = -\frac{\partial V_0(x)}{\partial x} g_0(x) - k_1 e$, with $k_1 > 0$, then

$$\frac{d}{dt} V_1(x, e) = -W(x) - k_1 e^2 < 0, \quad \forall (x, e) \neq 0,$$

thus proving stability of system Eq. 28.15.

Finally, assuming that $g_1(x, z) \neq 0$, $\forall (x, z) \in \mathbb{R}^{n+1}$, a stabilizing feedback for the original system in Eq. 28.14 can be recovered as

$$\begin{aligned}
u(x, z) &= \frac{1}{g_1(x, z)} \left(\frac{\partial u_0(x)}{\partial x} (f_0(x) + g_0(x)z) - f_1(x, z) + v \right) \\
&= \frac{1}{g_1(x, z)} \left(\frac{\partial u_0(x)}{\partial x} (f_0(x) + g_0(x)z) \right. \\
&\quad \left. - f_1(x, z) - \frac{\partial V_0(x)}{\partial x} g_0(x) - k_1(z - u_0(x)) \right).
\end{aligned} \tag{28.16}$$

Since the control law in Eq. 28.16 stabilizes system Eq. 28.14, with Lyapunov function V_1 , a similar argument can be used to recursively build a control law for a system in strict-feedback form of arbitrary order,

$$\begin{aligned}
\dot{x} &= f_0(x) + g_0(x)z_1, \\
\dot{z}_1 &= f_1(x, z_1) + g_1(x, z_1)z_2, \\
&\vdots \\
\dot{z}_m &= f_m(x, z_1, \dots, z_m) + g_m(x, z_m)u.
\end{aligned} \tag{28.17}$$

The procedure is summarized as follows: Start from the “inner” system, for which a stabilizing control law and a Lyapunov function are known. Define an error between the known control law and the actual input to the inner system. Augment the Lyapunov function with the square of the error. Design a new control law that

ensures the stability of the augmented system. Repeat using the augmented system just defined as the new inner system. This recursion, “stepping back” from the inner system all the way to the control input, gives the name to the method. A detailed description of control synthesis for small unmanned helicopters using backstepping techniques is provided in Raptis and Valavanis (2011).

28.3.3 Model Predictive Control (MPC)

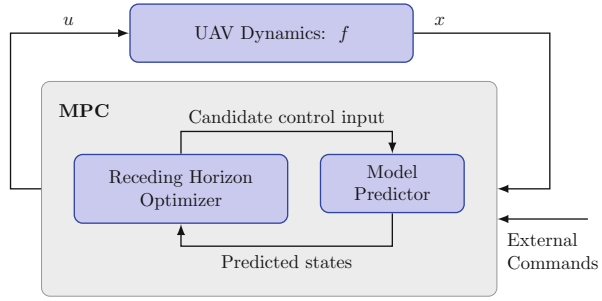

MPC has been successfully used for many years in industrial applications with relatively slow dynamics (e.g., chemical reactions (Maciejowski 2002; Kerrigan 2000; Mayne et al. 2000)); it is only in the past decade that the computational power has been available to enable online optimization for fast system dynamics typical in aerospace applications (early relevant demonstrations are in Manikonda et al. (1999), Dunbar and Murray (2002), Dunbar and Murray (2004), Dunbar (2007), Richards and How (2004), and Richards (2005)). MPC attempts to solve the following problem: Design an admissible piecewise continuous control input $u(t)$ that guarantees the system behaves like a reference model without violating the given state and input constraints. As such, a key benefit MPC is the ability to optimize the control input in the presence of state and input constraints. Furthermore, because MPC explicitly considers the operating constraints, it can operate closer to hard constraint boundaries than traditional control schemes.

MPC can be formulated using several types of cost function; however, due to the availability of robust quadratic solvers, the following formulation is popular: Find the optimal control $u(t)$ such that for given positive (semi)-definite matrices Q , R , and S , the following quadratic cost is minimized:

$$J_{\infty}(e, u) = \int_{t_0}^{\infty} e^T(t) Q e(t) + u^T(t) R u(t) dt, \quad x \in \Xi, u \in \Pi. \quad (28.18)$$

In the presence of constraints, a closed form solution for an infinite horizon optimization problem cannot be found in the general case (Camacho and Bordons 1999; Rawlings 2000; Nicolao et al. 2000; Mayne 2000). Hence, the approach in MPC is to numerically solve a receding horizon optimization (RHO) problem online over the interval $[t, t + N]$ to find the new control input at time $t + 1$; this process is then repeated over every discrete update (see, Fig. 28.3). The idea is that if the horizon is sufficiently large, the solution to the receding horizon optimization problem can guarantee stability. Let h be a mapping between the states x of the nonlinear dynamical system in Eq. 28.2 and the output z such that $z = h(x)$. If the function $h(x)$ is observable, this problem can be recast into a problem of minimizing a discrete output-based cost. Observability for linear systems was discussed in chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book. Local observability for nonlinear systems can be established in an analogous manner by considering the rank of the Jacobian matrix of $n - 1$ Lie derivatives of $h(x)$ along the trajectories of Eq. 28.2 (see, e.g., Kou et al. 1973; Nijmeijer and van der Schaft 1990). Typically, a quadratic cost function is preferred to leverage

Fig. 28.3 Schematic of a model predictive controller which minimizes a quadratic cost over a finite horizon

existing results in quadratic programming (Camacho and Bordons 1999; Rawlings 2000; Demircioglu and Karasu 2000). Let $z_{\text{rm}k}$ denote the sampled output of the reference model, and define the output error $\bar{e}_k = z_k - z_{\text{rm}k}$. Then the problem can be reformulated to finding the optimal sequence of inputs u_k such that the following quadratic cost function is minimized for given positive (semi)-definite matrices \bar{Q} and \bar{R} , subject to the reformulated output constraint $y \in \bar{\Xi}$, where $\bar{\Xi} = \{y : y = z_\sigma(x(t), u(t)), x \in \Xi\}$ and the input constraint $u \in \Pi$:

$$J_T(\bar{e}, u) = \sum_{k=t}^{t+N} \bar{e}_k^T \bar{Q} \bar{e}_k + u_k^T \bar{R} u_k + V_f(e_{t+N}), \quad y \in \bar{\Xi}, u \in \Pi, \quad (28.19)$$

where the term $V_f(e_{t+N})$ denotes a terminal penalty cost. Several computationally efficient nonlinear MPC algorithms have been proposed and their stability properties established (Zheng and Allgower 1998; Zheng 2000).

To numerically solve the RHO problem in Eq. 28.19, a prediction model $\hat{x} = \hat{f}(\hat{x})$ is required to predict how the system states behave in the future, where \hat{x} is the estimated state and \hat{f} is the prediction model. The prediction model is a central part of MPC, and in many cases (especially when the system dynamics are nonlinear or unstable), an inaccurate prediction model can result in instability (Rawlings 2000). In many MPC implementations, one of the most costly effort in control design is to develop a reliable prediction model (Camacho and Bordons 1999; Rawlings 2000; Lee 2000). Furthermore, approximations made in modeling, changes in the system dynamics due to wear and tear, reconfiguration of the system, or uncertainties introduced due to external effects can affect the accuracy of the predicted system response. Robustness of MPC methods to estimation errors (Findeisen et al. 2003; Michalska and Mayne 1995; Lee et al. 2002), plant variability (Chisci et al. 2001; Lee and Kouvaritakis 2000; Cuzzola et al. 2002; Richards 2005), and disturbances (Lee and Kouvaritakis 1999; Bemporad 1998; Kerrigan and Maciejowski 2001; Kerrigan and Mayne 2002; Richards and How 2007) remain active research areas. The resulting optimization problems are typically solved using linear matrix inequalities, linear programming, or quadratic programming. The key challenge here is to provide sufficient robustness guarantees while keeping the problem computationally tractable. The fact remains that without an accurate prediction model, the performance and stability guarantees remain very conservative (Rawlings 2000; Nicolao et al. 2000).

To this effect, some authors have recently explored adaptive MPC methods that estimate the modeling uncertainty (Camacho and Bordons 1999; Fukushima et al. 2007; Adetola et al. 2009; Karra et al. 2008). Another active area of research in MPC is that of analytically guaranteeing stability. It should be noted that stability and robustness guarantees for MPC when the system dynamics are linear are at least partially in place (Camacho and Bordons 1999). With an appropriate choice of $V_f(e_{t+N})$ and with terminal inequality state and input constraints (and in some cases without), stability guarantees for nonlinear MPC problems have been established (Nicolao et al. 2000; Zhang et al. 2010; Marruedo et al. 2002). However, due to the open loop nature of the optimization strategy, and dependence on the prediction model, guaranteeing stability and performance for a wide class of nonlinear systems still remains an active area of research. A challenge in implementing MPC methods is to ensure that the optimization problem can be solved in real time. While several computationally efficient nonlinear MPC strategies have been devised, ensuring that a feasible solution is obtained in face of processing and memory constraints remains an active challenge for MPC application on UAVs, where computational resources are often constrained (Sutton and Bitmead 2000).

28.3.4 Model Inversion-Based Control

28.3.4.1 Dynamic Model Inversion Using Differentially Flat Representation of Aircraft Dynamics

A complete derivation of the nonlinear six-degree-of-freedom UAV dynamics was presented in chapter ►[Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book. For trajectory tracking control using feedback linearization, simpler representations of UAV dynamics are often useful. One such representation is the differentially flat representation (see, e.g., Hauser and Hindman 1997). The dynamical system in Eq. 28.1 with output $y = h(x, u)$ is said to be differentially flat with flat output z if there exists a function g such that the state and input trajectories can be represented as a function of the flat output and a finite number of its derivatives:

$$(x, u) = g\left(y, \dot{y}, \ddot{y}, \dots, \frac{d^n y}{dt^n}\right). \quad (28.20)$$

In the following, assume that a smooth reference trajectory p_d is given for a UAV in the inertial frame (see chapter ►[Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book) and that the reference velocity \dot{p}_d and reference acceleration \ddot{p}_d can be calculated using the reference trajectory. Consider the case of a conventional fixed wing UAV that must be commanded a forward speed to maintain lift; hence, $\dot{p}_d \neq 0$. A right-handed orthonormal frame of reference wind axes can now be defined by requiring that the desired velocity vector is aligned with the x_W axis of the wind axis (see chapter ►[Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book for details), and the lift and drag forces are in the x_W – z_W plane of the wind axis, the z_W axis, such that there are no side forces. The acceleration can be written as

$$\ddot{p}_d = g + f_I/m, \quad (28.21)$$

where f_I is the sum of propulsive and aerodynamic forces on the aircraft in the inertial frame. Let R_{IW} denote the rotation matrix that transports vectors from the defined wind reference frame to the inertial frame. Then

$$\ddot{p}_d = g + R_{IW}a_W, \quad (28.22)$$

where a_W is the acceleration in the wind frame. Let $\omega = [\omega_1, \omega_2, \omega_3]^T$ denote the angular velocity in the wind frame, then the above equation can be differentiated to obtain

$$\frac{d^3 p_d}{dt^3} = R_{IW}(\omega \times a_W) + R_{IW}\dot{a}_W, \quad (28.23)$$

by using the relationship $\dot{R}_{IW}a_W = R_{IW}\hat{\omega}a_W = R_{IW}(\omega \times a_W)$ (see Sect. 27.2.2 of chapter [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book). Let a_t denote the tangential acceleration along the x_W direction, a_n denote the normal acceleration along the z_W direction, and V denote the forward speed. Furthermore, let $e_1 = [1, 0, 0]^T$. Then in coordinated flight $\dot{p}_d = VR_{IW}e_1$, hence

$$\ddot{p}_d = \dot{V}R_{IW}e_1 + VR_{IW}(\omega \times e_1). \quad (28.24)$$

Combining Eqs. 28.22 and 28.24, the following relationship can be formed:

$$\ddot{p}_d = R_{IW} \begin{bmatrix} \dot{V} \\ V\omega_3 \\ -V\omega_2 \end{bmatrix}. \quad (28.25)$$

Equation 28.25 allows the desired ω_2 and ω_3 to be calculated from the desired acceleration \ddot{p}_d . Furthermore, from Eq. 28.23,

$$\begin{bmatrix} \dot{a}_t \\ \omega_1 \\ \dot{a}_n \end{bmatrix} = \begin{bmatrix} -\omega_2 a_n \\ \omega_3 a_t / n \\ \omega_2 a_t \end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1/a_n & 0 \\ 0 & 0 & 1 \end{bmatrix} R_{IW}^T \frac{d^3 p_d}{dt^3}. \quad (28.26)$$

The above equation defines a differentially flat system of aircraft dynamics with flat output p_d and inputs $[\dot{a}_t, \omega_1, \dot{a}_n]$, if $V = \|\dot{p}_d\| \neq 0$ (nonzero forward speed) and $a_n \neq 0$ (nonzero normal acceleration). The desired tangential and normal accelerations required to track the path p_d can be controlled through the thrust $T(\delta_T)$ which is a function of the throttle input δ_T , the lift $L(\alpha)$, and the drag $D(\alpha)$ which are functions of the angle of attack α by noting that in the wind axes:

$$a_t = T(\delta_T) \cos \alpha - D(\alpha), \quad (28.27)$$

$$a_n = -T(\delta_T) \sin \alpha - L(\alpha).$$

To counter any external disturbances that cause trajectory deviation, a feedback term can be added. Let p be the actual position of the aircraft and u be the control input, and consider a system in which $\frac{d^3 p_d}{dt^3} = u$:

$$\frac{d}{dt} \begin{bmatrix} p \\ \dot{p} \\ \ddot{p} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} p \\ \dot{p} \\ \ddot{p} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} u. \quad (28.28)$$

Defining $e = p - p_d$, the above equation can be written in terms of the error:

$$\frac{d}{dt} \begin{bmatrix} e \\ \dot{e} \\ \ddot{e} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} e \\ \dot{e} \\ \ddot{e} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \left(u - \frac{d^3 p_d}{dt^3} \right). \quad (28.29)$$

Therefore, letting $u = \frac{d^3 p}{dt^3} - K [e \ \dot{e} \ \ddot{e}]^T$, where K is the stabilizing gain, and computing a_t, a_n, ω_1 from $(p, \dot{p}, \ddot{p}, u)$ guarantee asymptotic closed-loop stability of the system (see Hauser and Hindman 1997 for further detail of the particular approach presented). This approach is essentially that of feedback linearization and dynamic model inversion, which is explored in the general setting in the next section.

28.3.4.2 Approximate Dynamic Model Inversion

The idea in approximate dynamic inversion-based controllers is to use a (approximate) dynamic model of the UAV to assign control inputs based on desired angular rates and accelerations. Let $x(t) = [x_1^T(t), x_2^T(t)]^T \in \mathbb{R}^n$ be the known state vector, with $x_1(t) \in \mathbb{R}^{n_1}$ and $x_2(t) \in \mathbb{R}^{n_2}$; let $u(t) \in \mathbb{R}^{n_2}$ denote the control input; and consider the following multiple-input nonlinear uncertain dynamical system:

$$\begin{aligned} \dot{x}_1(t) &= x_2(t), \\ \dot{x}_2(t) &= f(x(t), u(t)), \end{aligned} \quad (28.30)$$

where the function f is assumed to be known and globally Lipschitz continuous, and control input u is assumed to be bounded and piecewise continuous. These conditions are required to ensure the existence and uniqueness of the solution to Eq. 28.30. Furthermore, a condition on controllability of f with respect to u must also be assumed. Note also the requirement on as many control inputs as the number of states directly affected by the input (x_2). For UAV control problem, this assumption can usually be met through the successive loop closure approach (see chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book). For example, for fixed wing control aileron, elevator, rudder, and throttle control directly affect roll, pitch, yaw rate, and velocity. This assumption can also meet for rotorcraft UAV velocity control with the attitudes acting as virtual inputs

for velocity dynamics and the three velocities acting as virtual inputs for the position dynamics (Johnson and Kannan 2005).

In dynamic model inversion-based control, the goal is to find the desired acceleration, referred to as the pseudo-control input $v(t) \in \mathbb{R}^{n_2}$, which can be used to find the control input u such that the system states track the output of a reference model. Let $z = (x, u)$, if the exact system model $f(z)$ in Eq. 28.30 is invertible; for a given $v(t)$, $u(t)$ can be found by inverting the system dynamics. However, since the exact system model is usually not invertible, let v be the output of an approximate inversion model \hat{f} such that $v = \hat{f}(x, u)$ is continuous and invertible with respect to u , that is, the operator $\hat{f}^{-1} : \mathbb{R}^{n+n_2} \rightarrow \mathbb{R}^l$ exists and assigns for every unique element of \mathbb{R}^{n+n_2} and a unique element of \mathbb{R}^l . An approximate inversion model that satisfies this requirement is required to guarantee that given a desired pseudo-control input $v \in \mathbb{R}^{n_2}$ a control command u can be found by dynamic inversion as follows:

$$u = \hat{f}^{-1}(x, v). \quad (28.31)$$

The model in Sect. 28.3.4.1 is an example of a differentially flat approximate inversion model. For the general system in Eq. 28.30, the use of an approximate inversion model results in a model error of the form

$$\dot{x}_2 = v + \Delta(x, u), \quad (28.32)$$

where Δ is the modeling error. The modeling error captures the difference between the system dynamics and the approximate inversion model:

$$\Delta(z) = f(z) - \hat{f}(z). \quad (28.33)$$

Note that if the control assignment function were known and invertible with respect to u , then an inversion model can be chosen such that the modeling error is only a function of the state x .

Often, UAV dynamics can be represented by models that are affine in control. In this case the existence of the approximate inversion model can be related directly to the invertibility of the control effectiveness matrix B (e.g., see Johnson 2000). For example, let $G \in \mathbb{R}^{n_2 \times n_2}$, and let $B \in \mathbb{R}^{n_2 \times l}$ denote the control assignment matrix and consider the following system:

$$\begin{aligned} \dot{x}_1(t) &= x_2(t), \\ \dot{x}_2(t) &= Gx_2(t) + B(\Theta(x) + u(t)), \end{aligned} \quad (28.34)$$

where $\Theta(x)$ is a nonlinear function. If $B^T B$ is invertible, and the pair (G, B) is controllable, one approximate inversion model is $v(t) = Bu(t)$, which results in a unique u for a unique v : $u(t) = (B^T B)^{-1} B^T v(t)$. Adding and subtracting $v = Bu$ yields Eq. 28.32, with $\Delta(x) = Gx_2 + B(\Theta(x) + u) - Bu = Gx_2 + B\Theta(x)$.

A reference model is used to characterize the desired response of the system:

$$\begin{aligned}\dot{x}_{1\text{rm}} &= x_{2\text{rm}}, \\ \dot{x}_{2\text{rm}} &= f_{\text{rm}}(x_{\text{rm}}, r),\end{aligned}\tag{28.35}$$

where $f_{\text{rm}}(x_{\text{rm}}(t), r(t))$ denote the reference model dynamics which are assumed to be continuously differentiable in x_{rm} for all $x_{\text{rm}} \in D_x \subset \mathbb{R}^n$. The command $r(t)$ is assumed to be bounded and piecewise continuous; furthermore, f_{rm} is assumed to be such that x_{rm} is bounded for a bounded reference input.

The pseudo-control input v is designed by combining a linear feedback part $v_{\text{pd}} = [K_1, K_2]e$ with $K_1 \in \mathbb{R}^{n_2 \times n_2}$ and $K_2 \in \mathbb{R}^{n_2 \times n_2}$, a linear feedforward part $v_{\text{rm}} = \dot{x}_{2\text{rm}}$, and an approximate feedback linearizing part $v_{\text{ai}}(z)$:

$$v = v_{\text{rm}} + v_{\text{pd}} - v_{\text{ai}}.\tag{28.36}$$

Defining the tracking error e as $e(t) = x_{\text{rm}}(t) - x(t)$ and using Eq. 28.32, the tracking error dynamics can be written as

$$\dot{e} = \dot{x}_{\text{rm}} - \begin{bmatrix} x_2 \\ v + \Delta \end{bmatrix}.\tag{28.37}$$

Letting $A = \begin{bmatrix} 0 & I_1 \\ -K_1 & -K_2 \end{bmatrix}$, $B = [0, I_2]^T$, where $0 \in \mathbb{R}^{n_2 \times n_2}$, $I_1 \in \mathbb{R}^{n_2 \times n_2}$, and $I_2 \in \mathbb{R}^{n_2 \times n_2}$ are the zero and identity matrices, and using Eq. 28.36 gives the following tracking error dynamics that are linear in e :

$$\dot{e} = Ae + B[v_{\text{ai}}(z) - \Delta(z)].\tag{28.38}$$

The baseline linear full-state feedback controller v_{pd} should be chosen such that A is a Hurwitz matrix. Furthermore, letting $v_{\text{ai}} = \Delta(z)$ using Eq. 28.33 ensures that the above tracking error dynamics is exponentially stable, and the states of the UAV track the reference model. This framework is depicted in (Fig. 28.4).

28.3.5 Model Reference Adaptive Control

The model reference adaptive (MRAC) control architecture has been widely studied for UAV control in presence of nonlinearities and modeling uncertainties (see, e.g., Johnson and Kannan 2005; Lavertsky and Wise 2005; Nguyen et al. 2006b; Patel et al. 2009). MRAC attempts to ensure that the controlled states track the output of an appropriately chosen reference model (see, e.g., Narendra and Annaswamy 1989; Ioannou and Sun 1996; Aström and Wittenmark 1995; Tao 2003). Most MRAC methods achieve this by using a parameterized model of the uncertainty, often referred to as the adaptive element and its parameters referred to as adaptive weights. Aircraft dynamics can often be separated into a linear part whose mathematical

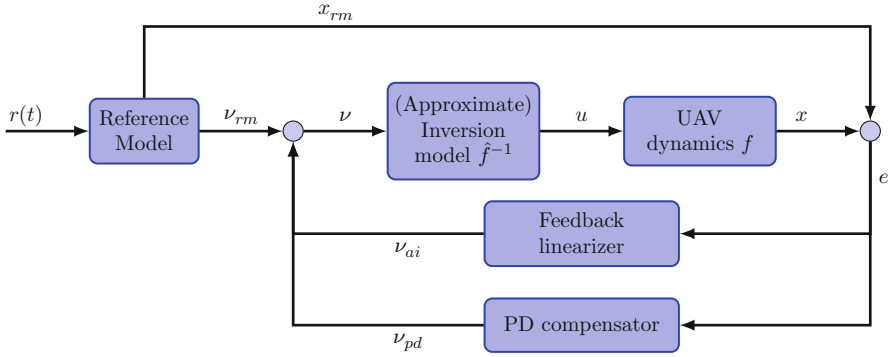

Fig. 28.4 Approximate dynamic model inversion framework using feedback linearization

model is fairly well known and an uncertain part that may contain unmodeled linear or nonlinear effects. This representation is also helpful in representing nonlinear external disturbances affecting the system dynamics. Therefore, one typical technique for implementing adaptive controllers is to augment a baseline linear controller, designed and verified using techniques discussed in chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book, with an adaptive controller that deals with nonlinearities and modeling uncertainties. Let $x(t) \in \mathfrak{R}^n$ be the known state vector, let $u \in \mathfrak{R}$ denote the control input, and consider a following system of this type:

$$\dot{x} = Ax(t) + B(u(t) + \Delta(z(t))), \quad (28.39)$$

where $A \in \mathfrak{R}^{n \times n}$, $B \in \mathfrak{R}^{n \times m}$, and $\Delta(x, u) \in \mathfrak{R}^m$ is a continuously differentiable function representing the uncertainty. It is assumed that the pair (A, B) is controllable (see chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book). For notational convenience, let $z = [x, u]$, and note that the function $\Delta(z)$ capturing the uncertain part of the dynamics is assumed to lie in the range space of the control effectiveness matrix B . More general formulations of adaptive control also assume that the matrix A is completely unknown (see, e.g., Narendra and Annaswamy 1989; Aström and Wittenmark 1995; Tao 2003; Ioannou and Sun 1996 and the chapter ► [Robust and Adaptive Control Methods for Aerial Vehicles](#) in this book).

A reference model can be designed that characterizes the desired response of the system

$$\dot{x}_{rm} = A_{rm}x_{rm}(t) + B_{rm}r(t), \quad (28.40)$$

where $A_{rm} \in \mathfrak{R}^{n \times n}$ is such that all of its eigenvalues are in the complex left-half plane, the pair (A, B) is controllable, and $r(t)$ denotes a bounded exogenous reference signal. These conditions are sufficient to guarantee that x_{rm} is bounded for a bounded reference signal $r(t)$. The tracking control law consists of a linear feedback part $u_{pd} = K(x_{rm}(t) - x(t))$, a linear feedforward part $u_{rm} = K_r[x_{rm}^T, r(t)]^T$, and an adaptive part $u_{ad}(x)$ and has the following form:

$$u = u_{rm} + u_{pd} - u_{ad}. \quad (28.41)$$

As before, define the tracking error $e(t) = x_{rm}(t) - x(t)$; with an appropriate choice of A_{rm} , B_{rm} , and u_{rm} such that $Bu_{rm} = (A_{rm} - A)x_{rm} + B_{rm}r(t)$ (conditions such as these are often required in MRAC and are referred to as *matching conditions*), the tracking error dynamics simplify to

$$\dot{e} = A_m e + B(u_{ad}(x, u) - \Delta(x, u)), \quad (28.42)$$

where the baseline full-state-feedback controller $u_{pd} = Kx$ is assumed to be designed such that $A_m = A - BK$ is a Hurwitz matrix. Hence, for any positive-definite matrix $Q \in \mathbb{R}^{n \times n}$, a positive-definite solution $P \in \mathbb{R}^{n \times n}$ exists to the Lyapunov equation

$$A_m^T P + P A_m = -Q. \quad (28.43)$$

MRAC architecture is depicted in Fig. 28.5. Several MRAC approaches (Narendra and Annaswamy 1989; Åström and Wittenmark 1995; Ioannou and Sun 1996; Tao 2003; Lavretsky 2009; Cao and Hovakimyan 2008) assume that the uncertainty $\Delta(z)$ can be linearly parameterized, that is, there exist a vector of constants $W = [w_1, w_2, \dots, w_m]^T$ and a vector of continuously differentiable functions $\Phi(z) = [\phi_1(z), \phi_2(z), \dots, \phi_m(z)]^T$ such that

$$\Delta(z) = W^* \Phi(z). \quad (28.44)$$

The case when the basis of the uncertainty is known, that is, the basis $\Phi(x)$ is known, has been referred to as the case of structured uncertainty (Chowdhary and Johnson

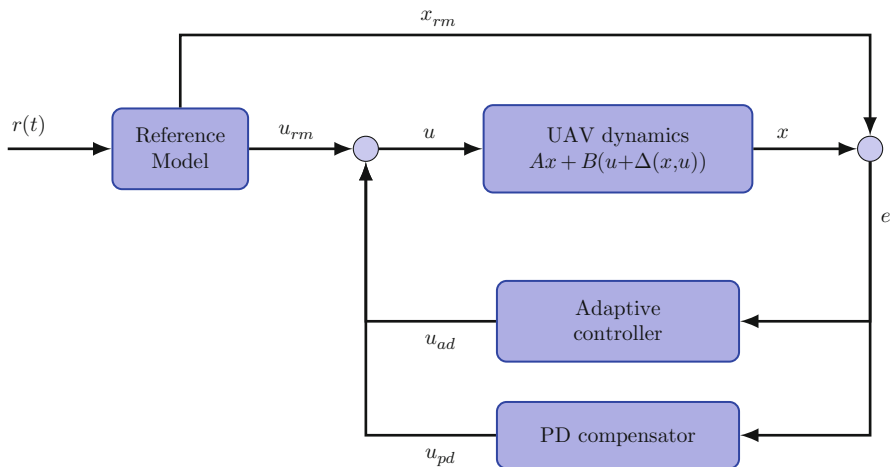

Fig. 28.5 Model reference control architecture that augments a baseline linear feedback-feedforward compensator

2010). In this case letting W denote the estimate W^* , the adaptive element is chosen as $u_{\text{ad}}(x) = W^T \Phi(x)$. For this case it is known that the adaptive law

$$\dot{W} = -\Gamma_W \Phi(z) e^T P B, \quad (28.45)$$

where Γ_W is a positive-definite learning rate matrix, results in $e(t) \rightarrow 0$. However, it should be noted that Eq. 28.50 does not guarantee the convergence (or even the boundedness) of W (Tao 2003; Narendra and Annaswamy 1987). A necessary and sufficient condition for guaranteeing $W(t) \rightarrow W$ is that $\Phi(t)$ be persistently exciting (PE) (Narendra and Annaswamy 1989; Ioannou and Sun 1996; Tao 2003; Boyd and Sastry 1986).

Several approaches have been explored to guarantee boundedness of the weights without needing PE; these include the classic σ -modification (Ioannou and Sun 1996), the e -modification (Narendra and Annaswamy 1989), the and projection-based adaptive control (Tao 2003; Pomet and Praly 1992). Let κ denote the σ -modification gain; then the σ -modification adaptive law is

$$\dot{W} = -\Gamma_W (\Phi(z(t)) e^T P B + \kappa W). \quad (28.46)$$

Thus, it can be seen that the goal of σ -modification is to add damping to the weight evolution. In e -modification, this damping is scaled by the norm of the error $\|e\|$. It should be noted that these adaptive laws guarantee the boundedness of the weights; however, they do not guarantee that the weights converge to their true values without PE.

A concurrent learning approach introduced in Chowdhary and Johnson (2010) guarantees exponential tracking error and weight convergence by concurrently using recorded data with current data without requiring PE. Other approaches that use recorded data include the Q -modification approach that guarantees convergence of the weights to a hyperplane where the ideal weights are contained (Volyanskyy et al. 2009), and the retrospective cost optimization approach (Santillo and Bernstein 2010). Other approaches to MRAC favor instantaneous domination of uncertainty over weight convergence, one such approach is L_1 adaptive control (Cao and Hovakimyan 2008). Several other approaches to MRAC also exist, including the composite adaptive control approach in which direct and indirect adaptive control are combined (Lavretsky 2009) and the observer-based reference dynamics modification in adaptive controllers in which transient performance is improved by drawing on parallels between the reference model and a Luenberger observer (Lavretsky 2011). The derivative-free MRAC in which a discrete derivative-free update law is used in a continuous framework (Yucelen and Calise 2010) and the optimal control modification (Nguyen 2010). Among approaches that deal with actuator time delays and constraints include the adaptive loop recovery modification which recovers nominal reference model dynamics in presence of time delays (Calise and Yucelen 2012), and the pseudo-control hedging which allows adaptive controllers to be implemented in presence of saturation (Johnson and Calise 2003).

In the more general case where the exact basis of the uncertainty is not a priori known, the adaptive part of the control law is often represented using a radial basis function (RBF) neural network (NN) (see, e.g., Sanner and Slotine 1992; Lewis 1999; Calise and Rysdyk 1998; Johnson and Kannan 2005; Chowdhary and Johnson 2011). For ease of notation let $z = [x, u]$; then the output of a RBF NN is given by

$$u_{\text{ad}}(z) = \hat{W}^T \sigma(z), \quad (28.47)$$

where $\hat{W} \in \Re^l$ and $\sigma = [1, \sigma_2(z), \sigma_3(z), \dots, \sigma_l(z)]^T$ is a vector of known radial basis functions. For $i = 2, 3, \dots, l$ let c_i denote the RBF centroid and μ_i denote the RBF width then for each RBF; then RBFs can be expressed as

$$\sigma_i(z) = e^{-\|z - c_i\|^2 / \mu_i}. \quad (28.48)$$

This approach relies on the universal approximation property of radial basis function neural networks (Park and Sandberg 1991) which asserts that given a fixed number of radial basis functions l , there exist ideal weights $W^* \in \Re^l$ and a real number $\tilde{\epsilon}$ such that

$$\Delta(z) = W^{*T} \sigma(z) + \tilde{\epsilon}, \quad (28.49)$$

where $\tilde{\epsilon}$ can be made arbitrarily small given sufficient number of radial basis functions. For this case, adaptive laws can be obtained by replacing $\Phi(z)$ in (Eq. 28.50) by $\sigma(z)$. For example, the adaptive law for an RBF NN adaptive element with σ -modification is

$$\dot{W} = -\Gamma_W (\sigma(z) e^T P B + \kappa W). \quad (28.50)$$

RBFs have gained significant popularity in adaptive control research because they are linearly parameterized. However, in practice, it is difficult to determine a priori how many RBFs should be chosen and where their centers should lie. Online adaptation and selection of RBF centers is an active research area (Sundararajan et al. 2002; Nardi 2000; Kingravi et al. 2012). Another approach that has been successful in practice is to use nonlinearly parameterized neural networks, including single hidden layer neural networks (see, e.g., Lewis 1999; Kannan 2005; Johnson and Kannan 2005; Chowdhary and Johnson 2011).

28.3.6 Approximate Model Inversion-Based MRAC

The key issue with the approximate model inversion scheme introduced in Sect. 28.3.4.2 is that the system dynamics $f(x, u)$ must be known in order to calculate v_{ai} to exactly cancel $\Delta(z)$. As this is often not the case, the following presents the approximate model inversion-based MRAC architecture (AMI-MRAC), which extends the dynamic model inversion-based control scheme of Sect. 28.3.4.2. Similar to the approach described there, the approach begins by choosing an approximate inversion model \hat{f} such that given a desired pseudo-control input

$v \in \mathbb{R}^{n_2}$, a control command u can be found by dynamic inversion as in Eq. 28.31. The parameters of the approximate inversion model do not have to be close to the real system model; however, in general, the mathematical structure should be similar to the real dynamical model. Typically, it is sufficient to map the inputs to the states that they directly affect; for example, it is sufficient to map the desired pitch rate to elevator deflection. Given the desired acceleration v (pseudo-control input) required to track the reference model, the control input can be found by $u = \hat{f}^{-1}(x, v)$. This results in a modeling error of the form

$$\Delta(z) = f(z) - \hat{f}(z). \quad (28.51)$$

The desired pseudo-control input can be formulated using the framework of dynamic model inversion as described in Sect. 28.3.4.2 as follows:

$$v = v_{rm} + v_{pd} - v_{ad}. \quad (28.52)$$

Note that the feedback linearizing part in (Eq. 28.36) has been replaced here with the output of an adaptive element v_{ad} . The tracking error dynamics of Eq. 28.37 now become

$$\dot{e} = Ae + B[v_{ad}(z) - \Delta(z)]. \quad (28.53)$$

This equation is similar to Eq. 28.42 of the MRAC architecture discussed in Sect. 28.3.5. Therefore, techniques similar to those discussed in Sect. 28.3.5 can be used. Particularly, if the uncertainty $\Delta(z)$ can be modeled using a linearly parameterized models such as in Eq. 28.44, then the adaptive element can take the form $v_{ad} = W(t)^T \Phi(z)$, and update law in Eq. 28.46 can be employed. It is also possible to use neural network adaptive elements in the same manner as Eq. 28.47. Note that with the formulation presented here the existence of a fixed point solution to $v_{ad} = \Delta(., v_{ad})$ needs to be assumed; sufficient conditions for guaranteeing this are also available (Kim 2003). AMI-MRAC-based adaptive controllers have been extensively flight-test verified on several fixed-wing and rotorcraft UAVs (see, e.g., Johnson and Kannan 2005; Johnson et al. 2006; Chowdhary and Johnson 2011; Chowdhary et al. 2012 and also the chapter ► [Adaptive Control of Unmanned Aerial Vehicles: Theory and Flight Tests](#) in this book). Figure 28.6 depicts the framework of an approximate model inversion-based MRAC architecture.

28.4 Model-Based Fault-Tolerant Control

Fault-tolerant controllers (FTC) are designed to maintain aircraft stability or reduce performance deterioration in case of failures (see, e.g., Patton and Chen 1997; Zhang and Jang 2008; Steinberg 2005). In general, there are mainly three types of failures (faults): sensor failure, actuator failure, and structural damage. Fault-tolerant control in the presence of sensor and actuator failures with identified failure characteristics has been studied (Patton and Chen 1997; Isermann 2006). On the other hand,

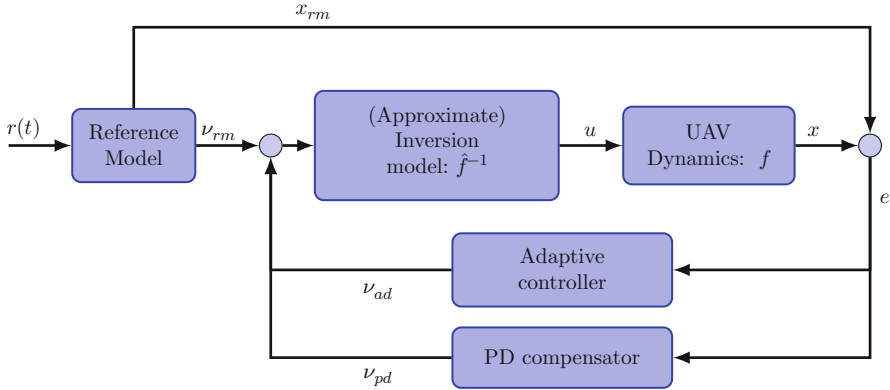

Fig. 28.6 Approximate dynamic model inversion based adaptive MRAC

fault-tolerant control for structural damage, including partial loss of wing, vertical tail loss, horizontal tail loss, and engine loss, has been explored (Crider 2004; Hajiyev and Caliskan 2003; Haoouzi and Verhaegen 2008; Hitachi 2009; Lombaerts et al. 2008; Lunze and Steffen 2006; Nguyen et al. 2006a, 2008; Boskovic et al. 2007; Chowdhary et al. 2011).

Adaptive control has been widely studied for fault-tolerant control in the presence of modeling uncertainty brought about by structural damage or actuator degradation (Idan et al. 2002; Lavertsky and Wise 2005; Steinberg 2005; Kutay et al. 2008; Chowdhary et al. 2011; Calise and Yucelen 2012). The idea has been to use adaptive control techniques similar to those described in Sect. 28.3.5 to adapt to changing dynamics. Adaptive control-based fault-tolerant controllers do not require prior system identification or modeling efforts. Developing adaptive fault-tolerant controllers with associated quantifiable metrics for performance and without requiring restrictive *matching conditions* is an open area of research. Alternatively, a model-based approach can also be used for fault-tolerant control. An overview of one such approach is presented here.

28.4.1 Control Design for Maximum Tolerance Range Using Model-Based Fault-Tolerant Control

Fault-tolerant control technique presented here is applicable to aircraft with possible damage that lies approximately in the body $x-z$ plane of symmetry, in other words *vertical* tail damage as illustrated in Fig. 28.7. A linear model of aircraft dynamics was derived in chapter ►Linear Flight Control Techniques for Unmanned Aerial Vehicles in this book. In that model A represents the matrix containing aerodynamic derivatives and B represents the matrix containing the control effectiveness derivatives. The states of the model considered here are $x(t) = [u, w, q, \theta, v, p, r, \phi]^T$ and the input given by $u(t) = [\delta e, \delta f, \delta a, \delta r]^T$ (see chapter ►Linear Flight Control Techniques for Unmanned Aerial Vehicles in this book for definitions of these

Fig. 28.7 UAV with partial structural damage

variables; details of the corresponding A and B matrices can be found in Li and Liu 2012). Variation to aerodynamic derivatives due to structural damage is approximately proportional to the percentage of loss in structure (Shah 2008). Therefore, the linearized motion of the damaged aircraft can be represented by a parameter-dependent model based on the baseline linear model of the aircraft, where the parameters provide a notion of the degree of damage:

$$\dot{x}(t) = (A - \mu \bar{A})x(t) + (B - \mu \bar{B})u(t), \quad \mu \in [0, 1], \quad (28.54)$$

where μ is the parameter representing the *damage degree*. Specifically, $\mu = 0$ represents the case of no damage, $\mu = 1$ represents complete tail loss, and $0 < \mu < 1$ represents partial vertical tail loss. The damage loss can be related to a maximum change in the aerodynamic derivatives (e.g., $\Delta C_{y\beta}$) and control effectiveness derivatives (e.g., $\Delta C_{y\delta_r}$) under damage in the following way:

$$\begin{bmatrix} \Delta C_{y\beta} & \Delta C_{n\beta} & \Delta C_{l\beta} \\ \Delta C_{y_p} & \Delta C_{n_p} & \Delta C_{l_p} \\ \Delta C_{y_r} & \Delta C_{n_r} & \Delta C_{l_r} \\ \Delta C_{y\delta_r} & \Delta C_{n\delta_r} & \Delta C_{l\delta_r} \end{bmatrix} = \mu \begin{bmatrix} \Delta C_{y\beta}^{\max} & \Delta C_{n\beta}^{\max} & \Delta C_{l\beta}^{\max} \\ \Delta C_{y_p}^{\max} & \Delta C_{n_p}^{\max} & \Delta C_{l_p}^{\max} \\ \Delta C_{y_r}^{\max} & \Delta C_{n_r}^{\max} & \Delta C_{l_r}^{\max} \\ \Delta C_{y\delta_r}^{\max} & \Delta C_{n\delta_r}^{\max} & \Delta C_{l\delta_r}^{\max} \end{bmatrix} \quad (28.55)$$

For a given linear controller gain K , let $J(K, \mu)$ denote the performance metric of an aircraft with possible vertical tail damage as a function of the degree of damage μ . For example, a quadratic performance metric can be used:

$$J = \int_0^\infty [x^T(t)Qx(t) + u^T(t)Ru(t)] dt, \quad (28.56)$$

where Q and R are weighting positive-definite matrices. In extreme damage cases, such as complete tail loss ($\mu = 1$), the aircraft may not be able to recover.

The question then is under what level of damage a fault-tolerant control could still stabilize the aircraft. This notion of the maximum tolerance range, defined as the maximum allowable damage degree, presents a valuable design criterion in fault-tolerant control development. For most aircraft configurations, and without considering differential throttle as a way to control yaw motion, it is reasonable to expect that the maximum tolerance range would be less than 1. The notion of maximum tolerance, denoted by μ_m , is captured using the following relationship:

$$\mu_m := \min \left\{ 1, \max_K \{ \mu_u \geq 0 : J(K, \mu) \text{ is satisfied for } \mu \in [0, \mu_u] \} \right\}. \quad (28.57)$$

This definition indicates that for damage degree $0 \leq \mu \leq \mu_m \leq 1$, the aircraft control system is able to guarantee the desired level of performance J (see, e.g., Eq. 28.56) with a certain controller K . In particular, $\mu_m = 0$ means that there is no tolerance for the desired performance, while $\mu_m = 1$ means that the control strategy can guarantee the performance requirement up to a total loss of vertical tail. The bigger the μ_m is, the more tolerant the system becomes. Moreover, this notion implies a trade-off between damage tolerance and performance requirement. Since damage degree is unpredictable, a passive fault-tolerant strategy is to design a controller to maintain the expected performance under possible damage.

This can be achieved through a robust control design technique in which an upper bound is established for a linear quadratic cost function for all the considered uncertainty (Petersen et al. 2000; Magni et al. 1997). Consider the parameterized system of Eq. 28.54 describing damaged aircraft dynamics. Let $\Delta A = -\mu \bar{A}$ and $\Delta B = -\mu \bar{B}$ be uncertainty matrices expressed as $\begin{bmatrix} \Delta A & \Delta B \end{bmatrix} = DF \begin{bmatrix} E_1 & E_2 \end{bmatrix}$. In these expression, F satisfies $F^T F \leq I$. D and E are matrices containing the structural information of ΔA and ΔB and are assumed to be known a priori. For the given structure of vertical damage, $D = -I$, $F = \mu I$, $E_1 = \bar{A}$, and $E_2 = \bar{B}$.

One control design approach for the uncertain system in Eq. 28.54 is presented here based on LMI. If the following LMI with respect to a positive matrix X , matrix W , and positive scalar ε ($\varepsilon > 0$) is feasible (Petersen et al. 2000; Yu 2002),

$$\begin{bmatrix} AX + BW + XA^T + W^T B^T + \varepsilon DD^T X E_1^T + W^T E_2^T X (Q^{1/2})^T W^T (R^{1/2})^T & E_1 X + E_2 W & -\varepsilon I & 0 & 0 \\ Q^{1/2} X & 0 & 0 & -I & 0 \\ R^{1/2} W & 0 & 0 & 0 & -I \end{bmatrix} < 0, \quad (28.58)$$

then there exists a state feedback guaranteed cost control law $K = WX^{-1}$, and the corresponding cost has an upper bound $J \leq x_0^T X^{-1} x_0$.

As described above, one can formulate the aircraft dynamic model as an uncertain system by defining

$$\begin{bmatrix} \Delta A & \Delta B \end{bmatrix} = DF \begin{bmatrix} E_1 & E_2 \end{bmatrix} =: \mu_m (-\Delta) \begin{bmatrix} \bar{A} & \bar{B} \end{bmatrix} \text{ with } |\Delta| < 1.$$

The weighting matrices Q and R in the linear quadratic criterion in Eq. 28.56 can be chosen to represent a desired performance criterion. They also serve as free design parameters that indirectly reduce the effect of control surface limits on maximum tolerance and performance.

The above result gives a method to design a guaranteed cost controller. A controller with the maximum tolerance μ_m can be obtained by testing the feasibility of LMI via the bisection algorithm (Skogestad and Postlethwaite 2005; Zhou et al. 1996).

Algorithm:

1. Take $\mu_d = 0$ and $\mu_t = 1$. If the LMI (Eq. 28.58) is feasible for $\mu_t = 1$, then $\mu_m = 1$, output the corresponding controller and stop.
2. Let $\mu = \frac{\mu_d + \mu_u}{2}$.
3. If the LMI (Eq. 28.58) is feasible for μ , then $\mu_d = \mu$, otherwise, $\mu_t = \mu$.
4. If $\mu_t - \mu_d < \delta$ (δ is a predetermined scalar and is small enough), then $\mu_m = \mu_t$, output the controller with respect to μ_t and stop. Otherwise, go to 2.

28.5 Ongoing Research

Future UAV applications are expected to continue to leverage S&R capabilities of UAVs and go beyond. Some envisioned applications and some of the associated technical challenges in the field of autonomous control are listed below (see Fig. 28.8):

UCAV. Unmanned combat aerial vehicles (UCAV) have been researched extensively. The goal is to create an autonomous multi-role fighter capable of air-to-air combat and targeted munition delivery. UCAVs are expected to be highly agile and need to be designed to tolerate severe damage. Furthermore, the lack of human pilot onboard means that UCAVs can be designed to tolerate much higher flight loads in order to perform extremely agile maneuvers. The main technical challenge here is to create autonomous controllers capable of reliably operating in nonlinear flight regimes for extended durations.

Transport UAVs. These UAVs are expected to autonomously deliver valuable and fragile payload to forward operating units. The technical challenge here is to enable reliable automated waypoint navigation in presence of external disturbances and changed mass properties and reliable vertical takeoff and landing capabilities in harsh terrains with significant uncertainties.

HALE. High-altitude long-endurance (HALE) aircraft are being designed to support persistent S&R missions at stratospheric altitude. The main differentiating factor here is the use of extended wingspan equipped with solar panels for in situ power generation. The technical challenges here are brought about by unmodeled flexible body modes.

Optionally Manned Aircraft. Optionally manned aircraft are envisioned to support both piloted and autonomous modes. The idea is to extend the utility of

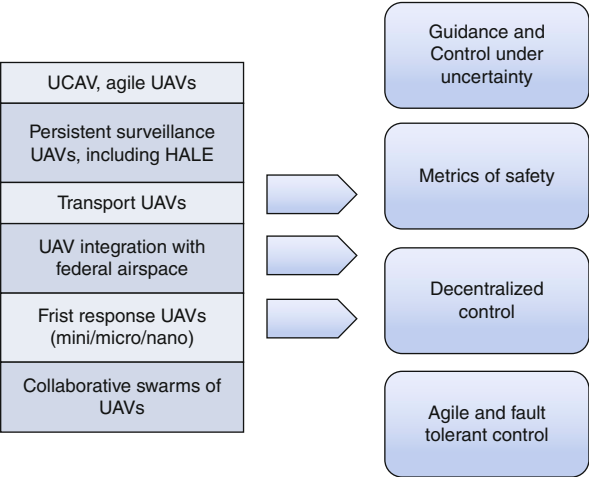

Fig. 28.8 Envisioned UAV applications and some related research thrusts

existing successful aircraft by enabling autonomous operation in absence of an onboard human pilot. The main technical challenge here is to ensure reliability and robustness to uncertainties, considering specifically that these aircraft may share airspace with manned aircraft.

Micro-/Nano-UAVs. UAVs with wingspan less than 30 cm are often referred to as micro-/nano-UAVs. These UAVs are characterized by high wing (or rotor blade) loading and are being designed, for example, to operate in the vicinity of human first responders. Some of these aircraft are expected to operate in dynamic or hostile indoor environments and are therefore required to be agile and low cost. Large-scale collaborative swarms of low-cost micro-UAVs have also been envisioned as flexible replacements to a single larger UAV. The key technical challenges here are creating low-cost, low-weight controllers capable of guaranteeing safe and agile operation in the vicinity of humans, and development of decentralized techniques for guidance and control.

In order to realize these visions, there is a need to develop robust and adaptive controllers that are able to guarantee excellent performance as the UAV performs agile maneuvers in nonlinear flight regime in presence of uncertainties. Furthermore, there is a significant thrust toward collaborative operation of manned and unmanned assets and toward UAVs sharing airspace with their manned counterparts. The predictable and adaptable behavior of UAVs as a part of such codependent networks is evermore important.

28.5.1 Integrated Guidance and Control Under Uncertainty

Guidance and control algorithms for autonomous systems are safety/mission critical. They need to ensure safe and efficient operation in presence of uncertainties

such as unmodeled dynamics, damage, sensor failure, and unknown environmental effects. Traditionally, control and guidance methods have often evolved separately. The ignored interconnections may lead to catastrophic failure if commanded trajectories end up exciting unmodeled dynamics such as unmodeled flexible dynamics (modes). Therefore, there is a need to establish a feedback between the guidance and command loops to ensure that the UAV is commanded a feasible trajectories. This is also important in order to avoid actuator saturation and particularly important if the UAV capabilities have been degraded due to damage (Chowdhary et al. 2010). Isolated works exist in the literature where authors have proposed a scheme to modify reference trajectories to accommodate saturation or to improve tracking performance (e.g., Johnson and Calise 2003; Lavretsky 2011); however, the results are problem specific and more general frameworks are required.

There has been significant recent research on UAV task allocation and planning algorithms. The algorithms developed here provide waypoints and reference commands to the guidance system in order to satisfy higher-level mission goals. There may be value in accounting specifically for the UAV's dynamic capabilities and health to improve planning performance.

28.5.2 Output Feedback Control in Presence of Non-Gaussian Noise and Estimation Errors

LQG theory provides a solution to designing optimal controllers for linear systems with Gaussian white measurement noise. However, such a generalized theory does not exist for nonlinear control. Furthermore, the choice of sensors on miniature UAVs in particular is often restricted to low-cost, low-weight options. Several of the standard sensors employed on miniature aircraft such as sonar altimeters, scanning lasers, and cameras do not have Gaussian noise properties. Therefore, even with an integrated navigation solution that fuses data from multiple sensors, the resulting state estimates may contain significant estimation error. One of the key future thrusts required therefore is a theory of output feedback control for nonlinear control implementations in presence of non-Gaussian noise.

28.5.3 Metrics on Stability and Performance of UAV Controllers

A strong theory exists for computing performance and stability metrics for linear time-invariant control laws. Examples of well-accepted metrics include gain and phase margin which quantify the ability of the controller to maintain stability in presence of unforeseen control effectiveness changes, time delays, and disturbances. However, these metrics do not easily generalize to nonlinear systems. On the other hand, several different groups have established that nonlinear control techniques in general can greatly improve command tracking performance over linear techniques. However, the inability to quantify stability and robustness of nonlinear controllers may pose a significant hurdle in wide acceptance of nonlinear techniques.

The problem is further complicated as controllers are implemented on digital computers while they are often designed using a continuous framework. Any further work in this area should avail the rich literature on the theory of sampled data systems.

28.5.4 Agile and Fault-Tolerant Control

Agile flight refers to flight conditions which cannot be easily represented by linear models linearized around equilibrium flight conditions. Agile flight is often characterized by rapid transitions between flight domains (e.g., hover flight domain and forward flight domain for rotorcraft UAVs), high wing (blade) loading, actuator saturation, and nonlinear flight regimes. The lack of a human pilot onboard means that the allowable g-force is not a limiting factor on the aggressive maneuvers a UAV platforms can potentially perform. Significant progress has been made in creating UAV autopilots that perform highly aggressive maneuvers. Authors in Gavrilets et al. (2004), Abbeel et al. (2007), Cutler and How (2012), and Johnson and Kannan (2005) have established control methods that can be used to perform specific agile maneuvers under test conditions. Future work in this area could lead to responsive agile flight maneuvers to meet higher-level mission requirements and quantifiable metrics of performance and stability during agile flight.

For some agile flight regimes, accurate modeling of the vehicle dynamics might be very difficult, requiring that models and/or control strategies be identified in real time, in essence pushing the capabilities discussed in Mettler (2003), Chowdhary and Lorenz (2005), Jategaonkar (2006), and Morelli (2000) to be online and for nonlinear models. In this case, model identification (or learning) combined with online optimization (e.g., model predictive control) (Favoreel et al. 1999; Ernst et al. 2006; Woodley et al. 2001) might provide an important direction to consider. The key challenge here is to simultaneously guarantee stability and performance while guaranteeing online learning of reasonable model approximations.

Fault-tolerant control (FTC) research for UAVs is focused on guaranteeing recoverable flight in presence of structural and actuator failures. Several directions exist in fault-tolerant flight control; excellent reviews can be found in Zhang and Jang (2008) and Steinberg (2005). Authors in Jourdan et al. (2010) and Chowdhary et al. (2012) have established through flight tests the effectiveness of fault-tolerant controllers in maintaining flight in presence of severe structural damage including loss of significant portions of the wing. Detection and diagnosis of structural faults is also being studied, along with detection of sensor anomalies.

Abstract

Typically, unmanned aerial vehicles are underactuated systems, that is, they have fewer independent control inputs than degrees of freedom. In a helicopter, for example, the body axes roll, pitch, yaw, and altitude are fully actuated. However, lateral and longitudinal translational motion is only possible by tilting the thrust vector. This chapter develops a six degree-of-freedom flight control algorithm that can track both position and attitude trajectories. Approximate inverse models for vehicle attitude and position dynamics are used for feedback linearization leading to an inner-loop that tracks attitude and angular rate and an outer-loop that tracks position and velocity commands. A single adaptive element is used to compensate for inversion errors (uncertainty) in both loops. A key challenge in realizing an adaptive control design on real aircraft is dealing with actuator magnitude and rate saturation. Such saturation elements cannot be easily captured in inverse models and leads to incorrect learning in the adaptive element during periods of saturation. A mechanism to exactly remove such incorrect learning is provided. Additionally, nonlinear reference models are introduced to mitigate the risks of the closed-loop system entering regions of the flight envelope that result in loss-of-controllability. The resulting adaptive controller accepts trajectory commands comprising of desired position, velocity, attitude, and angular velocity and produces normalized actuator signals required for flight control. A modification to the baseline adaptive control system is also provided that enables long-term retention of the uncertainty approximation within the adaptive element. This architecture is validated through flight tests on several fixed wing and rotorcraft UAVs, including a 145-lb helicopter UAV (Yamaha RMAX or GTMax), a scale model fixed-wing aircraft (GTEdge), and a small ducted fan (GTSpy).

29.1 Introduction

The U.S. Department of Defense Integrated Unmanned Systems Roadmap (2011) defines four levels of autonomy for unmanned systems. Level 1 involves manual operator control. Level 2 assumes automatic control while using humans to delegate waypoints. Level 3 assumes the UAV is capable of performing high-level activities using sensed data when given some directions by a human. Level 4 assumes that the UAV is capable of taking a top-level goal, breaking it into tasks and executing them along with the contingency replanning necessary to accomplish a top-level goal. Level 4 approaches the abstract and high-level goals that are provided to human soldiers in today’s battlefield.

Level 2 behavior is available in almost all UAVs today. However, this accomplishment is after at least two decades of development with multiple efforts for each type of vehicle. The current U.S. Department of Defense focus is on research, development, and procurement of technologies that encompass Level 3 and Level 4 autonomous operations while assuming Level 2 is available. The key to developing fully autonomous Level 4-type behaviors is the ability to plan and also deal with contingencies. At the flight control system level this translates to the closed-loop system being robust and adaptive to changes in the environment and vehicle dynamics. To motivate further, future unmanned systems will involve verification and validation using formal approaches where an amount of trust in autonomy is generated. Current conventional FAA certification practices will be superseded with certification methods that allow integration of UAV's into the civil airspace. One straightforward metric that may be used for *trust in flight control* is the variance in trajectory tracking with uncertainty in the dynamics and environment. Consequently, the vehicles may be required to perform at their limits in order to maintain the required performance. Most current control systems still do not leverage the full flight envelope of small helicopters, at least, unless significant and expensive system identification and validation has been conducted.

Currently, fast algorithms to plan routes around obstacles are available (Frazzoli et al. 2002; Karaman and Frazzoli 2011). To be truly useful, these routes would include high-speed dashes, tight turns around buildings, avoiding dynamic obstacles and other required aggressive maneuvers. Allowing control saturation and adaptation allows higher-level planning algorithms to provide optimistic trajectories which are then tracked by the flight controller to the best of the vehicles ability. The following is a description of some key elements that affect flight control stability and performance.

Parametric uncertainty arises from uncertainty in the mass, inertia properties, and aerodynamic characteristics. This limits the safe operational envelope of the vehicle to flight regimes where control designs are valid and parametric uncertainty is small. The effects of parametric uncertainty and unmodeled dynamics can be handled using a combination of system identification (Gavrilets et al. 2001; Civita et al. 2002a; Mettler 2002) and robust control techniques (Civita et al. 2002b, 2003; Gavrilets et al. 2002). However, system identification is expensive and when changes happen in real-time, for e.g., an unexpected payload is attached or deployed, the available previously-identified models may not fit the current aircraft configuration. In this chapter, parametric uncertainty arises due to approximate inversion and appears as an unknown nonlinear function of the states and controls (unstructured). An adaptive element (neural network) is then used as a nonlinear function approximator to instantaneously cancel the inversion error.

Unmodeled dynamics arise when the vehicle model used for control design neglects parts of the real system's dynamics. Examples include the Bell-Hillier stabilizer bar and the flapping dynamics of the helicopter rotor blades. For most autonomous flight control work, the flapping dynamics may be safely neglected, whereas the Bell-Hillier stabilizer bar found on small rotorcraft cannot be ignored when high-bandwidth attitude control is desired. This chapter assumes state

feedback of rigid-body states keeping the control design simpler by leveraging the control design's robustness to unmodeled dynamics. Related adaptive designs that use an output-feedback controller formulation to explicitly deal with unmodeled dynamics are described in Calise et al. (2001) with experimental results in Corban et al. (2003).

Actuator magnitude and rate saturation limit control authority and thus the closed-loop stability and performance. Addressing input dynamics constitutes an important class of control design methods for systems with bounded actuation and includes Sontag's universal formula approach using control Lyapunov functions (Lin and Sontag 1991) and others (Bemporad et al. 1997; Pappas 1996). Avoiding saturation, however, usually results in either conservative or highly complex control laws leading to possibly very conservative domains of attraction and slow convergence. See Bernstein and Michel (1995) and the references therein for a survey of early work on constrained control.

Other related works on rotorcraft control may be found in Kendoul et al. (2006, 2007, 2010) and a recent survey on guidance, navigation and control methods for rotorcraft is available in Kendoul (2012).

29.1.1 Approach

Helicopters have six degrees of freedom when considering just the rigid body modes and 4 independent controls are available to control them. Traditionally, the control variables lateral stick, δ_{lat} ; longitudinal stick, δ_{lon} ; and pedal, δ_{ped} , control moments around the roll, pitch, and yaw axes, respectively. Finally, the collective input, δ_{coll} , produces thrust along the main rotor shaft. The rotational dynamics are fully actuated, whereas the translational dynamics are underactuated, but controllable. The rotor thrust has to be oriented using the aircraft's pitch and roll attitude to produce translational accelerations.

An overall architecture of the approach is shown in Fig. 29.1 with details in Fig. 29.6. The outer loop is responsible for tracking desired translational accelerations. It generates δ_{coll} to vary rotor thrust along the main shaft and also generates the desired roll and pitch angles to orient the thrust vector to generate linear accelerations in these two underactuated degrees of freedom. Note here that the desired pitch and roll angles are commands to the inner-loop controller. In this respect the inner loop acts like a (virtual) actuator as far as the outer loop is concerned. Similarly, the inner loop generates the actuator deflections necessary to control the rotational dynamics. Of course, here the inner-loop's output actuation signal is subject to the real actuator dynamics of the physical aircraft. In both loops, approximate models of the rotational (inner loop) and translational (outer loop) dynamics are dynamically inverted to produce the actuator deflections (and desired pitch and roll) necessary to achieve the desired angular and linear accelerations. These desired accelerations are generated using reference models dictating the desired ideal closed-loop response. The cascaded inner-outer loop architecture used here is commonly employed in aerospace control applications due to the different

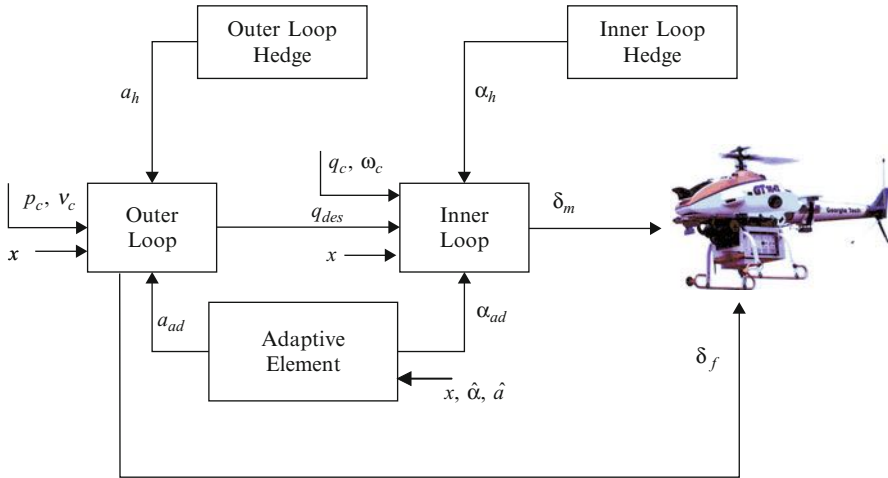

Fig. 29.1 Overall architecture

dynamical time-scales of the two loops. Chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book discusses relevant details of cascaded control systems for UAVs.

Adaptation is introduced in all six degrees of freedom to account for inversion errors arising from the approximate models used for inversion purposes. There is no particular restriction on the inversion that results in *desired* actuator deflections to be bounded. Hence, at large desired accelerations, large actuator deflections may be commanded. Such saturation and dynamics will now appear in the adaptation training signal. This is also true in the case of the outer loop because the commanded pitch and roll attitudes are now subject to the closed-loop dynamics of the inner loop in addition to the actuator dynamics of the δ_{coll} actuator.

These nonlinearities appear in the stability analysis by way of their appearance in the error dynamics. The pseudocontrol hedging signal (PCH) is introduced in the outer-loop and inner-loop reference models in a manner that exactly removes elements of actuator saturation from the training signal for the adaptive element. The reference models themselves are nonlinear and prescribe the aggressiveness with which external commands are achieved. Thus, a comprehensive nonlinear, adaptive, trajectory tracking controller capable of adapting to uncertainties in all six degrees of freedom is developed. It must be noted that although the concrete example used throughout this chapter is one of a helicopter, the controller is not specific to a helicopter UAS. The development is generic; the only difference between a helicopter, a fixed-wing aircraft, or other esoteric aircraft is the manner in which the available controls are categorized and the approximate models used for dynamic inversion purposes.

An underlying assumption of this work is that the nonlinear modeling error uncertainty can be approximated by a continuous function over the flight domain of an aircraft. The goal is to capture an approximation of the uncertainty using

universal approximators such as neural networks. This universal approximation property guarantees that given a sufficient number of neurons, there exists an optimal set of (a priori unknown) weights that can approximate the uncertainty to a desired minimum approximation error. Once these weights are found, the learned dynamics can be used for online planning and health-monitoring purposes. The baseline adaptive laws developed in later sections of this chapter are designed to cancel instantaneous model error but do not necessarily guarantee convergence to the ideal weights during normal course of operation (Johnson and Kannan 2005; Kannan and Johnson 2010b; Kannan 2005). To alleviate this restriction, a modification, the *concurrent-learning adaptive control method*, is introduced that greatly improves the convergence of weights to their ideal values in real-world conditions (Chowdhary and Johnson 2011b). The method can in fact guarantee exponential convergence of the neural network weights to a neighborhood of their ideal values for linearly parameterized neural networks (Chowdhary 2010).

The adaptive controller described in this chapter has been extensively validated in flight on several aircrafts regularly since 2002. The range of aircraft types include the Yamaha RMAX (GTMax) helicopter (Fig. 29.2); an 11-in. ducted fan, the GTSpy (Fig. 29.3); a tailless fixed-wing aircraft, the D6; and a high-thrust-to-weight-ratio aircraft, the GTEdge (Fig. 29.4). The GTEdge is a tilt-body fixed-wing aircraft and capable of hovering on its propeller and flying like a regular fixed-wing aircraft. An interesting set of maneuvers performed by the GTEdge is the hover \Rightarrow forward flight \Rightarrow hover, all using the same adaptive control system. The methods discussed here have also been implemented on smaller aircraft such as

Fig. 29.2 The GTMax helicopter

Fig. 29.3 The GTSpy 11-in. ducted fan

the GT Twinstar (Fig. 29.5), a foam-built twin-engine aircraft; the GT Logo, a small rotorcraft of about 1-m rotor diameter; and the GTQ (Chowdhary et al. 2011b), a miniature quadrotor. On the GT Twinstar, a variant of the algorithms presented here was used for flight with 25 % right wing missing (Chowdhary et al. 2010, 2011a, 2012).

29.2 Control of an Air Vehicle

29.2.1 Vehicle Dynamics

Consider an air vehicle modeled as a nonlinear system of the form

$$\dot{p} = v, \quad (29.1)$$

$$\dot{v} = a(p, v, q, \omega, \delta_f, \delta_m), \quad (29.2)$$

$$\dot{q} = \dot{q}(q, \omega), \quad (29.3)$$

$$\dot{\omega} = \alpha(p, v, q, \omega, \delta_f, \delta_m), \quad (29.4)$$

Fig. 29.4 The GTEdge aircraft with a high (greater than 1) thrust-to-weight ratio

Fig. 29.5 The GT Twinstar foam-built twin-engine aircraft equipped for fault-tolerant control work (see, e.g., Chowdhary et al. [2011a](#))

where $p \in \mathcal{R}^3$ is the position vector, $v \in \mathcal{R}^3$ is the velocity of the vehicle, $q \in \mathcal{R}^4$ is the attitude quaternion, and $\omega \in \mathcal{R}^3$ is the angular velocity. Equation (29.2) represents translational dynamics and Eq. (29.4) represents the attitude dynamics. Together, they represent rigid body dynamics and flat-earth kinematics as given in Etkin (1972) and Stevens and Lewis (2003) and discussed in detail in the chapter ► [Linear Flight Control Techniques for Unmanned Aerial Vehicles](#) in this book. Equation (29.3) represents the quaternion propagation equations (Stevens and Lewis 2003). The use of quaternions, though not a minimal representation of attitude, avoids numerical and singularity problems that Euler-angle-based representations have. This enables the control system to be all attitude capable as required for aggressive maneuvering. The state vector x may now be defined as $x \triangleq [p^T \ v^T \ q^T \ \omega^T]^T$.

Remark 29.1. The objective is to design a control system that can track a given position, velocity, attitude, and angular rate trajectory. The consolidated trajectory command is given by $[p_c^T \ v_c^T \ q_c^T \ \omega_c^T]^T$.

The control vectors are denoted by δ_f and δ_m and represent actual physical actuators on the aircraft, where δ_f denotes the primary force-generating actuators and δ_m denotes the primary moment generating actuators. For a helicopter, the main force effector is the rotor thrust which is controlled by changing main rotor collective δ_{coll} . Hence, $\delta_f \in \mathcal{R} = \delta_{coll}$. There are three primary moment control surfaces, the lateral cyclic δ_{lat} , longitudinal cyclic δ_{lon} , and tail rotor pitch, also called the pedal input δ_{ped} . Hence, $\delta_m \in \mathcal{R}^3 = [\delta_{lat} \ \delta_{lon} \ \delta_{ped}]^T$. In this chapter, the primary moment producing controls are treated as the inner-loop control effector, whereas the $\delta_f = \delta_{coll}$ is treated as an outer-loop control effector. In general, both control inputs, δ_f and δ_m , may each produce both forces and moments. The helicopter is an underactuated system, and hence, the aircraft attitude, q , is treated like a *virtual actuator* used to tilt the main rotor thrust in order to produce desired translational accelerations in the longitudinal and lateral directions. Thus, it is not possible to track the commanded pitch and roll for a helicopter independently. It is only possible to track the heading component of the attitude q_c and body-yaw rate ω_3 independently. Direct control over the translational accelerations in the *body* – *z* – *axis* is possible using δ_{coll} .

The consolidated control vector δ is defined as

$$\delta \triangleq [\delta_f^T \ \delta_m^T]^T;$$

the actuators themselves may have dynamics represented by

$$\dot{\delta} = \begin{bmatrix} \dot{\delta}_m \\ \dot{\delta}_f \end{bmatrix} = \begin{bmatrix} g_m(x, \delta_m, \delta_{m_{des}}) \\ g_f(x, \delta_f, \delta_{f_{des}}) \end{bmatrix} = g(x, \delta, \delta_{des}), \quad (29.5)$$

where $g(\cdot)$ is generally unknown.

Remark 29.2. It is possible to extend the architecture in order to treat actuator dynamics as simply another system in cascade with the translational and attitude dynamics, and the control design would include an outer, inner, and actuator loop with the actuator loop being the lowest block in the cascade. However, unless the physical actuators need to be stabilized, their internal dynamics may be assumed to be asymptotically stable. In this chapter, rate and higher-order dynamics are ignored, but magnitude saturation will be handled explicitly. It can be shown that such an assumption is possible because the control design is robust to the unmodeled dynamics (Kannan 2005).

29.2.2 Control Design

The control architecture is based on a model reference adaptive control architecture (see Fig. 29.6). Noting that Eqs. (29.1) and (29.3) represent exactly known kinematics, approximate models for translational acceleration, \hat{a} , and a model for angular acceleration, $\hat{\alpha}$, need to be established.

$$\begin{bmatrix} a_{des} \\ \alpha_{des} \end{bmatrix} = \begin{bmatrix} \hat{a}(p, v, q_{des}, \omega, \delta_{f_{des}}, \hat{\delta}_m) \\ \hat{\alpha}(p, v, q, \omega, \hat{\delta}_f, \delta_{m_{des}}) \end{bmatrix}.$$

Here, a_{des} and α_{des} are commonly referred to as the pseudocontrol and represent desired accelerations. Additionally, $\delta_{f_{des}}, \delta_{m_{des}}, q_{des}$ are the control inputs and attitude expected to achieve the desired pseudocontrol. This form assumes that translational dynamics are coupled strongly with attitude dynamics, as is the case for a helicopter. From the outer-loop's point of view, q (attitude) is like a *virtual actuator* that generates translational accelerations and q_{des} is the desired attitude that the outer-loop inversion expects will contribute toward achieving the desired translational acceleration, a_{des} . The dynamics of q appear like actuator dynamics to the outer loop.

Remark 29.3. Although the models are approximate, their functional dependence on vehicle rigid body and actuator states are stated accurately for completeness. It is likely that a specific approximate model that is introduced might drop some of this dependency.

Remark 29.4. The attitude quaternion q_{des} will be used to augment the externally commanded attitude q_c to achieve the desired translational accelerations. Ideally, the trajectory generator would generate a commanded attitude q_c that is consistent with the translational acceleration profile needed to track $x_c(t)$ and $v_c(t)$. If not, the outer-loop inverse takes care of correcting it by an amount necessary to achieve the desired translational accelerations in the longitudinal and lateral directions.

The models have a functional dependence on current actuator position. Because actuator positions are often not measured on small unmanned aerial

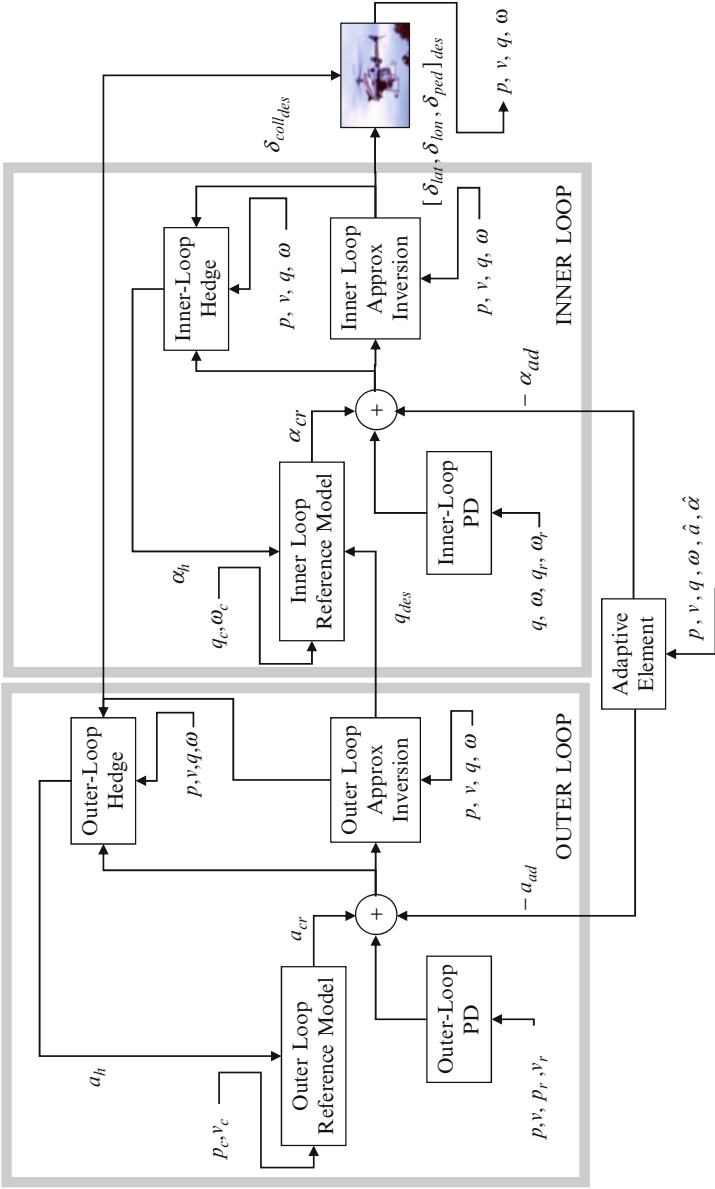

Fig. 29.6 Detailed inner- and outer-loop controller architecture for an autonomous helicopter

vehicles, estimates of the actuator positions $\hat{\delta}_m, \hat{\delta}_f$ can be used. When the actuator positions are directly measured, they may be regarded as known $\hat{\delta}_m = \delta_m$ and $\hat{\delta}_f = \delta_f$. In fact, in the outer-loop's case, good estimates of the roll and pitch attitude virtual actuators are available using inertial sensors and a navigation filter. The approximate models may now be inverted to obtain the desired control and attitude

$$\begin{bmatrix} \delta_{f_{des}} \\ q_{des} \end{bmatrix} = \begin{bmatrix} \hat{a}_{\delta_f}^{-1}(p, v, a_{des_{\delta_f}}, \omega, \hat{\delta}_m) \\ \hat{a}_q^{-1}(p, v, a_{des_q}, \omega, \hat{\delta}_m) \end{bmatrix} \quad (29.6)$$

$$\delta_{m_{des}} = \hat{\alpha}^{-1}(p, v, q, \omega, \hat{\delta}_f, \alpha_{des}),$$

with $a_{des_{\delta_f}} + a_{des_q} = a_{des}$, $\hat{a}_{\delta_f}, \hat{a}_q$ formulated to be consistent with Eq. (29.6) and where actuator estimates are given by actuator models

$$\dot{\hat{\delta}} = \begin{bmatrix} \dot{\hat{\delta}}_f \\ \dot{\hat{\delta}}_m \end{bmatrix} = \begin{bmatrix} \hat{g}_f(x, \hat{\delta}_f, \delta_{f_{des}}) \\ \hat{g}_m(x, \hat{\delta}_m, \delta_{m_{des}}) \end{bmatrix} = \hat{g}(x, \hat{\delta}, \delta_{des}). \quad (29.7)$$

Introducing the inverse control law Eq. (29.6) into Eqs. (29.2) and (29.4) results in the following closed-loop translational and attitude dynamics:

$$\begin{aligned} \dot{v} &= a_{des} + \bar{\Delta}_a(x, \delta, \hat{\delta}) - a_h \\ \dot{\omega} &= \alpha_{des} + \bar{\Delta}_\alpha(x, \delta, \hat{\delta}) - \alpha_h, \end{aligned} \quad (29.8)$$

where

$$\bar{\Delta}(x, \delta, \hat{\delta}) = \begin{bmatrix} \bar{\Delta}_a(x, \delta, \hat{\delta}) \\ \bar{\Delta}_\alpha(x, \delta, \hat{\delta}) \end{bmatrix} = \begin{bmatrix} a(x, \delta) - \hat{a}(x, \hat{\delta}) \\ \alpha(x, \delta) - \hat{\alpha}(x, \hat{\delta}) \end{bmatrix}, \quad (29.9)$$

are static nonlinear functions (model error) that arise due to imperfect model inversion and errors in the actuator model \hat{g} . The main discrepancy between $g(\cdot)$ and $\hat{g}(\cdot)$ is the lack of a magnitude-saturation function in \hat{g} . This is required in order to maintain invertibility. The signals, a_h and α_h , represent the pseudocontrol that *cannot be achieved* due to actuator input characteristics such as saturation. If the model inversion were perfect and no magnitude saturation were to occur, $\bar{\Delta}$, a_h and α_h would vanish leaving only the pseudocontrols a_{des} and α_{des} .

Two tasks now remain, (1) stabilize the feedback linearized dynamics and (2) address the effects of model error. The desired accelerations may be designed as

$$\begin{aligned} a_{des} &= a_{cr} + a_{pd} - \bar{a}_{ad} \\ \alpha_{des} &= \alpha_{cr} + \alpha_{pd} - \bar{\alpha}_{ad}, \end{aligned} \quad (29.10)$$

where a_{cr} and α_{cr} are outputs of reference models for the translational and attitude dynamics, respectively. a_{pd} and α_{pd} are outputs of proportional-derivative (PD) compensators; and finally, \tilde{a}_{ad} and $\tilde{\alpha}_{ad}$ are the outputs of an adaptive element designed to cancel model error $\tilde{\Delta}$. The effects of input dynamics, represented by a_h, α_h , will first be addressed in the following section by designing the reference model dynamics such that they do not appear in the tracking error dynamics. The reference model, tracking error dynamics, and boundedness are discussed in the following sections with details of the adaptive element left to Appendix Sect. A.

29.2.3 Reference Model and Hedging

Any dynamics and nonlinearities associated with the actuators δ_m, δ_f have not yet been considered in the design. If they become saturated (position or rate), the reference models will continue to demand tracking as though full authority were still available. Furthermore, the inner loop appears like an actuator with dynamics to the outer loop. Practical operational limits on the maximum attitude of the aircraft may have also been imposed in the inner-loop reference model. This implies that the outer-loop desired attitude augmentation q_{des} may not actually be achievable or at the very least is subject to the inner-loop dynamics.

If the reference model is designed as

$$\begin{aligned}\dot{v}_r &= a_{cr}(p_r, v_r, p_c, v_c) \\ \dot{\omega}_r &= \alpha_{cr}(q_r, \omega_r, q_c \oplus q_{des}, \omega_c),\end{aligned}\tag{29.11}$$

where p_r and v_r are the outer-loop reference model states and q_r, ω_r are the inner-loop reference model states. The external command signal is $x_c = [p_c^T \ v_c^T \ q_c^T \ \omega_c^T]^T$. The attitude rotation desired by the outer loop is now added to the commands for the inner-loop controller. Here, $q_c \oplus q_{des}$ denotes quaternion multiplication (Stevens and Lewis 2003) and effectively concatenates the two rotations.

If tracking error dynamics is computed by subtracting Eq.(29.10) from Eq.(29.11), the un-achievable acceleration a_h, α_h will appear in the tracking error dynamics. When an adaptive element such as a neural network or integrator is introduced, these effects of input dynamics propagate into the training signal and eventually result in the adaptive element attempting to correct for them, leading to incorrect adaptation.

Tackling this issue involves redesigning the reference model by subtracting the deficit accelerations (pseudocontrol hedging):

$$\dot{v}_r = a_{cr}(p_r, v_r, p_c, v_c) - a_h,\tag{29.12}$$

$$\dot{\omega}_r = \alpha_{cr}(q_r, \omega_r, q_c \oplus q_{des}, \omega_c) - \alpha_h, l\tag{29.13}$$

where a_h and α_h are the differences between commanded pseudocontrol and an estimate of the achieved pseudocontrol. It is an estimate because actual actuator positions may not be known. Additionally, the aircraft state vectors p, v, q, ω are estimated using a Kalman filter (Christophersen et al. 2006; Chowdhary et al. 2011b). However, for purposes of control design, they are assumed to be known, and thus the virtual actuators such as attitude may be assumed to be known in the PCH computation. This assumption may have to be revisited in the case where the control/observer pair is not assumed to be separable, perhaps in a tough localization problem where the control inputs directly affect the observability of the aircraft states.

The PCH signals are given by

$$\begin{aligned} a_h &= \hat{a}(p, v, q_{des}, \omega, \delta_{f_{des}}, \hat{\delta}_m) - \hat{a}(p, v, q, \omega, \hat{\delta}_f, \hat{\delta}_m) \\ &= a_{des} - \hat{a}(p, v, q, \omega, \hat{\delta}_f, \hat{\delta}_m), \end{aligned} \quad (29.14)$$

$$\begin{aligned} \alpha_h &= \hat{\alpha}(p, v, q, \omega, \delta_{f_{des}}, \delta_{m_{des}}) - \hat{\alpha}(p, v, q, \omega, \hat{\delta}_f, \hat{\delta}_m) \\ &= \alpha_{des} - \hat{\alpha}(p, v, q, \omega, \hat{\delta}_f, \hat{\delta}_m). \end{aligned} \quad (29.15)$$

The hedge signals a_h, α_h , do not directly affect the reference model output a_{cr}, α_{cr} , but do so only through subsequent changes in the reference model states.

The command tracking error may now be defined as e_r

$$e_r \triangleq \begin{bmatrix} p_c - p_r \\ v_c - v_r \\ \tilde{Q}(q_c, q_r) \\ \omega_c - \omega_r \end{bmatrix}, \quad (29.16)$$

with corresponding command tracking error dynamics given by

$$\dot{e}_r = \begin{bmatrix} v_c - v_r \\ a_c - (a_{cr} - a_h) \\ \omega_c - \omega_r \\ \alpha_c - (\alpha_{cr} - \alpha_h) \end{bmatrix}. \quad (29.17)$$

The particular form of the reference model dynamics chosen for the translational dynamics, a_{cr} , and attitude dynamics, α_{cr} , has profound effects on the overall response and controllability of the system. This is fully expounded in Chap. 4 of Kannan (2005) and in Kannan and Johnson (2010a). Also see Kannan and Johnson (2003) for a discussion on the effects of reference model poles when various elements saturate.

As a summary, three reference models were considered:

- A *linear reference model* will attempt to elicit a linear response in the plant when no such response is possible (peaking) as the plant is nonlinear, especially with the magnitude saturation of actuators.
- The *nested saturation-based reference model* is an alternative to the linear reference model containing saturations functions appearing in a nested form and is based on the work by Teel (1996, 1997). This form allows one to restrict the evolution of states in a prescribable manner.
- The *constrained linear reference model* is a special case of the nested saturation-based reference model that is locally linear near the origin.

For the quadratic candidate Lyapunov functions chosen in Kannan (2005), only the nested-saturation and constrained linear reference models have their Lyapunov derivative bounds on the PCH signals a_h, α_h . In this chapter, the constrained reference model is used with equations given later in Sect. 29.4.2.

29.2.4 Tracking Error Dynamics

The tracking error vector is defined as, e as

$$e \triangleq \begin{bmatrix} p_r - p \\ v_r - v \\ \tilde{Q}(q_r, q) \\ \omega_r - \omega \end{bmatrix}, \quad (29.18)$$

where $\tilde{Q} : \mathcal{R}^4 \times \mathcal{R}^4 \mapsto \mathcal{R}^3$ is a function (Johnson 2000) that, given two quaternions, results in an error angle vector with three components. An expression for \tilde{Q} is given by

$$\begin{aligned} \tilde{Q}(p, q) &= 2 \operatorname{sgn}(q_1 p_1 + q_2 p_2 + q_3 p_3 + q_4 p_4) \times \\ &\quad \begin{bmatrix} -q_1 p_2 + q_2 p_1 + q_3 p_4 - q_4 p_3 \\ -q_1 p_3 - q_2 p_4 + q_3 p_1 + q_4 p_2 \\ -q_1 p_4 + q_2 p_3 - q_3 p_2 + q_4 p_1 \end{bmatrix}. \end{aligned} \quad (29.19)$$

The output of the PD compensators may be written as

$$\begin{bmatrix} a_{pd} \\ \alpha_{pd} \end{bmatrix} = \begin{bmatrix} R_p & R_d & 0 & 0 \\ 0 & 0 & K_p & K_d \end{bmatrix} e, \quad (29.20)$$

where $R_p, R_d \in \mathcal{R}^{3 \times 3}$, $K_p, K_d \in \mathcal{R}^{3 \times 3}$ are linear gain positive-definite matrices whose choice is discussed below. The tracking error dynamics may be found by directly differentiating Eq. (29.18):

$$\dot{e} = \begin{bmatrix} v_r - v \\ \dot{v}_r - \dot{v} \\ \omega_r - \omega \\ \dot{\omega}_r - \dot{\omega} \end{bmatrix}.$$

Considering \dot{e}_2 ,

$$\begin{aligned} \dot{e}_2 &= \dot{v}_r - \dot{v} \\ &= a_{cr} - a_h - a(x, \delta) \\ &= a_{cr} - a_{des} + \hat{a}(x, \hat{\delta}) - a(x, \delta) \\ &= a_{cr} - a_{pd} - a_{cr} + \bar{a}_{ad} + \hat{a}(x, \hat{\delta}) - a(x, \delta) \\ &= -a_{pd} - (a(x, \delta) - \hat{a}(x, \hat{\delta}) - \bar{a}_{ad}) \\ &= -a_{pd} - (\bar{\Delta}_a(x, \delta, \hat{\delta}) - \bar{a}_{ad}), \end{aligned}$$

\dot{e}_4 may be found similarly. Then, the overall tracking error dynamics may now be expressed as

$$\dot{e} = Ae + B \left[\bar{v}_{ad} - \bar{\Delta}(x, \delta, \hat{\delta}) \right], \quad (29.21)$$

where $\bar{\Delta}$ is given by Eq. (29.9),

$$\bar{v}_{ad} = \begin{bmatrix} \bar{a}_{ad} \\ \bar{\alpha}_{ad} \end{bmatrix}, A = \begin{bmatrix} 0 & I & 0 & 0 \\ -R_p & -R_d & 0 & 0 \\ 0 & 0 & 0 & I \\ 0 & 0 & -K_p & -K_d \end{bmatrix}, \quad B = \begin{bmatrix} 0 & 0 \\ I & 0 \\ 0 & 0 \\ 0 & I \end{bmatrix}, \quad (29.22)$$

and so the linear gain matrices must be chosen such that A is Hurwitz's. Now, \bar{v}_{ad} remains to be designed in order to cancel the effect of $\bar{\Delta}$.

Note that commands, δ_{mdes} , δ_{fdes} , q_{des} , do not appear in the tracking error dynamics. PCH allows adaptation to continue when the actual control signal has been replaced by any arbitrary signal and thus allows switching between manual and automatic flight during flight tests without any transients. Furthermore, if the actuator is considered ideal and the actual position and the commanded position are equal, addition of the PCH signals a_h , α_h has no effect on any system signal.

The adaptive signal \bar{v}_{ad} contains two terms

$$\bar{v}_{ad} = v_{ad} + v_r = \begin{bmatrix} a_{ad} + a_r \\ \alpha_{ad} + \alpha_r \end{bmatrix},$$

where v_{ad} is the output of the single hidden layer (SHL) neural network (NN) described in Appendix Sect. A. For an air vehicle with adaptation in all degrees of freedom, $v_{ad} \in \mathcal{R}^6$, where the first three outputs, a_{ad} , approximate Δ_a and the

last three outputs, α_{ad} , approximate Δ_α , is consistent with the definition of the error in Eq. (29.18). The term $v_r = [a_r^T, \alpha_r^T]^T \in \mathcal{R}^6$ is a robustifying signal that arises in the proofs of boundedness found in Kannan (2005).

29.2.5 Boundedness

Noting that the plant states are given by

$$x(t) = x_r(t) - e(t), \quad (29.23)$$

boundedness of the reference model states $x_r(t)$ is sufficient to establish boundedness of the plant states $x(t)$. However, the reference model dynamics now include the PCH signal which could be arbitrary and large. The problem of actuator saturation has effectively been moved from affecting the tracking error dynamics to affecting the command tracking error dynamics of the reference model. If boundedness of 29.17 can be established, then an assumption that the external command $x_c(t)$ is bounded is sufficient to establish boundedness of the overall system. The following assumptions are required to guarantee boundedness:

Assumption 1 *The external command x_c is bounded:*

$$\|x_c\| \leq \bar{x}_c.$$

Assumption 2 *The NN approximation $\Delta(x, \hat{\delta}) = v_{ad}(x, \hat{\delta}) + \epsilon$ holds in a compact domain \mathcal{D} , which is large enough such that $\mathcal{D}_{x_c} \times \mathcal{D}_{e_r} \times \mathcal{D}_e \times \mathcal{D}_{\bar{z}}$ maps into \mathcal{D} . This assumption is required to leverage the universal approximation property of SHL NN (Hornik et al. 1989a).*

Assumption 3 *The norm of the ideal weights (V^*, W^*) is bounded by a known positive value,*

$$0 < \|Z^*\|_F \leq \bar{Z},$$

where $\|\cdot\|_F$ denotes the Frobenius norm. This is justified due to the universal approximation property of SHL NN if the previous assumption holds (Hornik et al. 1989a).

Assumption 4 *Note that Δ depends on v_{ad} through the pseudocontrol v , whereas \bar{v}_{ad} has to be designed to cancel Δ . Hence, the existence and uniqueness of a fixed-point solution for $v_{ad} = \Delta(x, v_{ad})$ is assumed. Sufficient conditions (Calise et al. 2001) for this assumption are also available.*

Assumption 5 *Noting that the null-controllable region of the plant \mathcal{C}_x is not necessarily a connected or closed set, assume that $\mathcal{D} \subseteq \mathcal{C}_x$ and that \mathcal{D} in addition to being compact is also convex.*

The adaptive element training signal, r ; adaptive element output, v_{ad} ; and robustifying term, v_r , are given by

$$\begin{aligned} r &= (e^T P B)^T \\ \bar{v}_{ad} &= v_{ad} + v_r \\ v_{ad} &= W^T \sigma(V^T \bar{x}) \\ v_r &= -K_r (\|Z\|_F + \bar{Z}) r \frac{\|e\|}{\|r\|}. \end{aligned}$$

Theorem 29.1. Consider the system given by (29.1)–(29.4), with the inverse law (29.6), reference models (29.35) and (29.36) which is consistent with (29.12) and (29.13), where the gains are the same as those selected such that the system matrix in (29.21) is Hurwitz and Assumptions 1–5 are met. If $K_r > 0 \in \mathcal{R}^{k \times k}$ is chosen sufficiently large with lower limit stated in the proof, and adaptive element weights W, V satisfy the adaptation laws

$$\begin{aligned} \dot{W} &= -[(\sigma - \sigma' V^T \bar{x}) r^T + \kappa \|e\| W] \Gamma_W \\ \dot{V} &= -\Gamma_V [\bar{x} (r^T W^T \sigma') + \kappa \|e\| V], \end{aligned} \quad (29.24)$$

with $\Gamma_W, \Gamma_V > 0$, $\kappa > 0$ with lower limit stated in the proof, and the external command $x_c(t)$ is such that $e_r(t) \in \Omega(P_r, \rho)$, for some $\rho > 0$, then, the command tracking error, e_r ; the reference model tracking error, e ; and adaptive element weights (\tilde{W}, \tilde{V}) are uniformly ultimately bounded. Further, the plant states, x , are ultimately bounded.

Proof. See proof of Theorem 4 in Kannan (2005). □

Remark 29.5. The update laws $\dot{W}(t), \dot{V}(t)$ closely resembles the backpropagation method of tuning neural network weights (Rumelhart and Williams 1986; Suykens et al. 1996; Haykin 1998; Kim and Lewis 1998). However, it is important to note that the training signal r is different from that of the backpropagation-based learning laws.

29.3 Concurrent Learning

The single hidden layer neural-network-based adaptive elements used in this chapter are known to have the universal approximation property (Haykin 1998; Hornik et al. 1989a), that is, given sufficient number of hidden layer neurons there exists a set of ideal weights W^*, V^* that brings the neural network output to within an ϵ neighborhood of the modeling error $\bar{\Delta}(x, \delta)$ (uncertainty). The adaptive laws in Eq. (29.24) are designed to minimize the instantaneous tracking error e . Although Theorem 29.1 guarantees boundedness of the tracking error e , it cannot

be guaranteed that the adaptive weights will approach the ideal weights over the long term during a normal course of operation. It is useful to drive the weights closer toward their ideal values, as the resulting NN representation forms a good approximation of the uncertainty, which can result in improved performance and can be used for planning and health-monitoring purposes.

One limitation of the adaptive laws in Eq. (29.24) (without the e -modification term) is that at any instant of time, they are constrained to search for the ideal weights only in the direction of instantaneous tracking error reduction. In that sense these adaptive laws are equivalent to a gradient-descent or a greedy update. Therefore, the adaptive weights may not approach the ideal weights unless all directions in which the weights can evolve to reduce the tracking error are explored infinitely often during the course of operation. Intuitively, this explains why *persistence of excitation* is required to guarantee weight convergence for most adaptive laws (see, e.g., Boyd and Sastry 1986). The idea in concurrent learning is to use specifically selected and online recorded data to ensure parameter convergence without requiring persistent excitation. If data is recorded when the system states are exciting and if invariant system properties, such as modeling error information, can be inferred from the recorded data, then weight convergence can be guaranteed without requiring persistent excitation (Chowdhary 2010). In an implementation of a concurrent-learning adaptive controller, each measured data point is evaluated to determine whether it should be added to a *history stack*. The maximum number of recorded data points is limited, and when this number is reached, new data points replace old points. Note that the history stack is not intended to be a buffer of last p states. The approximation modeling error at a recorded data point, which is an invariant system property, is inferred from the recorded data point by noting that $\Delta(x_i, \delta_i) \approx \hat{x}_i - v(x_i, \delta_i)$ where \hat{x}_i is the smoothed estimate of \dot{x}_i (Chowdhary and Johnson 2011b; Gelb 1974). Adaptation happens concurrently on recorded and current data such that the instantaneous tracking error and the modeling error at all recorded data points simultaneously reduces (Chowdhary and Johnson 2010, 2011b; Chowdhary 2010).

It was shown in Chowdhary (2010) and Chowdhary and Johnson (2010) that for linearly parameterized uncertainties, the requirement on persistency of excitation can be relaxed if online recorded data is used concurrently with instantaneous data for adaptation. If the uncertainty can be linearly parameterized, then

$$\bar{\Delta}(x, \delta) = W^{*T} \phi(x, \delta) + \epsilon(x, \delta) \quad (29.25)$$

where $W^* \in \mathbb{R}^l$ denotes the ideal weights that guarantee for a given basis function $\phi(x, \delta) \in \mathbb{R}^l$ $\sup_{\delta} \|\epsilon(x, \delta)\| \leq \bar{\epsilon}$ for some positive constant $\bar{\epsilon}$. In this case, the adaptive element can also be linearly parameterized in the form $v_{ad} = W^T \phi(x, \delta)$. In certain UAV applications, the basis functions for the modeling error are known (see, e.g., the problem of wing-rock control (Singh et al. 1995)), in which case, the existence of an unknown ideal weight vector W^* can be established such that $\bar{\epsilon} = 0$. The representation in (29.25) can also be guaranteed for any continuous modeling error approximated over a compact domain if elements of ϕ consist of set of Gaussian radial basis functions and a scalar bias term b_w (see Park and Sandberg

1991; Haykin 1998). For either of these linearly parameterized representations of the uncertainty, the following theorem can be proven (Chowdhary 2010; Chowdhary and Johnson 2010, 2011a):

Theorem 29.2. *Consider the system given by (29.1)–(29.4), with the inverse law (29.6), reference models (29.35) and (29.36) which is consistent with (29.12) and (29.13), where the gains are the same as those selected such that the system matrix in (29.21) is Hurwitz. Assume further that the uncertainty is linearly parameterizable using an appropriate set of bases over a compact domain D and that Assumptions 4 and 5 hold. For each recorded data point j , let $\epsilon_i(t) = W^T(t)\phi(x_i, \delta_i) - \hat{\Delta}(x_i, \delta_i)$, with $\hat{\Delta}(x_i, \delta_i) = \hat{x}_i - v(x_i, \delta_i)$. Now consider the following update law for the weights of the RBF NN:*

$$\dot{W} = -\Gamma_W \sigma(z) e^T P B - \sum_{j=1}^p \Gamma_W \sigma(x_i, \delta_i) \epsilon_j^T, \quad (29.26)$$

and assume that $Z = [\phi(z_1), \dots, \phi(z_p)]$ and $\text{rank}(Z) = l$. Let B_α be the largest compact ball in D , and assume $\zeta(0) \in B_\alpha$, define $\delta = \max(\beta, \frac{2\|PB\|\bar{\epsilon}}{\lambda_{\min}(Q)} + \frac{p\bar{\epsilon}\sqrt{l}}{\lambda_{\min}(\Omega)})$, and assume that D is sufficiently large such that $m = \alpha - \delta$ is a positive scalar. If the states x_{rm} of the bounded-input bounded-output reference model of (29.11) remains bounded in the compact ball $B_m = \{x_{rm} : \|x_{rm}\| \leq m\}$ for all $t \geq 0$, then the tracking error e and the weight error $\tilde{W} = W - W^*$ are uniformly ultimately bounded. Furthermore, if the representation in (29.25) is exact over the entire operating domain, that is, $\bar{\epsilon} = 0$, then the tracking error and weight error converge exponentially fast to a compact ball around the origin for arbitrary initial conditions, with the rate of convergence directly proportional to the minimum singular value of the history stack matrix Z .

Remark 29.6. The size of the compact ball around the origin where the weight and tracking error converge is dependent on the representation error $\bar{\epsilon}$ and the estimation error $\check{\epsilon} = \max_i \|\dot{x}_i - \hat{x}_i\|$. The former can be reduced by choosing appropriate number of RBFs across the operating domain, and the latter can be reduced by an appropriate implementation of a fixed point smoother. Note that $\hat{x}(t)$ is not needed at a current instant t . Therefore, an appropriate implementation of a fixed-point smoother alleviates several issues faced in estimating $\hat{x}(t)$ by using recorded data before and after a data point is recorded to form very accurate estimates of \hat{x}_i (Gelb 1974; Chowdhary and Johnson 2011b).

The history stack matrix $Z = [\phi(z_1), \dots, \phi(z_p)]$ is not a buffer of last p states. It can be updated online by including data points that are of significant interest over the course of operation. In the linearly parameterized case, convergence is guaranteed as soon as the history stack becomes full ranked. New data points could replace existing data points once the history stack reaches a predetermined size. It was shown in Chowdhary and Johnson (2011a) that the rate of convergence of the tracking error and weights is directly proportional to the minimum singular

value of Z . This provides a useful metric to determine which data points are most useful for improving convergence. Consequently, an algorithm for adding points that improve the minimum singular value of Z for the case of linearly parameterizable uncertainty was presented in Chowdhary and Johnson (2011a). The main limitation of the linearly parameterized RBF NN representation of the uncertainty is that the RBF centers need to be preallocated over an estimated compact domain of operation D . Therefore, if the system evolves outside of D , all benefits of using adaptive control are lost. This can be addressed by evolving the RBF basis to reflect the current domain of operation; a reproducing kernel Hilbert space approach for accomplishing this was presented in Kingravi et al. (2012).

On the other hand, the nonlinearly parameterized NN described in Appendix Sect. A is more flexible: it only requires the uncertainties to be bounded over a compact set, but does not require that the domain of operation be known. However, it is typically more difficult to analyze due to the nonlinear parameterizations. In Chowdhary and Johnson (2011b), a concurrent-learning adaptive law was proposed for SHL NN and was validated in flight on the GTMax rotorcraft (see Sect. 29.5.5). In particular, the following theorem can be proven (Chowdhary and Johnson 2011b; Chowdhary 2010):

Theorem 29.3. *Consider the system given by (29.1)–(29.4), with the inverse law (29.6), reference models (29.35) and (29.36) which is consistent with (29.12) and (29.13), where the gains are the same as those selected such that the system matrix in (29.21) is Hurwitz and Assumptions 1–5 are met. Let $i \in \mathfrak{S}$ denote the index of an online recorded data point z_i , define $r_{b_i}(t) = v_{ad}(z_i) - \hat{\Delta}(z_i)$, where $\hat{\Delta}(z) = \hat{\dot{x}}_i - v_i$ and $\hat{\dot{x}}_i$ is the smoothed estimate of \dot{x}_i , and consider the following adaptive law:*

$$\begin{aligned} \dot{W}(t) = & -(\sigma(V^T(t)\bar{x}(t)) - \sigma'(V^T(t)\bar{x}(t))V^T(t)\bar{x}(t))r^T(t)\Gamma_w - k\|e(t)\|W(t) \\ & - W_c(t) \sum_{i=1}^p (\sigma(V^T(t)\bar{x}_i) - \sigma'(V^T(t)\bar{x}_i)V^T(t)\bar{x}_i)r_{b_i}^T(t)\Gamma_w, \end{aligned} \quad (29.27)$$

$$\begin{aligned} \dot{V}(t) = & -\Gamma_V \bar{x}(t)r^T(t)W^T(t)\sigma'(V^T(t)\bar{x}(t)) - k\|e(t)\|V(t) - \\ & V_c(t) \sum_{i=1}^p \Gamma_V \bar{x}_i r_{b_i}^T(t)W^T(t)\sigma'(V^T(t)\bar{x}_i), \end{aligned} \quad (29.28)$$

where W_c , V_c are orthogonal projection operators that restrict the update based on the recorded data in the null-space of update based on current data:

$$\begin{aligned} W_c = & I - \frac{(\sigma(V^T \bar{x}) - \sigma'(V^T \bar{x})V^T \bar{x})(\sigma(V^T \bar{x}) - \sigma'(V^T \bar{x})V^T \bar{x})^T}{(\sigma(V^T \bar{x}) - \sigma'(V^T \bar{x})V^T \bar{x})^T (\sigma(V^T \bar{x}) - \sigma'(V^T \bar{x})V^T \bar{x})}, \\ V_c = & I - \frac{\Gamma_V \bar{x} \bar{x}^T \Gamma_V}{\bar{x}^T \Gamma_V \Gamma_V \bar{x}}, \end{aligned} \quad (29.29)$$

with $\Gamma_W, \Gamma_V > 0$, $\kappa > 0$ with lower limit stated in the proof, and the external command $x_c(t)$ is such that $e_r(t) \in \Omega(P_r, \rho)$, for some $\rho > 0$, then, the command tracking error, e_r ; the reference model tracking error, e ; and adaptive element weights (\tilde{W}, \tilde{V}) are uniformly ultimately bounded. Further, the plant states, x , are ultimately bounded.

For the nonlinearly parameterized neural network, the simplest way to record a data point $x(t)$ online is to ensure that for a given $\bar{\theta} \in \mathbb{R}^+$,

$$\frac{\|x(t) - x_k\|^2}{\|x(t)\|} \geq \bar{\theta}, \quad (29.30)$$

where x_k is the last recorded data point. The points can be stored in an online history stack which contains a maximum of \bar{p} points. Once the maximum number of recorded points are reached, points are added such that the newest point replaces the oldest one.

29.4 Helicopter Specific Design

Consider the application of the combined inner-outer-loop adaptive architecture to the trajectory control of a helicopter. The dynamics (Munzinger 1998; Mettler 2002; Gavrillets et al. 2001) of the helicopter may be modeled in the same form as Eqs. (29.1)–(29.4). Most small helicopters include a Bell-Hiller stabilizer bar, which provides lagged rate feedback and is a source of unmodeled dynamics. The nonlinear model used for simulation in this work included the stabilizer bar dynamics. Additionally, blade flapping and other aspects such as gear and engine dynamics were also modeled.

29.4.1 Approximate Model

An approximate model for the attitude dynamics of the helicopter was generated by linearizing the nonlinear model around hover and neglecting coupling between the attitude and translational dynamics as well as the stabilizer bar:

$$\alpha_{des} = \hat{A}_1 \begin{bmatrix} p \\ q \\ r \end{bmatrix} + \hat{A}_2 \begin{bmatrix} u \\ v \\ w \end{bmatrix} + \hat{B} \left(\underbrace{\begin{bmatrix} \delta_{lat} \\ \delta_{lon} \\ \delta_{ped} \end{bmatrix}}_{des} - \underbrace{\begin{bmatrix} \delta_{lat} \\ \delta_{lon} \\ \delta_{ped} \end{bmatrix}}_{trim} \right), \quad (29.31)$$

or

$$\alpha_{des} = \hat{A}_1 \omega_B + \hat{A}_2 v_B + \hat{B}(\delta_{m_{des}} - \delta_{m_{trim}}),$$

where \hat{A}_1 and \hat{A}_2 represent the attitude and translational dynamics, respectively, and ω_B represents the angular velocity of the body with respect to the earth expressed in the body frame. The body velocity vector with respect to the earth expressed in the body frame is given by v_B , and $\delta_{m_{trim}}$ is the trim control vector that is consistent with the linear model. Choosing the control matrix \hat{B} such that it is invertible, the moment controls may be evaluated as

$$\delta_{m_{des}} = \hat{B}^{-1}(\alpha_{des} - \hat{A}_1\omega_B - \hat{A}_2v_B) + \delta_{m_{trim}}.$$

The translational dynamics may be modeled as a point mass with a thrust vector that may be oriented in a given direction as illustrated in Fig. 29.7. More involved inverses (Lipp and Prasad 1993) may be used, but the simple relationships between thrust, attitude, and accelerations suffice when used with adaptation

$$a_{des} = \begin{bmatrix} 0 \\ 0 \\ Z_{\delta_{coll}} \end{bmatrix} (\delta_{coll_{des}} - \delta_{coll_{trim}}) + L_{bv}g, \quad (29.32)$$

Fig. 29.7 Point mass model for outerloop inversion

where $Z_{\delta_{coll}}$ is the control derivative for acceleration in the vertical axis. L_{bv} is the direction cosine matrix that transforms a vector from the vehicle (or local) frame to the body frame and g is an assumed gravity vector. The desired specific force along the body z axis may be evaluated as

$$f_{sf} = (a_{des} - L_{bv}g)_3.$$

The required collective input may be evaluated as

$$\delta_{coll_{des}} = \frac{f_{sf}}{Z_{\delta_{coll}}} + \delta_{coll_{trim}}.$$

The attitude augmentation required in order to orient the thrust vector to attain the desired translational accelerations are given by the following small angle corrections from the current reference body attitude and attitude command:

$$\Delta\Phi_1 = \frac{a_{des2}}{f_{sf}}, \quad \Delta\Phi_2 = -\frac{a_{des1}}{f_{sf}}, \quad \Delta\Phi_3 = 0, \quad (29.33)$$

For this simplified helicopter model, heading change has no effect on accelerations in the x, y plane, and hence $\Delta\Phi_3 = 0$. These three correction angles may now be used to generate the attitude quaternion correction desired by the outer loop. Thus,

$$q_{des} = q(\Delta\Phi_1, \Delta\Phi_2, \Delta\Phi_3), \quad (29.34)$$

where $q(\cdot)$ is a function (Stevens and Lewis 2003) that expresses an Euler-angle-based rotation as a quaternion. The overall detailed controller architecture is shown in Fig. 29.6.

Remark 29.7. If the desired specific force f_{sf} is close to zero, which occurs when the desired acceleration in the body z axis is the same as the component of gravity vector along that axis, then, Eq. (29.33) is undefined. To overcome this problem, one can impose a restriction where 29.33 is only computed if $|f_{sf}| > \bar{f}_{sf}$, where $\bar{f}_{sf} > 0$ and is a lower limit. Essentially it means do not bother using attitude unless the desired specific force is greater than \bar{f}_{sf} .

29.4.2 Reference Model

Using a linear a_{cr} and α_{cr} in Eqs. (29.12) and (29.13) results in the following reference model dynamics:

$$\begin{aligned} \dot{v}_r &= R_p(p_c - p_r) + R_d(v_c - v_r) - a_h \\ \dot{\omega}_r &= K_p(\tilde{Q}(q_c \oplus q_{des}, q_r)) + K_d(\omega_c - \omega_r) - \alpha_h, \end{aligned}$$

where R_p, R_d, K_p, K_d are the same gains used for the PD compensator in Eq. (29.20). If limits on the angular rate or translational velocities are to be imposed, then they may be easily included in the reference model dynamics by choosing the following constrained linear reference for a_{cr} and α_{cr} :

$$a_{cr} = R_d[v_c - v_r + \sigma(R_d^{-1}R_p(p_c - p_r), v_{lim})], \quad (29.35)$$

$$\alpha_{cr} = K_d[\omega_c - \omega_r + \sigma(K_d^{-1}K_p\tilde{Q}(q_c \oplus q_{des}, q_r), \omega_{lim})]. \quad (29.36)$$

This reference model has prescribable aggressiveness, where $\sigma(\cdot)$ is a saturation function and v_{lim}, ω_{lim} are the translational and angular rate limits, respectively.

Remark 29.8. Note that there are no limits placed on the externally commanded position, velocity, angular rate, or attitude. For example, in the translational reference model, if a large position step is commanded, $p_c = [1,000, 0, 0]^T$ ft and $v_c = [0, 0, 0]^T$ ft/s, the speed at which this large step will be achieved is v_{lim} . On the other hand if $p_c = \int v_c dt$ and $v_c = [60, 0, 0]^T$ ft/s, the speed of the vehicle will be 60 ft/s. Similarly, ω_{lim} dictates how fast large attitude errors will be corrected. Additionally, aggressiveness with which translational accelerations will be pursued by tilting the body may be governed by limiting the magnitude of q_{des} to the scalar limit q_{lim} .

29.4.3 Choice of Gain Linear Dynamics

When the combined adaptive inner-outer-loop controller for position and attitude control is implemented, the poles for the combined error dynamics must be selected appropriately. The following analysis applies to the situation where inversion model error is compensated for accurately by the NN, and it is assumed that the system is exactly feedback linearized. The inner loop and outer loop each represent a second-order system, and the resulting position dynamics $p(s)/p_c(s)$ are fourth order in directions perpendicular to the rotor spin axis.

When the closed-loop longitudinal dynamics, near hover, are considered, and with an acknowledgment of an abuse of notation, it may be written as

$$\ddot{x} = a_{des} = \ddot{x}_c + R_d(\dot{x}_c - \dot{x}) + R_p(x_c - x), \quad (29.37)$$

$$\ddot{\theta} = \alpha_{des} = \ddot{\theta}_g + K_d(\dot{\theta}_g - \dot{\theta}) + K_p(\theta_g - \theta), \quad (29.38)$$

where R_p, R_d, K_p , and K_d are the PD compensator gains for the inner loop (pitch angle) and outer loop (fore-aft position). Now x is the position, θ the attitude, and θ_g the attitude command. Normally, $\theta_g = \theta_c + \theta_{des}$ where θ_c is the external command and θ_{des} the outer-loop-generated attitude command. Here, it is assumed that the external attitude command and its derivatives are zero; hence, $\theta_g = \theta_{des}$. In the following development, the transfer function $x(s)/x_c(s)$ is found and used to place

the poles of the combined inner-outer-loop system in terms of the PD compensator gains.

When contributions of $\dot{\theta}_g(s)$ and $\ddot{\theta}_g(s)$, are ignored, the pitch dynamics Eq. 29.38 may be rewritten in the form of a transfer function as

$$\theta(s) = \frac{\theta(s)}{\theta_g(s)} \theta_g(s) = \frac{K_p}{s^2 + K_d s + K_p} \theta_g(s). \quad (29.39)$$

If the outer-loop linearizing transformation used to arrive at Eq. 29.37 has the form $\ddot{x} = f\theta$, where $f = -g$ and g is gravity, it may be written as

$$s^2 x(s) = f\theta(s). \quad (29.40)$$

The outer-loop attitude command may be generated as

$$\theta_{des} = \frac{\ddot{x}_{des}}{f} = \frac{a_{des}}{f}. \quad (29.41)$$

Note that $\theta_g = \theta_{des}$; if $\theta_c = 0$,

$$\theta_g = \theta_{des} = \frac{1}{f} [\ddot{x}_c + R_d(\dot{x}_c - \dot{x}) + R_p(x_c - x)]. \quad (29.42)$$

When Eqs. (29.39) and (29.42) are used in Eq. 29.40,

$$s^2 x(s) = \frac{K_p [s^2 x_c + R_d s(x_c - x) + R_p(x_c - x)]}{s^2 + K_d s + K_p}. \quad (29.43)$$

Rearranging the above equation results in the following transfer function:

$$\frac{x(s)}{x_c(s)} = \frac{K_p s^2 + K_p R_d s + K_p R_p}{s^4 + K_d s^3 + K_p s^2 + K_p R_d s + K_p R_p}. \quad (29.44)$$

One way to choose the gains is by examining a fourth-order characteristic polynomial written as the product of two second-order systems

$$\begin{aligned} \Upsilon(s) &= (s^2 + 2\zeta_o \omega_o + \omega_o^2)(s^2 + 2\zeta_i \omega_i + \omega_i^2) \\ &= s^4 + (2\zeta_i \omega_i + 2\zeta_o \omega_o) s^3 \\ &\quad + (\omega_i^2 + 4\zeta_o \omega_o \zeta_i \omega_i + \omega_o^2) s^2 + (2\zeta_o \omega_o \omega_i^2 + 2\omega_o^2 \zeta_i \omega_i) s + \omega_o^2 \omega_i^2, \end{aligned} \quad (29.45)$$

where the subscripts i, o represent the inner- and outer-loop values, respectively.

Comparing the coefficients of the poles of Eqs. (29.44) and (29.45) allows the gains to be expressed as a function of the desired pole locations for each axis in turn

$$\begin{aligned}
R_p &= \frac{\omega_o^2 \omega_i^2}{\omega_i^2 + 4\zeta_o \omega_o \zeta_i \omega_i + \omega_o^2} \\
R_d &= 2 \frac{\omega_o \omega_i (\zeta_o \omega_i + \omega_o \zeta_i)}{\omega_i^2 + 4\zeta_o \omega_o \zeta_i \omega_i + \omega_o^2} \\
K_p &= \omega_i^2 + 4\zeta_o \omega_o \zeta_i \omega_i + \omega_o^2 \\
K_d &= 2\zeta_i \omega_i + 2\zeta_o \omega_o.
\end{aligned} \tag{29.46}$$

Additionally, the zeros of the transfer function given by Eq. 29.44 affect the transient response. Thus, ω_i , ζ_i , ω_o , ζ_o must be selected such that performance is acceptable.

29.4.4 Imposing Response Characteristics

The methods presented in this chapter do not contain assumptions that limit its application to unmanned helicopters. Manned rotorcraft normally have to meet standards, such as those specified in the Aeronautical Design Standard-33 (2000) handling qualities specifications. Control system performance (Civita et al. 2002b; Rysdyk and Calise 2005) may be evaluated by imposing response requirements and computing metrics prescribed in the ADS-33. When there is no saturation, the hedging signals a_h , α_h are zero. When it is assumed that the adaptation has reached its ideal values of (V^*, W^*) , then

$$\begin{aligned}
\dot{v} &= a_{cr} + a_{pd} + \epsilon_a \\
\dot{\omega} &= \alpha_{cr} + \alpha_{pd} + \epsilon_\alpha,
\end{aligned}$$

where ϵ_a and ϵ_α are bounded by $\bar{\epsilon}$. Additionally, the Lyapunov analysis provides guaranteed model following, which implies a_{pd} and α_{pd} are small. Thus, $\dot{v} \approx a_{cr}$ and $\dot{\omega} \approx \alpha_{cr}$. Hence, as long as the preceding assumptions are valid over the bandwidth of interest, the desired response characteristics may be encoded into the reference model a_{cr} and α_{cr} .

29.5 Experimental Results

The proposed guidance and control architecture was applied to the Georgia Institute of Technology Yamaha RMAX helicopter (GTMax) shown in Fig. 29.2. The GTMax helicopter weighs about 157 lb and has a main rotor radius of 5.05 ft. Nominal rotor speed is 850 revolutions per minute. Its practical payload capability is about 66 lb with a flight endurance of greater than 60 min. It is also equipped with a Bell-Hillier stabilizer bar. Its avionics package includes a Pentium 266 flight control computer, an inertial measurement unit (IMU), a global positioning system, a 3-axis magnetometer, and a sonar altimeter. The control laws presented in this

chapter were first implemented in simulation (Kannan et al. 2004) using a nonlinear helicopter model that included flapping and stabilizer bar dynamics. Wind and gust models were also included. Additionally, models of sensors with associated noise characteristics were implemented. Many aspects of hardware such as the output of sensor model data as serial packets was simulated. This introduced digitization errors as would exist in real life and also allowed testing of many flight-specific components such as sensor drivers. The navigation system (Christophersen et al. 2006) consists of a 17-state Kalman filter to estimate variables such as attitude and terrain altitude. The navigation filter was executed at 100 Hz and corresponds to the highest rate at which the IMU is able to provide data. Controller calculations occurred at 50 Hz. The control laws were first implemented as C-code and tested in simulation. Because almost all aspects specific to flight testing were included in the simulation environment, a subset of the code from the simulation environment was implemented on the main flight computer. During flight, Ethernet and serial-based data links provided a link to the ground station computer that allowed monitoring and uploading of waypoints. A simple kinematics-based trajectory generator (with limits on accelerations) was used to generate smooth consistent trajectories (p_c, v_c, q_c, ω_c) for the controller. Various moderately aggressive maneuvers were performed during flight to test the performance of the trajectory tracking controller. Controller testing began with simple hover followed by step responses and waypoint navigation. Following initial flight tests, aggressiveness of the trajectory was increased by relaxing acceleration limits in the trajectory generator and relaxing ω_{lim} and v_{lim} in the reference models. Tracking error performance was increased by increasing the desired bandwidth of the controllers. Selected results from these flight tests are provided in the following sections.

29.5.1 Parameter Selections

The controller parameters for the inner loop involved choosing K_p, K_d based on a natural frequency of 2.5, 2, 3 rad/s for the roll, pitch, and yaw channels, respectively, and damping ratio of 1.0. For the outer loop, R_p, R_d were chosen based on a natural frequency of 2, 2.5, 3 rad/s for the x, y, and z body axes, all with a damping ratio of unity. The NN was chosen to have five hidden-layer neurons. The inputs to the network included body axis velocities and rates as well as the estimated pseudocontrols, that is, $x_{in} = [v_B^T, \omega_B^T, \hat{a}^T, \hat{\alpha}^T]$. The output layer learning rates Γ_W were set to unity for all channels, and a learning rate of $\Gamma_V = 10$ was set for all inputs. Limits on maximum translation rate and angular rate in the reference model dynamics were set to $v_{lim} = 10$ ft/s and $\omega_{lim} = 2$ rad/s. Additionally, attitude corrections from the outer loop, q_{des} were limited to 30° .

With regard to actuator magnitude limits, the helicopter has a radio-control transmitter that the pilot may use to fly the vehicle manually. The full deflections available on the transmitter sticks in each of the channels were mapped as $\delta_{lat}, \delta_{lon}, \delta_{ped} \in [-1, 1]$, corresponding to the full range of lateral tilt and longitudinal tilt of the swash plate and full range of tail rotor blade pitch. The collective

was mapped as $\delta_{coll} \in [-2.5, 1]$, corresponding to the full range of main rotor blade pitch available to the human pilot. The dynamic characteristics of the actuators were not investigated in detail. Instead, conservative rate limits were artificially imposed in software. Noting that $\delta = [\delta_{coll}, \delta_{lat}, \delta_{lon}, \delta_{ped}]^T$, the actuator model used for PCH purposes as well as artificially limiting the controller output has form

$$\dot{\delta} = \lim_{\lambda \rightarrow +\infty} \sigma \left(\lambda (\sigma(\delta_{des}, \delta_{\min}, \delta_{\max}) - \hat{\delta}), \dot{\delta}_{\min}, \dot{\delta}_{\max} \right), \quad (29.47)$$

where $\hat{\delta}$ is limited to lie in the interval $[\delta_{\min}, \delta_{\max}]$. The discrete implementation has the form

$$\begin{aligned} \hat{\delta}[k+1] = \sigma \left(\hat{\delta}[k] + \sigma \left(\sigma(\delta_{des}, \delta_{\min}, \delta_{\max}) - \hat{\delta}[k], \Delta T \dot{\delta}_{\min}, \Delta T \dot{\delta}_{\max} \right), \right. \\ \left. \delta_{\min}, \delta_{\max} \right), \end{aligned} \quad (29.48)$$

where ΔT is the sampling time. The magnitude limits were set to

$$\begin{aligned} \delta_{\min} &= [-2.5, -1, -1, -1]^T \\ \delta_{\max} &= [1, 1, 1, 1]^T \end{aligned} \quad (29.49)$$

units, and the rate limits were set to

$$\begin{aligned} \dot{\delta}_{\min} &= [-4, -2, -2, -2]^T \\ \dot{\delta}_{\max} &= [4, 2, 2, 2]^T \end{aligned} \quad (29.50)$$

units per second.

29.5.2 Flight Test

Finally, the controller was flight tested on the GTMax helicopter shown in Fig. 29.2. A lateral-position step response is shown in Fig. 29.8. The vehicle heading was regulated due north during this maneuver. Lateral control deflections during the maneuver were recorded and are also shown. A step heading command response and pedal control history is shown in Fig. 29.9. It should be noted that during flight tests, states were sampled at varying rates in order to conserve memory and data link bandwidth. The trajectory commands p_c, v_c, q_c, ω_c were sampled at 1 Hz; actuator deflections $\delta_{coll}, \delta_{lon}, \delta_{lat}$, and δ_{ped} were sampled at 50 Hz; and vehicle position and speed was sampled at 50 Hz. Since the command vector is sampled at a low rate (1 Hz), a step command appears as a fast ramp in figures.

Fig. 29.8 Response to a 20-ft step in the lateral direction

Fig. 29.9 Response to a 90° heading command

During takeoff and landing phases, a range sensor (sonar) is used to maintain and update the estimated local terrain altitude in the navigation system. The sonar is valid up to 8 ft above the terrain, sufficient for landing and takeoff purposes. Figure 29.10 illustrates the altitude and collective profile during a landing. The vehicle starts at an initial hover at 300 ft, followed by a descent at 7 ft/s until the vehicle is 15 ft above the estimated terrain. The vehicle then descends at 0.5 ft/s until weight on skids is automatically detected at which point the collective is slowly ramped down. Automatic takeoff (Fig. 29.11) is similar where the collective is slowly ramped up until weight on skids is no longer detected. It should be noted that NN adaptation is active at all times except when weight on skids is active. Additionally, when weight is on skids, the collective ramp-up during takeoff and ramp-down during landing is open loop.

The approximate model used to compute the dynamic inverse (Eqs. (29.32) and (29.31)) is based on a linear model of the dynamics in hover. To evaluate controller performance at different points of the envelope, the vehicle was commanded to track a trajectory that accelerated up to a speed of 100 ft/s. To account for wind, an upwind and downwind legs were flown. In the upwind leg, the vehicle accelerated up to 80 ft/s, and during the downwind leg, the vehicle accelerated up to a speed of 97 ft/s as shown in Fig. 29.12. Collective and longitudinal control deflections are also shown. In the upwind leg, the collective is saturated and the vehicle is unable to accelerate further. The longitudinal control deflections behave nominally as the vehicle accelerates and decelerates through a wide range of the envelope. The NN is able to adapt to rapidly changing flight conditions, from the baseline inverting design at hover through to the maximum speed of the aircraft. A conventional proportional-integral-derivative design would have required scheduling of gains throughout the speed range. More significantly, classical design would require accurate models at each point, unlike this design which does not. In addition to flight at high speeds, tracking performance was evaluated at moderate speeds, where a square pattern was flown at 30 ft/s for which position tracking is shown in Fig. 29.13. External command position tracking errors are shown in Fig. 29.14 with a peak total position error 3.3 ft and standard deviation of 0.8 ft.

Many maneuvers such as high-speed flight are quasi steady, in the sense that once in the maneuver, control deflection changes are only necessary for disturbance rejection. To evaluate performance where the controls have to vary significantly in order to track the commanded trajectory, the helicopter was commanded to perform a circular maneuver in the north-east plane with constant altitude and a constantly changing heading. The trajectory equations for this maneuver are given by

$$p_c = \begin{bmatrix} \frac{V}{\omega} \cos(\omega t) \\ \frac{V}{\omega} \sin(\omega t) \\ -h \end{bmatrix}, \quad v_c = \begin{bmatrix} -V \sin(\omega t) \\ V \cos(\omega t) \\ 0 \end{bmatrix},$$

$$\psi_c = \omega t f,$$

Fig. 29.10 Automatic landing maneuver

Fig. 29.11 Automatic takeoff maneuver

Fig. 29.12 High-speed forward flight up to 97 ft/s

Fig. 29.13 Flying a square pattern at 30 ft/s

where t is current time and h is a constant altitude command. V is speed of the maneuver, ω is angular speed of the helicopter around the maneuver origin, and f is number of 360° changes in heading to be performed per circuit. If $\omega = \pi/2$ rad/s, the helicopter will complete the circular circuit once every 4 s. If $f = 1$, the helicopter will rotate anticlockwise 360° once per circuit. Figure 29.15 shows the response to such a trajectory with parameters $\omega = 0.5$ rad/s, $f = 1$, $V = 10$ ft/s. After the initial transition into the circular maneuver, the tracking is seen to be within 5 ft. To visualize the maneuver easily, superimposed still images of the vehicle during the circular maneuver are shown. Both anticlockwise and clockwise heading changes during the maneuver were tested by changing the parameter from $f = 1$ (anticlockwise) to $f = -1$ (clockwise) at $t = 55$ s. Figure 29.16 shows that heading tracking is good in both cases. The time history of the pedal input δ_{ped} and all other controls during the maneuver is also shown and illustrates how the vehicle has to exercise all of its controls during this maneuver.

Next, the ability of the controller to track a previous manually flown maneuver was tested. First, a human pilot flew a figure-eight, three-dimensional pattern with the vehicle. Vehicle state was recorded and was then played back as commands to the adaptive controller. A 3D plot of the pilot and controller flown trajectories are shown in Fig. 29.17 along with projected ground track. Overall, the tracking in position was measured to be within 11.3 ft of the desired pilot-flown trajectory with a standard deviation of 4.7 ft.

Fig. 29.14 Command tracking errors while flying a square pattern at 30 ft/s

Finally, a tactically useful maneuver was flown to test controller performance at high speeds and pitch attitudes. The objective of the maneuver is to make a 180-degree velocity change from a forward flight condition of 70 ft/s north to a 70 ft/s forward flight going south. The trajectory command and response in the north-altitude plane is shown in Fig. 29.18 along with the pitch angle. A time history of the altitude and the collective control deflection is shown in Fig. 29.19. During the maneuver, the helicopter is commanded to increase altitude by up to 50 ft in order to minimize saturation of the down collective. In the deceleration phase, the vehicle is able to track the command trajectory well; however, in accelerating to 70 ft/s going south, tracking performance suffers. In both the acceleration and deceleration phases, poor tracking corresponds with saturation of the collective control. The oscillations in altitude in Fig. 29.19 are expected and are due to control saturation which limits the vehicle's descent rate. The large pitch attitudes experienced are what the outer-loop inversion evaluates as being required to perform such rapid decelerations and accelerations. This experiment is an example of maneuvering where the commanded trajectory is more aggressive than the capability of the vehicle and is reflected by the extended periods of saturation. It is possible to operate at the limits of the vehicle primarily due to PCH which protects the adaptation process.

29.5.3 Application to a Ducted Fan

Following tests on the GTMax helicopter, the control method presented in this chapter was applied to other smaller aircraft. The algorithms were ported to a custom DSP/FPGA hardware device (the FCS20) along with a small sensor board that contained gyroscopes and accelerometers for inertial sensing and a GPS. The avionics package weighed less than 1 lb and fell within the payload capacity of the 11-in. ducted fan (GTSpy). The GTSpy has a maximum takeoff weight of 5.5 lb and is driven by a two-bladed fixed-pitch propeller. The propeller is enclosed in an annular wing duct with an outer diameter of 11 in. Vanes located directly beneath the propeller move in order to provide yaw control about the propeller axis. Two sets of control surfaces located further below the propeller move in order to provide pitch and roll moments. Maneuvering is accomplished by tilting the thrust vector with the control surfaces relying primarily on inflow for dynamic pressure during hover. Following satisfactory tethered tests, the vehicle was untethered and allowed to fly simple missions. Figure 29.20 shows a plan view of a small 50-ft box maneuver and the GTSpy's tracking. The large deviation on the eastern side of the box is most likely due to a wind gust. Another maneuver performed was the mid-air deployment of the GTSpy. The GTSpy was mounted on the GTMax helicopter with its engine on and then deployed from a safe altitude. The GTSpy was able to recover from the initial deployment transient and maintain attitude and position within 5 s of launch. Figure 29.21 shows the GTSpy and GTMax during

Fig. 29.20 The GTSpy performing a box maneuver

Fig. 29.21 Deployment of the GTSpy ducted fan from the GTMax helicopter

the deployment transient. Both the GTMax and GTSpy were under computer control during this maneuver and is the first known deployment of a rotorcraft from another rotorcraft.

29.5.4 Application to a Fixed-Wing Aircraft

The control method presented in this chapter was further applied to a high thrust-to-weight ratio, fixed-wing aircraft with conventional aircraft controls and a fixed-pitch two-bladed propeller. The dynamic inverse used for control purposes approximated the aircraft in hover mode where the body axis was defined as

$$x_{heli} = L_2(-\pi/2)x_{airplane}$$

where L_2 is a rotation matrix around the airplane's body y-axis. Hence, the ailerons control helicopter yaw, the rudder controls helicopter roll, and the elevators continue to control pitch. The external commands provided to the control algorithm contains a commanded pitch angle as a function of speed. Inner-loop gains were based on 2.5, 1.5, 2.5 rad/s for the (helicopter) roll, pitch and yaw axes, respectively. Outer-loop gains were based on 1.5, 1.0, 0.7 rad/s for the x, y, and z helicopter body axes, respectively. The output layer learning rates Γ_W were set to unity on all channels and a learning rate of Γ_V was set for all inputs. Reference model parameters were set to $v_{lim} = 10$ ft/s and $\omega_{lim} = 1.0$ rad/s. The control effectiveness B was scaled based on speed in order to reflect the reduced control authority of the control surfaces in hover. Flight tests were initiated with the airplane performing circular orbits and

gradually lowering airspeed until hover. The reverse transition to forward flight was accomplished by a more aggressive command into forward flight.

The following figures illustrate the response of the aircraft during transitions between hover and forward flight. Figure 29.22 shows the vehicle in forward flight at 80 ft/s performing a circular orbit. At $t = 26$ s a transition to hover is initiated by supplying external trajectory commands that lower the vehicle's speed. Transition is completed at $t = 35$ s with a low residual speed of approximately 5 ft/s. At $t = 55$ s a transition back to forward flight at 80 ft/s is initiated and completed at $t = 65$ s. During hover, $t \in [35, 55]$, the control deflections are seen to be significantly higher due to the lower effectiveness at lower speeds. The ailerons are saturated for significant intervals in a particular direction in order to counteract engine torque.

Figure 29.23 illustrates the (helicopter) pitch angle during transitions as well as the throttle control deflections. In forward flight, the pitch angle is approximately -75° and varies in hover due to reduced control effectiveness and the presence of a steady wind. Additionally, Fig. 29.24 shows the position trajectory during transitions, whereas Fig. 29.25 is a snapshot of the aircraft during the maneuver.

29.5.5 Implementation of Concurrent-Learning Adaptive Controller on a VTOL UAV

Flight-test results of the concurrent-learning adaptive law described in Sect. 29.3 are presented in this section. The test vehicle is the GTMax rotorcraft UAV. The modification to the adaptive controller described in Sect. 29.2.2 include the concurrent-learning adaptive law of equations (Eq. 29.27) for a nonlinearly parameterized SHL NN. Data points were selected online based on Eq. 29.30 and were stored in a history stack limited to carrying 20 points. Once the history stack was full, a new data point was added by replacing the oldest data point. A fixed point smoother was used to estimate \dot{x}_j for a recorded data point using both forward and a backward Kalman filter (Chowdhary and Johnson 2011b; Gelb 1974). Typically this induced a selectable time delay introduced by the time required for the smoother to converge, however, this does not affect the instantaneous tracking error.

29.5.5.1 Repeated Forward-Step Maneuvers

The repeated forward-step maneuvers are chosen in order to create a relatively simple situation in which the controller performance can be compared over several similar maneuvers. By using concurrent-learning NN, improved performance is expected through repeated maneuvers and a faster convergence of weights. Figure 29.26 shows the body frame states from recorded flight data for a chain of forward-step inputs. Figure 29.27a, b shows the evolution of inner- and outer-loop errors. These results assert the stability (in the ultimate boundedness sense) of the combined concurrent and online learning approach.

Figure 29.28b, d show the evolution of NN W and V weights as the rotorcraft performs repeated step maneuvers and the NN is trained using the

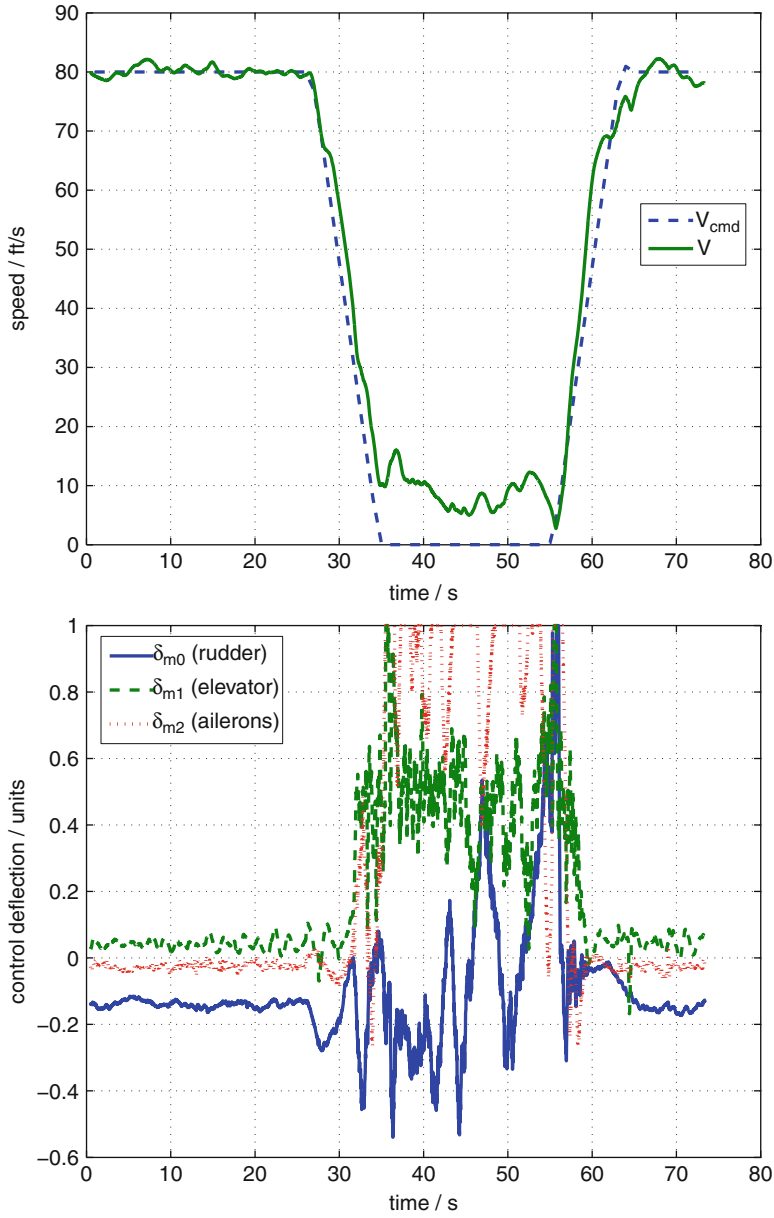

Fig. 29.22 GTEdge speed profile and control deflections during transitions between hover and forward flight

Fig. 29.23 GTEdge pitch angle, throttle profile during transitions between hover and forward flight

Fig. 29.24 GTEdge trajectory during transitions

Fig. 29.25 GTEdge during a transition

concurrent-learning method of Theorem 29.3. The NN V weights (Fig. 29.28b) appear to go to constant values when concurrent-learning adaptation is used, this can be contrasted with Fig. 29.28a which shows the V weight adaptation for a similar maneuver without concurrent-learning. NN W weights for both cases remain bounded, however it is seen that with concurrent learning adaptation the NN W weights seem to separate, this indicates alleviation of the rank-1 condition experienced by the baseline adaptive law relying only on instantaneous data (Chowdhary

Fig. 29.26 Recorded body frame states for repeated forward steps

and Johnson 2011b). The flight test results indicate a noticeable improvement in the error profile. In Fig. 29.26 it is seen that the UAV tends not to have a smaller component of body lateral velocity (v) through each successive step. This is also seen in Fig. 29.27b where it is noted that the error in v (body y axis velocity) reduces through successive steps. These effects in combination indicate that the combined online and concurrent-learning system is able to improve performance over the baseline controller through repeated maneuvers, indicating long-term learning. These results are of particular interest, since the maneuvers performed were conservative, and the baseline adaptive MRAC controller had already been extensively tuned.

29.5.5.2 Aggressive Trajectory Tracking Maneuvers

Flight-test results are presented for concurrent-learning adaptive controllers while tracking repeatedly an elliptical trajectory with aggressive velocity (50 ft/s) and acceleration (20 ft/s^2) profile. Since these maneuvers involve state commands in more than one system state it is harder to visually inspect the data and see whether an improvement in performance is seen, therefore the Euclidian norm of

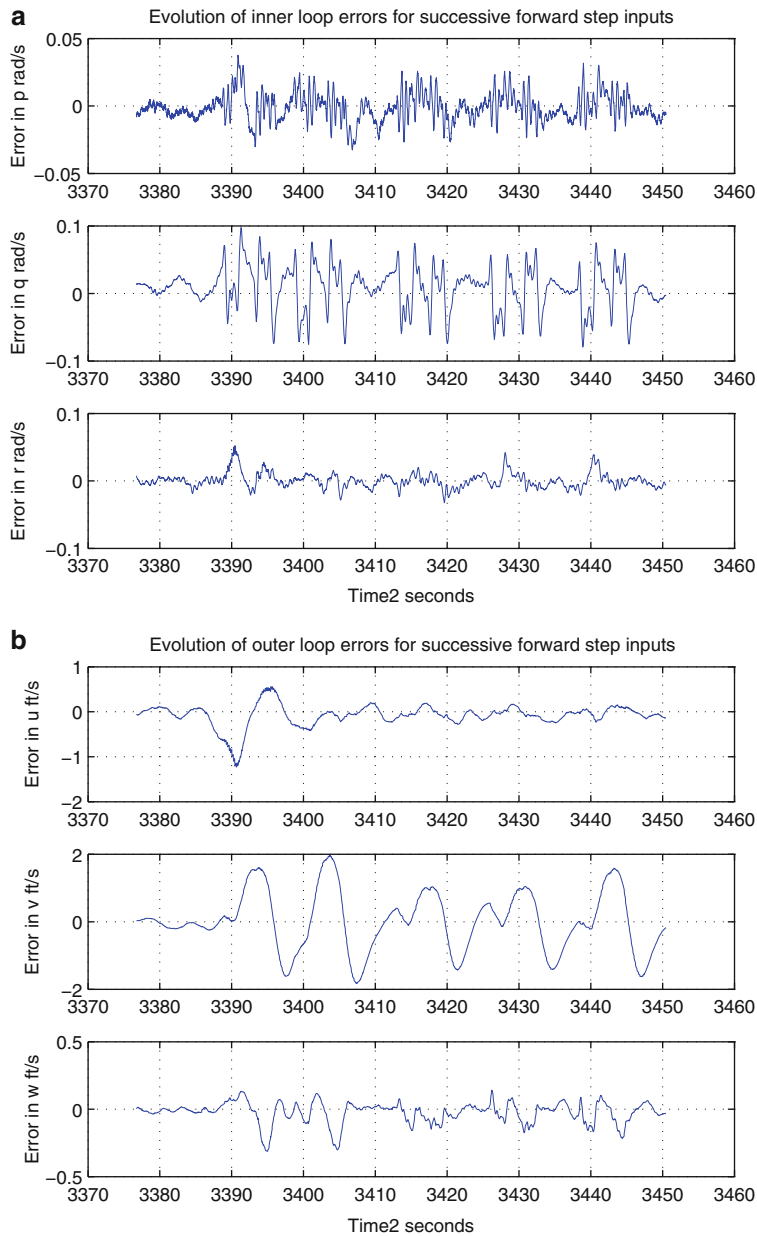

Fig. 29.27 GTMax recorded tracking errors for successive forward-step inputs with concurrent learning. **(a)** Evolution of inner loop errors with concurrent adaptation. **(b)** Evolution of outer loop errors with concurrent adaptation

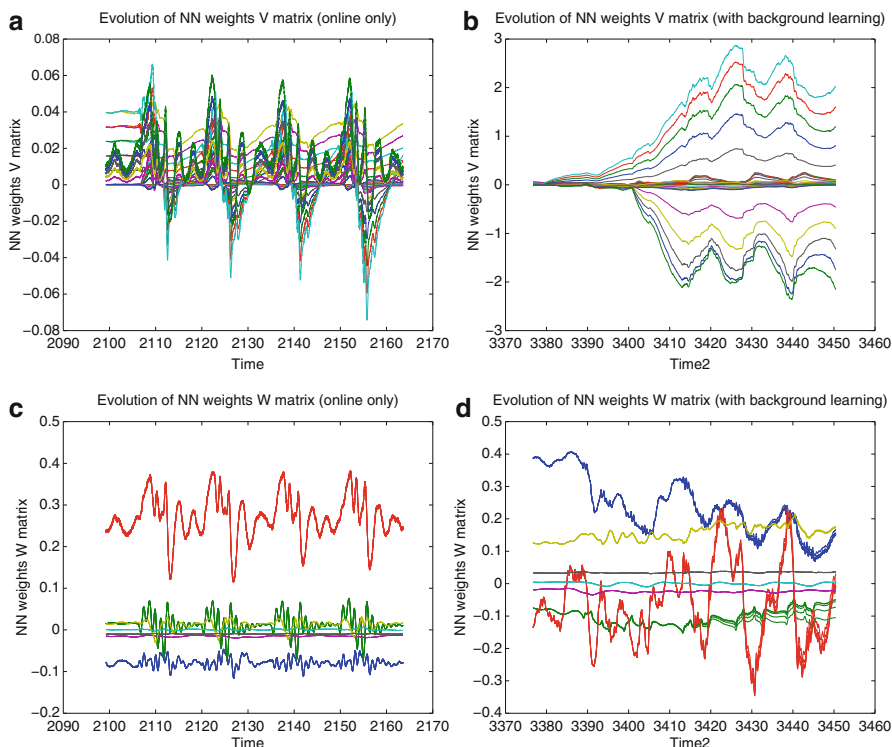

Fig. 29.28 Comparison of weight convergence on GTMax with and without concurrent learning. (a) Evolution of V matrix weights with only online adaptation. (b) Evolution of V matrix weights with concurrent adaptation. (c) Evolution of W matrix weights with only online adaptation. (d) Evolution of W matrix weights with concurrent adaptation

the error signal at each time step is used as a rudimentary metric. Figure 29.29 shows the recorded inner- and outer-loop states as the rotorcraft repeatedly tracks an oval trajectory pattern. In this flight, the first two ovals (until $t = 5415$ s) are tracked with a commanded acceleration of 30 ft/s^2 , while the rest of the ovals are tracked at 20 ft/s^2 . In the following both these parts of the flight test are discussed separately.

29.5.5.3 Aggressive Trajectory Tracking with Saturation in the Collective Channel

Due to the aggressive acceleration profile of 30 ft/s^2 the rotorcraft collective channels were observed to saturate while performing high velocity turns. This leads to an interesting challenge for the adaptive controller equipped with pseudocontrol hedging. Figure 29.30 shows the evolution of the innerloop and outerloop tracking error. It can be clearly seen that the tracking error in the u (body x axis velocity)

Fig. 29.29 Recorded body frame states for repeated oval maneuvers

channel reduces in the second pass through the ellipse indicating long-term learning by the combined online and concurrent-learning adaptive control system. This result is further characterized by the noticeable reduction in the norm of the tracking error at every time step as shown in Fig. 29.31.

29.5.5.4 Aggressive Trajectory Tracking Maneuver

For the results presented in this section, the acceleration profile was reduced to 20 ft/s^2 . At this acceleration profile, no saturation in the collective input was noted. Figure 29.32 shows the evolution of tracking error, and Fig. 29.33a shows the plot of the norm of the tracking error at each time step.

29.5.5.5 Aggressive Trajectory Tracking Maneuvers with Only Online Learning NN

The performance of the concurrent-learning adaptive controller is compared with the traditional instantaneous update-based adaptive controllers for the maneuvers described in Sect. 29.5.5.3.

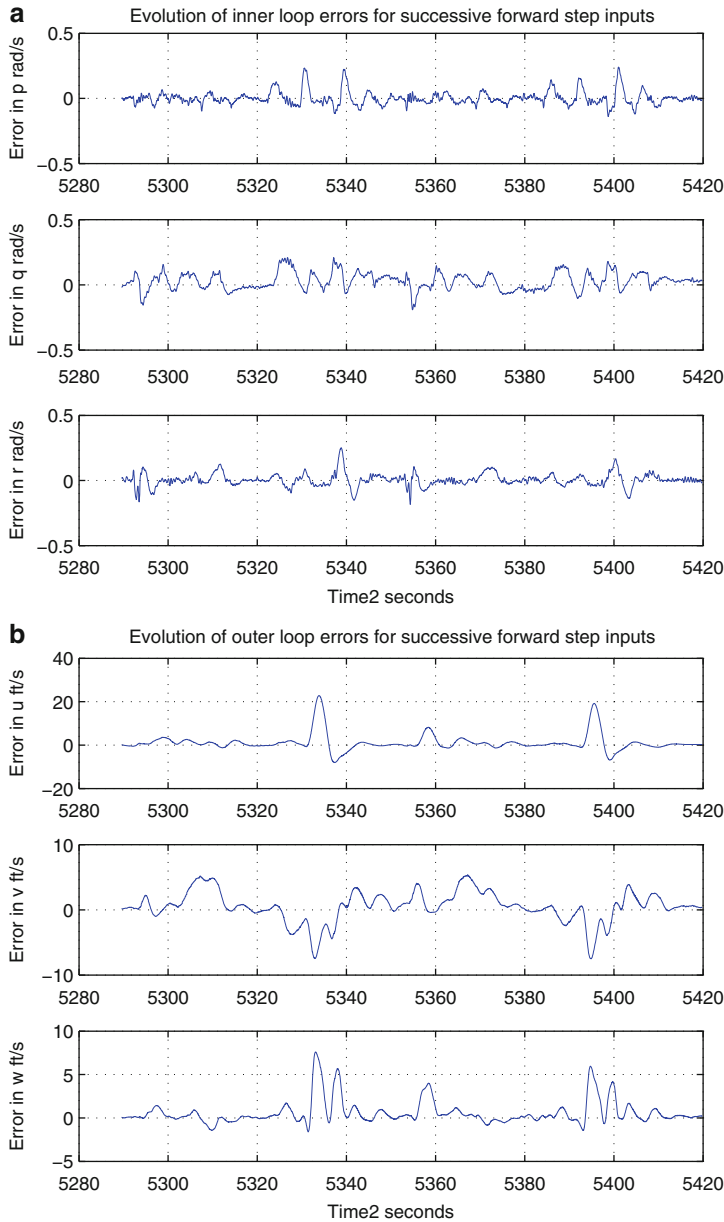

Fig. 29.30 GTMax recorded tracking errors for aggressive maneuvers with saturation in collective channels with concurrent learning. (a) Evolution of inner-loop errors with concurrent adaptation. (b) Evolution of outer-loop errors with concurrent adaptation

Fig. 29.31 Plot of the norm of the error at each time step for aggressive trajectory tracking with collective saturation

It is instructive to compare Fig. 29.34b, d which show the evolution of the NN weights with only instantaneous learning with Fig. 29.34a, c which show evolution of the NN weights with concurrent learning. Although absolute convergence of weights is not seen, as expected due to Theorem 29.3, it is interesting to see that when concurrent learning is on, the weights tend to be less oscillatory than when only instantaneous learning is used. Also, with combined online and concurrent learning, the weights do not tend to go to zero as the rotorcraft hovers between two successive tracking maneuvers. Figure 29.33b shows the plot of the tracking error norm as a function of time without concurrent learning. Comparing this figure with Fig. 29.33a, it can be clearly seen that the norm of the error vector is much higher when only online learning is used. This indicates that the combined online and concurrent-learning adaptive controller has improved trajectory tracking performance.

In summary, the flight test results ascertain an expected improvement in tracking performance. Furthermore, the evolution of the neural network W and V matrix weights were observed to have different characteristics when concurrent learning was employed, including weight separation, a tendency toward weight convergence in some cases, and different numerical values of the adaptive weights. This difference in neural network weight behavior demonstrates the effect of overcoming the rank 1 condition.

29.6 Conclusion

The objective in this chapter has been to provide an affordable control design solution that uses minimal prior knowledge of the vehicle dynamics. This is accomplished by relying on adaptation to cover the flight envelope of the helicopter

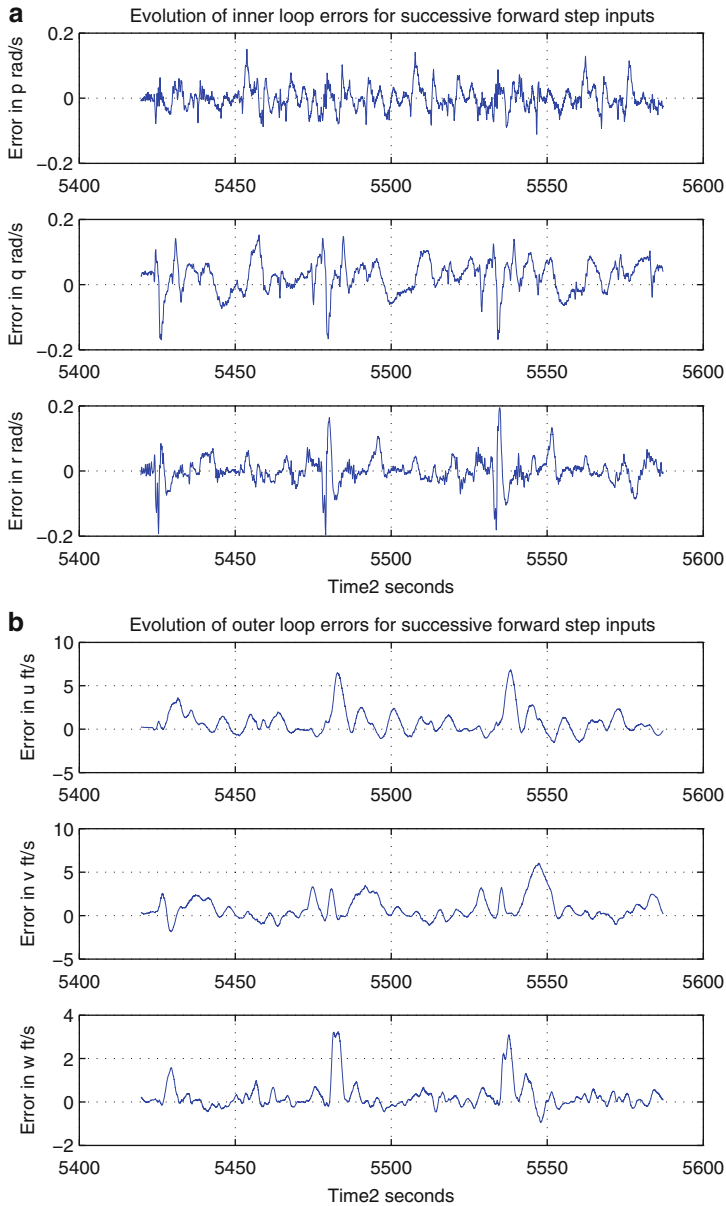

Fig. 29.32 GTMax recorded tracking errors for aggressive maneuvers with concurrent learning. (a) Evolution of inner-loop errors with concurrent adaptation. (b) Evolution of outer-loop errors with concurrent adaptation

under nominal conditions. Under mission-specific variations in the environment and system dynamics due to payload changes or damage, adaptation allows little or no human intervention after deployment. This approach is also in agreement with the DoD UAS Roadmap which subscribes to the following view on UAVs: “...affordability will be treated as a key performance parameter (KPP) equal to, if not more important than, schedule and technical performance...”.

Fig. 29.35 Neural network with one hidden layer

A Adaptive Element

Single hidden layer (SHL) perceptron NNs are universal approximators (Hornik et al. 1989b; Spooner et al. 2002; Lewis 1999). Hence, given a sufficient number of hidden layer neurons and appropriate inputs, it is possible to train the network online to cancel model error.

Figure 29.35 shows the structure of a generic single hidden layer network whose input-output map may be expressed as

$$v_{ad_k} = b_w \theta_{w_k} + \sum_{j=1}^{n_2} w_{jk} \sigma_j(z_j), \quad (29.51)$$

where $k = 1, \dots, n_3$, b_w is the outer layer bias, θ_{w_k} is the k th threshold. w_{jk} represents the outer layer weights, z_j is the input to the neurons, and the scalar σ_j is a sigmoidal activation function

$$\sigma_j(z_j) = \frac{1}{1 + e^{-az_j}}, \quad (29.52)$$

where a is the so-called activation potential and may have a distinct value for each neuron. z_j is the input to the j th hidden layer neuron and is given by

$$z_j = b_v \theta_{v_j} + \sum_{i=1}^{n_1} v_{ij} x_{in_i}, \quad (29.53)$$

where b_v is the inner layer bias and θ_{v_j} is the j th threshold. Here, n_1, n_2 , and n_3 are the number of inputs, hidden layer neurons, and outputs, respectively. x_{in_i} , $i = 1, \dots, n_1$, denotes the inputs to the NN. For convenience, define the following weight matrices:

$$V \triangleq \begin{bmatrix} \theta_{v,1} & \cdots & \theta_{v,n_2} \\ v_{1,1} & \cdots & v_{1,n_2} \\ \vdots & \ddots & \vdots \\ v_{n_1,1} & \cdots & v_{n_1,n_2} \end{bmatrix}, \quad (29.54)$$

$$W \triangleq \begin{bmatrix} \theta_{w,1} & \cdots & \theta_{w,n_3} \\ w_{1,1} & \cdots & w_{1,n_3} \\ \vdots & \ddots & \vdots \\ w_{n_2,1} & \cdots & w_{n_2,n_3} \end{bmatrix}, \quad (29.55)$$

$$Z \triangleq \begin{bmatrix} V & 0 \\ 0 & W \end{bmatrix}. \quad (29.56)$$

Additionally, define the $\sigma(z)$ vector as

$$\sigma^T(z) \triangleq [b_w \sigma(z_1) \cdots \sigma(z_{n_2})], \quad (29.57)$$

where $b_w > 0$ allows for the thresholds, θ_w , to be included in the weight matrix W . Also, $z = V^T \bar{x}$, where

$$\bar{x}^T = [b_v x_{\text{in}}^T], \quad (29.58)$$

where $b_v > 0$ is an input bias that allows for thresholds θ_v to be included in the weight matrix V . The input-output map of the SHL network may now be written in concise form as

$$v_{ad} = W^T \sigma(V^T \bar{x}). \quad (29.59)$$

The NN may be used to approximate a nonlinear function, such as $\Delta(\cdot)$. The universal approximation property (Hornik et al. 1989b) of NNs ensures that given an $\bar{\epsilon} > 0$, then $\forall \bar{x} \in \mathcal{D}$, where \mathcal{D} is a compact set, \exists an \bar{n}_2 , and an ideal set of weights (V^*, W^*) brings the output of the NN to within an ϵ -neighborhood of the function approximation error. This ϵ is bounded by $\bar{\epsilon}$ which is defined by

$$\bar{\epsilon} = \sup_{\bar{x} \in \mathcal{D}} \|W^T \sigma(V^T \bar{x}) - \Delta(\bar{x})\|. \quad (29.60)$$

The weights (V^*, W^*) may be viewed as optimal values of (V, W) in the sense that they minimize $\bar{\epsilon}$ on \mathcal{D} . These values are not necessarily unique. The universal approximation property thus implies that if the NN inputs x_{in} are chosen to reflect the functional dependency of $\Delta(\cdot)$, then $\bar{\epsilon}$ may be made arbitrarily small given a sufficient number of hidden layer neurons, n_2 .

Abstract

This chapter contains a collection of reliable, efficient, robust, and adaptive control methods for aerial vehicles. It begins with a brief overview of flight dynamics models suitable for flight control design. The first control design method represents the well-understood and now-classical linear quadratic regulator (LQR) command tracker, with proportional-integral (PI) feedback connections. Such a system is the backbone of all other methods presented in this chapter. The main intent here is to demonstrate the design of predictable, formally justified, yet numerically efficient flight controllers, with an LQR PI baseline and with a direct model reference adaptive control (MRAC), as an augmentation

to the baseline. Through extensive simulation, analysis, and actual flight testing, it has been found that (LQR PI + adaptive) – controllers provide robust stability and maintain tracking performance, when operated in the presence of “unknown unknowns” in the vehicle dynamics and in often “unfriendly” operational environment. Finally, a note is in order: All control methods described in this chapter were successfully flight tested and validated on a wide range of aerial vehicles.

30.1 Introduction

Robust control is an online policy capable of regulating systems (such as aerial vehicles) with bounded uncertainties in their dynamics. A robust controller would work satisfactorily for a set of plants, whether linear or nonlinear, while assuming the worst case conditions on uncertainties in the vehicle dynamics. Excluding ad hoc designs, all reliable control methods are model based. One often starts with a mathematical model of the vehicle. Such a model would be valid in a preset domain. The model may or may not be accurate in capturing significant effects in the vehicle dynamics. In order to overcome modeling deficiencies, one should seek a robust solution, designed based on the model, yet capable of controlling the real vehicle, and not just the model. It would also be highly desirable to have a controller whose performance “gracefully degrades” in the presence of uncertainties so that it would not abruptly break down when unprecedented events occur.

Embedding robustness properties into a control solution must be treated as one of the main criteria in any control design. For example, achieving closed-loop stability and tracking performance, while providing adequate stability margins, are the main goals, especially when dealing with linear system approximations of real processes. Methods and techniques to achieve this goal will be provided. Once a robust control solution is found, its robustness properties can be further extended to cover a wider class of uncertainties in the system dynamics. Such a problem could be addressed within the framework of adaptive control. It may allow the designer to cope with unbounded state-dependent nonlinear uncertainties that may exist in the vehicle dynamics.

What is the difference between robust and adaptive controllers? A robust controller is designed to operate under the worst case condition assumption. Such a controller may use excessive actions to accomplish the goal. In contrast, an adaptive controller would try to perform an online estimation of the process uncertainty, and then produce a control input to anticipate, overcome, or minimize the undesirable deviations from the prescribed closed-loop plant behavior. In addition to their adaptive properties, these controllers can be constructed to “learn” or equivalently to remember prior events. In this context, the notion of learning refers to remembering certain patterns, and then acting based on prior knowledge or “memory.” For instance, a tracking error integrator in a feedback loop is a learning controller. It accumulates and integrates regulation errors based on previous and current data.

It will be shown that an adaptive controller represents a nonlinear extension of a linear feedback integrator. In other words, adaptive loops form their output by integrating nonlinear functions of the system tracking errors.

A discussion of whether adaptive controllers outperform robust systems or vice versa is of no merit. One can argue that it is rather a seamless combination of both controllers that works best, in the sense of maintaining closed-loop stability, enforcing robustness to uncertainties, and delivering target performance, all and all while operating in the presence of unanticipated events.

30.2 Aircraft Flight Dynamics Equations of Motion

Six-degrees-of-freedom (6-DoF) rigid aircraft equations of motion can be derived based on Newton's second law of motion. These dynamics are often expressed in the aircraft-fixed body axes coordinate system (Etkin 1982; McRuer et al. 1990; Stevens and Lewis 1992). In general, the 6-DoF equations of motion represent a continuous dynamical multi-input–multi-output system in the standard state-space form,

$$\dot{x} = f(x, u), \quad y = h(x, u) \quad (30.1)$$

with the state x , the control input u , and the measured/regulated output y . An attempt to use the fully coupled model (30.1) for control design would most likely result in an impractical control solution of unnecessary complexity and with a highly undesirable sensitivity due to model data. This phenomenon immediately presents a modeling-for-control challenge: How detailed does a control-oriented model need to be, so that the resulting control solution is simple, robust, effective, and works per design specifications, when applied to a real vehicle? The answer to this question of course depends on the application of interest. In the next section, simplified flight dynamics models for control design purposes will be constructed.

30.3 Simplified Flight Dynamics for Control Design

The 6-DoF motion of an aerial vehicle can be decomposed into a mean or a steady-state motion near an operating point (called “trim”) and perturbation dynamics around the trim conditions. Such a decomposition allows one to reduce the overall nonlinear fully coupled 6-DoF aircraft dynamics into a tractable form, suitable for control design and analysis. The notion of “trimming an aircraft” refers to finding a balance, or equilibrium, between aerodynamic, propulsive, and gravitational forces and moments that are constantly acting on the vehicle. In flight, an aircraft is trimmed by setting its primary controls to values that would result in the desired steady-state flight conditions. The trim function would be performed by a pilot or by an automatic flight control system.

Fig. 30.1 Aircraft operational flight envelope, as a function of altitude and airspeed

In mathematical terms, one is looking for a system equilibrium pair $(\vec{x}_{eq}, \vec{u}_{eq})$ in (30.1) such that the translational and angular accelerations are zeroed out:

$$0 = f(x_{eq}, u_{eq}) \quad (30.2)$$

These are steady-state flight conditions. Accelerated flight equilibrium is also possible.

An aircraft would have many distinct equilibrium points throughout the vehicle flight operational envelope (Fig. 30.1).

These trim points depend first hand on altitude and airspeed. Based on available trim flight conditions, the main idea behind constructing control-oriented models and then performing flight control design consists of several distinct steps. They are:

1. Cover the flight envelope with a dense set of trim points.
2. Write simplified linear models around each of the trim point.
3. Use these dynamics to design fixed-point flight controllers per point.
4. Interpolate (i.e., gain schedule based on flight conditions) to combine linear controllers.

The result is a gain-scheduled flight control system that would be valid for the entire operational envelope. In what follows, only Step 2 will be discussed, and linear simplified models (deviation dynamics from equilibrium) for a selected trim point will be defined.

When a conventional aircraft is trimmed wings level, at selected flight conditions, the vehicle dynamics naturally decouples into longitudinal and lateral-directional modes. Each of these modes is presented separately.

30.3.1 Longitudinal Dynamics

The aircraft longitudinal dynamics describe changes in forward, vertical, and pitching motion of the vehicle. These dynamics can be further decomposed into fast and slow components, or modes. The former is called the short-period and the

latter is the phugoid. Typically, there would be a time-scale separation between the two modes. The short-period describes fast coupling between the aircraft angle of attack and the pitch rate. The phugoid represents a much slower (when compared to the short-period) dynamic interchange between the vehicle altitude and airspeed, or, equivalently, between the aircraft potential and kinetic energy levels.

The short-period and the phugoid modes can be revealed after the aircraft model is linearized around a trim point (an equilibrium). For clarity of presentation, it is assumed that the thrust line is aligned with the vehicle x -axis. Then, the aircraft longitudinal equations of motion are

$$\begin{pmatrix} \dot{v}_T \\ \dot{\alpha} \\ \dot{q} \\ \dot{\theta} \end{pmatrix} = \begin{pmatrix} X_V & X_\alpha & 0 & -g \cos \gamma_0 \\ \frac{Z_V}{V_0} & \frac{Z_\alpha}{V_0} & 1 + \frac{Z_q}{V_0} & -\frac{g \sin \gamma_0}{V_0} \\ M_V & M_\alpha & M_q & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} v_T \\ \alpha \\ q \\ \theta \end{pmatrix} + \begin{pmatrix} X_{\delta_{th}} \cos \alpha_0 & X_{\delta_e} \\ -X_{\delta_{th}} \sin \alpha_0 & \frac{Z_{\delta_e}}{V_0} \\ M_{\delta_{th}} & M_{\delta_e} \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \delta_{th} \\ \delta_e \end{pmatrix} \quad (30.3)$$

where V_0 is the trimmed airspeed and α_0 is trimmed angle of attack, $\gamma_0 = \theta_0 - \alpha_0$ is the trimmed flight path angle, θ_0 is the trimmed pitch angle, δ_{th} is the throttle position, and δ_e is the elevator position. The model states (v_T , α , q , θ) and the control inputs (δ_{th} , δ_e) are incremental due to their trimmed values. Also in (30.3), the matrix components represent constant (for fixed flight conditions) stability and control derivatives of the aircraft forces and moments, with respect to the longitudinal states and control inputs. When aircraft-specific values of these derivatives are substituted into model (30.3), most often the open-loop system eigenvalues will consist of a fast (short-period) and a slow (phugoid) pair of complex conjugate numbers. Such a decomposition explains the time-scale separation in the longitudinal dynamics of an aircraft.

The short-period mode is defined by the dynamics of α and q . Extracting those from model (30.3) yields

$$\begin{pmatrix} \dot{\alpha} \\ \dot{q} \end{pmatrix} = \begin{pmatrix} \frac{Z_\alpha}{V_0} & 1 + \frac{Z_q}{V_0} \\ M_\alpha & M_q \end{pmatrix} \begin{pmatrix} \alpha \\ q \end{pmatrix} + \begin{pmatrix} \frac{Z_{\delta_e}}{V_0} \\ M_{\delta_e} \end{pmatrix} \delta_e \quad (30.4)$$

These dynamics describe aircraft motion on a short interval of time, due to elevator input. In aerospace applications, the short-period system is utilized quite often to support the development of robust and adaptive control technologies.

30.3.2 Lateral-Directional Dynamics

Assuming constant thrust, airspeed, and angle of attack, lateral-directional dynamics of an aircraft can be derived by linearization of the 6-DoF system (30.2), around a selected trim point. The resulting dynamics are

$$\begin{pmatrix} \dot{\varphi} \\ \dot{\beta} \\ \dot{p}_s \\ \dot{r}_s \end{pmatrix} = \begin{pmatrix} 0 & 0 & \frac{\cos \gamma_0}{\cos \theta_0} & \frac{\sin \gamma_0}{\cos \theta_0} \\ \frac{g \cos \theta_0}{V_0} & \frac{Y_\beta}{V_0} & \frac{Y_p}{V_0} & \frac{Y_r}{V_0} - 1 \\ 0 & L_\beta & L_p & L_r \\ 0 & N_\beta & N_p & N_r \end{pmatrix} \begin{pmatrix} \varphi \\ \beta \\ p_s \\ r_s \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ \frac{Y_{\delta_{\text{ail}}}}{V_0} & \frac{Y_{\delta_{\text{rud}}}}{V_0} \\ L_{\delta_{\text{ail}}} & L_{\delta_{\text{rud}}} \\ N_{\delta_{\text{ail}}} & N_{\delta_{\text{rud}}} \end{pmatrix} \begin{pmatrix} \delta_{\text{ail}} \\ \delta_{\text{rud}} \end{pmatrix} \quad (30.5)$$

When the airspeed is sufficiently high, the gravity term in (30.5) becomes negligible: $\frac{g \cos \theta_0}{V_0} \approx 0$. In this case, the bank dynamics can be eliminated:

$$\begin{pmatrix} \dot{\beta} \\ \dot{p}_s \\ \dot{r}_s \end{pmatrix} = \begin{pmatrix} \frac{Y_\beta}{V_0} & \frac{Y_p}{V_0} & \frac{Y_r}{V_0} - 1 \\ L_\beta & L_p & L_r \\ N_\beta & N_p & N_r \end{pmatrix} \begin{pmatrix} \beta \\ p_s \\ r_s \end{pmatrix} + \begin{pmatrix} \frac{Y_{\delta_{\text{ail}}}}{V_0} & \frac{Y_{\delta_{\text{rud}}}}{V_0} \\ L_{\delta_{\text{ail}}} & L_{\delta_{\text{rud}}} \\ N_{\delta_{\text{ail}}} & N_{\delta_{\text{rud}}} \end{pmatrix} \begin{pmatrix} \delta_{\text{ail}} \\ \delta_{\text{rud}} \end{pmatrix} \quad (30.6)$$

The resulting third-order lateral-directional linear model would be suitable for a control design where the goal is to regulate the vehicle roll and yaw rates, as well as the angle of sideslip.

30.3.3 Model Generalizations for Adaptive Control Design

The aircraft short-period dynamics (30.4), as well as the lateral-directional models (30.5) and (30.6), belong to a class of linear time-invariant controllable systems in the form

$$\dot{x} = Ax + Bu \quad (30.7)$$

with the n -dimensional state x , the m -dimensional control u , the p -dimensional output:

$$y = Cx + Du \quad (30.8)$$

and with the matrices (A, B, C, D) of the corresponding dimensions.

In the next section, methods to construct and analyze robust linear LQR-optimal controllers are presented. The focus is on adaptive control techniques, with the goal of maintaining closed-loop stability and robustness in the presence of unexpected events. Specifically, inserting uncertainties into (30.7) and (30.8) results in the dynamical system

$$\dot{x} = Ax + B \Lambda (u + f(x)) \quad (30.9)$$

where the $(m \times m)$ -matrix Λ represents control actuation failures and the m -dimensional state-dependent vector function $f(x)$ denotes all other “unknown unknowns” in the system dynamics. The uncertain model (30.9) constitutes an attempt to embed extra realism into the “ideal” system (30.7). The uncertainties in (30.9) are called “matched,” in the sense that they enter the system dynamics through control channels. So, as long as Λ is invertible, the system controllability property is preserved. It so happens that the matched uncertainty assumption implies

existence of at least one control solution, capable of steering the system state along the desired trajectories.

Of interest are command tracking problems with nonmatched but bounded uncertainties, such as time-dependent noise and environmental disturbances, represented by an n -dimensional uniformly bounded piece-wise continuous vector function $\xi(t)$:

$$\dot{x} = Ax + B\Lambda(u + f(x)) + \xi(t) \quad (30.10)$$

Care must be taken in specifying conditions on $\xi(t)$ that preserve controllability of the system. So as long as the system remains controllable, the unwanted effects caused by bounded noise and disturbances can be mitigated through proper control synthesis. The forthcoming sections explore robust and adaptive methods to control uncertain systems, such as (30.9) and (30.10).

Readers may find the matched uncertainty assumption to be restrictive. Some may even argue that there are many dynamical systems, stemming from realistic applications, that do not satisfy the matching conditions. This is a true statement indeed. However, in aerospace applications, matched uncertainties are of primary concern. They represent unknown aerodynamic and thrust effects that may exist in the vehicle moments. These uncertainties are “matched” by available controls (such as elevator, aileron, rudder, etc.), in the sense that the moments explicitly depend on the control inputs, and the latter can be selected to counter (i.e., cancel or dominate) the matched uncertainties. In essence, moment regulation for an aircraft implies total control of the vehicle, and uncertain dynamical systems in the form of (30.10) can be utilized to achieve that goal. Finally, it is worth noting that the adaptive control methods presented in this chapter can be extended to handle systems with nonlinear-in-control matched uncertainties and with nonmatched uncertain dynamics, but these extensions are outside of the present scope.

30.4 Model Following LQR PI Command Tracking

For a linear time-invariant (LTI) system, such as (30.7), a model following command tracking control design can be defined to represent an LQR-optimal controller, with PI feedback connections. Overall, this design method generalizes the well-known servomechanism approach to a model following design.

Consider an LTI system in the form

$$\begin{aligned} \dot{x}_p &= A_p x_p + B_p u \\ y_p &= C_p x_p + D_p u \end{aligned} \quad (30.11)$$

where $x_p \in R^{n_p}$ is the n_p -dimensional state vector, $u \in R^{m_p}$ is the m_p -dimensional vector of controls, $y_p \in R^{p_p}$ is the system p_p -dimensional vector of regulated outputs with $p_p \leq m_p$, and plant matrices (A_p, B_p, C_p, D_p) are of the corresponding dimensions. Moreover, it is assumed that matrix pair (A_p, B_p) is

stabilizable and the entire state vector x_p is available online as the system output measurement.

The control task of interest is command tracking, that is, one needs to find u such that the regulated output y_p tracks its target $y_{\text{ref}} \in \mathbb{R}^{p_p}$, while all other signals in the system remain bounded.

Desired dynamics of the target output y_{ref} is defined via the reference model:

$$\begin{aligned}\dot{x}_{\text{ref}} &= A_{\text{ref}} x_{\text{ref}} + B_{\text{ref}} r(t) \\ y_{\text{ref}} &= C_{\text{ref}} x_{\text{ref}} + D_{\text{ref}} r(t)\end{aligned}\quad (30.12)$$

where $x_{\text{ref}} \in \mathbb{R}^{n_{\text{ref}}}$ is the state of the reference dynamics, $r(t)$ represents a bounded external command, and matrices $(A_{\text{ref}}, B_{\text{ref}}, C_{\text{ref}}, D_{\text{ref}})$ are of the corresponding dimensions, with A_{ref} being Hurwitz. Furthermore, it is assumed that the system DC gain matrix is unity, that is

$$DC_{\text{gain}}^{\text{ref}} = -C_{\text{ref}} A_{\text{ref}}^{-1} B_{\text{ref}} + D_{\text{ref}} = I_{m_p \times m_p} \quad (30.13)$$

Note that the dimension of the reference model $n_{\text{ref}} \geq p_p$, and it does not have to be the same as the dimension of the plant n_p .

Extended open-loop dynamics is formed as a combination of the plant and the reference model:

$$\underbrace{\begin{pmatrix} \dot{x}_p \\ \dot{x}_{\text{ref}} \end{pmatrix}}_{\dot{x}} = \underbrace{\begin{pmatrix} A_p & 0_{n_p \times n_{\text{ref}}} \\ 0_{n_{\text{ref}} \times n_p} & A_{\text{ref}} \end{pmatrix}}_A \underbrace{\begin{pmatrix} x_p \\ x_{\text{ref}} \end{pmatrix}}_x + \underbrace{\begin{pmatrix} B_p \\ 0_{n_{\text{ref}} \times m_p} \end{pmatrix}}_B u + \underbrace{\begin{pmatrix} 0_{n_p \times m_p} \\ B_{\text{ref}} \end{pmatrix}}_{B_r} r(t) \quad (30.14)$$

Its regulated output can be written as

$$y = y_p - y_{\text{ref}} = C_p x_p + D_p u - C_{\text{ref}} x_{\text{ref}} - D_{\text{ref}} r(t) \quad (30.15)$$

or, equivalently in matrix form as

$$y = \underbrace{(C_p - C_{\text{ref}})}_C \underbrace{\begin{pmatrix} x_p \\ x_{\text{ref}} \end{pmatrix}}_x + \underbrace{D_p}_D u + \underbrace{(-D_{\text{ref}})}_{D_r} r(t) \quad (30.16)$$

Combining (30.14) and (30.16) yields extended open-loop dynamics in matrix form:

$$\begin{aligned}\dot{x} &= A x + B u + B_r r(t) \\ y &= C x + D u + D_r r(t)\end{aligned}\quad (30.17)$$

Note the explicit presence of the command $r(t)$ in the plant formulation (30.17). This is one way to embed a reference model tracking into the control problem

formulation. Once again, one must choose the reference model data such that the extended system (30.17) remains controllable.

In terms of (30.17), the control task consists of finding u such that the system output y asymptotically tends to the origin. In other words, the control design task is output stabilization in the presence of any known, bounded, and possibly time-varying external command signal $r(t)$.

In order to track a step-input command with zero errors (type-1 response), integral control will be employed. A convenient technique for designing a practical tracker is the command-generator tracker (CGT) method, where the tracking problem is converted into a regulator problem (Franklin et al. 1986). Toward that end, integrated tracking error vector e_{yI} is introduced into the system dynamics (30.17):

$$\begin{aligned}\dot{e}_{yI} &= y \\ \dot{x} &= Ax + Bu + B_r r \\ y &= Cx + Du + D_r r\end{aligned}\tag{30.18}$$

Rewriting the dynamics in matrix form gives

$$\underbrace{\begin{pmatrix} \dot{e}_{yI} \\ \dot{x} \end{pmatrix}}_{\dot{\tilde{x}}} = \underbrace{\begin{pmatrix} 0_{p_p \times p_p} & C \\ 0_{n_p \times p_p} & A \end{pmatrix}}_{\tilde{A}} \underbrace{\begin{pmatrix} e_{yI} \\ x \end{pmatrix}}_{\tilde{x}} + \underbrace{\begin{pmatrix} D_p \\ B \end{pmatrix}}_{\tilde{B}} u + \underbrace{\begin{pmatrix} D_r \\ B_r \end{pmatrix}}_{\tilde{B}_r} r(t)\tag{30.19}$$

with the regulated output defined as

$$y = \underbrace{(0_{p_p \times p_p} \ C)}_{\tilde{C}} \underbrace{\begin{pmatrix} e_{yI} \\ x \end{pmatrix}}_{\tilde{x}} + \underbrace{D}_{\tilde{D}} u + \underbrace{D_r}_{\tilde{D}_r} r(t)\tag{30.20}$$

Assuming that the matrix pair (\tilde{A}, \tilde{B}) is controllable, control design for the open-loop dynamics in (30.19) can now be performed using LQR servomechanism approach. Toward that end, assume constant external command $r(t) = r$, utilize matrices as defined in (30.19) and (30.20):

$$\tilde{A} = \begin{pmatrix} 0_{p_p \times p_p} & C \\ 0_{n_p \times p_p} & A \end{pmatrix}, \quad \tilde{B} = \begin{pmatrix} D \\ B \end{pmatrix}, \quad \tilde{D} = D, \quad \tilde{D}_r = D_r\tag{30.21}$$

and consider stabilization of

$$\dot{z} = \tilde{A}z + \tilde{B}v\tag{30.22}$$

where

$$z = \begin{pmatrix} \dot{e}_{yI} \\ \dot{x} \end{pmatrix}, \quad v = \dot{u}\tag{30.23}$$

It is easy to see that dynamics (30.22) are obtained by differentiating (30.19) while assuming constant external command $r(t) = r$. Next, the newly introduced control

input v in (30.22) is chosen to minimize the LQR performance index (cost):

$$J = \int_0^{\infty} (z^T Q z + v^T R v) dt \quad (30.24)$$

where $Q = Q^T \geq 0$ and $R = R^T > 0$ are the LQR weight matrices. Then, the algebraic Riccati equation

$$\tilde{A}^T P + P \tilde{A} + Q - P \tilde{B} R^{-1} \tilde{B}^T P = 0 \quad (30.25)$$

has a unique positive definite symmetric solution $P = P^T > 0$. Based on the latter, the corresponding LQR-optimal control strategy is given in feedback form:

$$\dot{u} = v = - \underbrace{R^{-1} \tilde{B}^T P}_K z = -K z = - \begin{pmatrix} K_I & K_P \end{pmatrix} \begin{pmatrix} \dot{e}_y \\ x \end{pmatrix} \quad (30.26)$$

Integrating both sides and ignoring constants of integration yields the LQR-optimal control solution in PI feedback form:

$$u = -K_I e_{yI} - K_P x = K_I \frac{(y_{\text{ref}} - y)}{s} - K_P x = \boxed{K_I \frac{(y_{\text{ref}} - y)}{s} - K_P^x x - K_P^{x_{\text{ref}}} x_{\text{ref}}} \quad (30.27)$$

where proportional gains K_P^x and $K_P^{x_{\text{ref}}}$ are defined below

$$K_P = \begin{pmatrix} K_P^x & K_P^{x_{\text{ref}}} \end{pmatrix} \quad (30.28)$$

Using LQR feedback (30.27) to control plant dynamics (30.11) will force the system-regulated output y_p to track its command target y_{ref} , which in turn tracks a step-input external command r with zero steady-state error. As a result, the system output y_p will converge to r exponentially fast (for a step input and in steady state). The model following command tracking problem is solved. Figure 30.2 shows the corresponding closed-loop system block-diagram.

Fig. 30.2 Model following LQR PI control block-diagram

Fig. 30.3 Servomechanism
LQR PI control
block-diagram

The plant and the model shown in the figure are defined by (30.11) and (30.12), respectively. The reference model dynamics in (30.12) should not be confused with the assumed dynamics of the external command r . Most often, the assumed dynamics is defined as $\dot{r} = 0$, that is, the system is required to track step inputs with zero error. On the other hand, the reference model can be viewed as the command prefilter, that is the system will track the output of the reference model rather than the command itself. Thus, the main purpose of the reference model is to smooth out the command r before it goes into the system, and the model following state feedback LQR PI controller is designed to do precisely that.

If $(A_{\text{ref}}, B_{\text{ref}}, C_{\text{ref}})$ are set to zero and D_{ref} is the identity matrix, then according to (30.12), $y_{\text{ref}} = r(t)$ and the model following architecture from Fig. 30.2 reduces to the standard servomechanism control block-diagram (Fig. 30.3).

Note that in this case, the extended system remains controllable as long as

$$\text{rank} \begin{pmatrix} A_p & B_p \\ C_p & D_p \end{pmatrix} = n_p + m$$

which places restrictions on the regulated output selection.

30.4.1 Design Example: Lateral-Directional LQR PI Control with Explicit Model Following

In order to gain insights into the design, consider the aircraft lateral-directional dynamics (30.6), with the regulated output, whose components are the vehicle roll rate p_s and the angle of sideslip (AOS) β :

$$\underbrace{\begin{pmatrix} \dot{\beta} \\ \dot{p}_s \\ \dot{r}_s \end{pmatrix}}_{\dot{x}_p} = \underbrace{\begin{pmatrix} \frac{Y_{\beta}}{V_0} & \frac{Y_p}{V_0} & \frac{Y_r}{V_0} - 1 \\ L_{\beta} & L_p & L_r \\ N_{\beta} & N_p & N_r \end{pmatrix}}_{A_p} \underbrace{\begin{pmatrix} \beta \\ p_s \\ r_s \end{pmatrix}}_{x_p} + \underbrace{\begin{pmatrix} \frac{Y_{\delta_a}}{V_0} & \frac{Y_{\delta_r}}{V_0} \\ L_{\delta_a} & L_{\delta_r} \\ N_{\delta_a} & N_{\delta_r} \end{pmatrix}}_{B_p} \underbrace{\begin{pmatrix} \delta_{\text{ail}} \\ \delta_{\text{rud}} \end{pmatrix}}_u \quad (30.29)$$

$$y_p = \begin{pmatrix} p_s \\ \beta \end{pmatrix} = \underbrace{\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}}_{C_p} x_p + \underbrace{0_{2 \times 2}}_{D_p} u$$

where (p_s, r_s) are the aircraft roll and yaw angular rates in stability axes, $(\delta_{ail}, \delta_{rud})$ are the control inputs (aileron and rudder deflections), and V_0 is the aircraft true airspeed (trimmed). The rest of the parameters in the model represent the vehicle stability and control derivatives. In (30.29), $n_p = 3$, $m_p = p_p = 2$.

The control task is to construct aileron δ_{ail} and rudder δ_{rud} such that the aircraft roll rate p_s and AOS β track their step-input commands, p_{cmd} and β_{cmd} , respectively, while all other signals in the system remain bounded.

Desired roll rate and AOS dynamics are defined by the LTI reference model:

$$\begin{aligned} \underbrace{\begin{pmatrix} \dot{p}_{ref} \\ \dot{\beta}_{ref} \end{pmatrix}}_{\dot{x}_{ref}} &= \underbrace{\begin{pmatrix} -\frac{1}{\tau_p} & 0 \\ 0 & -\frac{1}{\tau_\beta} \end{pmatrix}}_{A_{ref}} \underbrace{\begin{pmatrix} p_{ref} \\ \beta_{ref} \end{pmatrix}}_{x_{ref}} + \underbrace{\begin{pmatrix} \frac{1}{\tau_p} & 0 \\ 0 & \frac{1}{\tau_\beta} \end{pmatrix}}_{B_{ref}} \underbrace{\begin{pmatrix} p_{cmd} \\ \beta_{cmd} \end{pmatrix}}_{r(t)} \\ y_{ref} &= \underbrace{\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}}_{C_{ref}} x_{ref} + \underbrace{0_{2 \times 2}}_{D_{ref}} r(t) \end{aligned} \quad (30.30)$$

where τ_p and τ_β are small positive time constants that define the desired roll rate and the AOS dynamics, correspondingly. It is easy to check that the DC gain of the reference model is unity.

From (30.29) and (30.30) it follows that

$$n_p = 3, \quad p_p = m_p = 2, \quad n_{ref} = 2 \quad (30.31)$$

Using (30.14) gives extended open-loop dynamics:

$$\underbrace{\begin{pmatrix} \dot{x}_p \\ \dot{x}_{ref} \end{pmatrix}}_{\dot{x}} = \underbrace{\begin{pmatrix} A_p & 0_{3 \times 2} \\ 0_{2 \times 3} & A_{ref} \end{pmatrix}}_A \underbrace{\begin{pmatrix} x_p \\ x_{ref} \end{pmatrix}}_x + \underbrace{\begin{pmatrix} B_p \\ 0_{2 \times 2} \end{pmatrix}}_B \underbrace{\begin{pmatrix} \delta_{ail} \\ \delta_{rud} \end{pmatrix}}_u + \underbrace{\begin{pmatrix} 0_{3 \times 2} \\ B_{ref} \end{pmatrix}}_{B_r} \underbrace{\begin{pmatrix} p_{cmd} \\ \beta_{cmd} \end{pmatrix}}_{r(t)} \quad (30.32)$$

where matrix pairs (A_p, B_p) and (A_{ref}, B_{ref}) are as in (30.29) and (30.30). According to (30.15), the system-regulated output is

$$y = y_p - y_{ref} = C_p x_p - C_{ref} x_{ref} = \underbrace{(C_p - C_{ref})}_C x + \underbrace{0_{2 \times 2}}_D u + \underbrace{0_{2 \times 2}}_{D_r} r(t) \quad (30.33)$$

Per (30.18), the extended dynamics (30.32) are augmented with the roll rate and AOS integrated tracking errors:

$$\begin{aligned} \dot{e}_{pI} &= p - p_{ref} \\ \dot{e}_{\beta I} &= \beta - \beta_{ref} \\ \dot{x} &= A x + B u + B_r r(t) \\ y &= C x \end{aligned} \quad (30.34)$$

The integrated tracking error vector e_{yI} has two components: integrated roll rate error e_{pI} and integrated AOS error $e_{\beta I}$. Similar to (30.19), one gets

$$\underbrace{\begin{pmatrix} \dot{e}_{yI} \\ \dot{x} \end{pmatrix}}_{\dot{\tilde{x}}} = \underbrace{\begin{pmatrix} 0_{2 \times 2} & C \\ 0_{5 \times 2} & A \end{pmatrix}}_{\tilde{A}} \underbrace{\begin{pmatrix} e_{yI} \\ x \end{pmatrix}}_{\tilde{x}} + \underbrace{\begin{pmatrix} 0_{2 \times 2} \\ B \end{pmatrix}}_{\tilde{B}} u + \underbrace{\begin{pmatrix} 0_{2 \times 2} \\ B_r \end{pmatrix}}_{\tilde{B}_r} r(t) \quad (30.35)$$

with the regulated output as in (30.20).

$$y = \begin{pmatrix} p - p_{\text{ref}} \\ \beta - \beta_{\text{ref}} \end{pmatrix} = \underbrace{\begin{pmatrix} 0_{2 \times 2} & C \end{pmatrix}}_{\tilde{C}} \tilde{x} + \underbrace{0_{m_p \times m_p}}_{\tilde{D}} u + \underbrace{0_{m_p \times m_p}}_{\tilde{D}_r} r(t) \quad (30.36)$$

Using matrices (\tilde{A}, \tilde{B}) from (30.35), choosing LQR weights (Q, R) appropriately, and solving the algebraic Riccati equation (30.25), yields the LQR PI matrix of optimal gains (see (30.26)):

$$K = R^{-1} \tilde{B}^T P \quad (30.37)$$

Partitioning the gains as in (30.28), the LQR-optimal control solution can be written in the form of (30.27):

$$u = K_I \frac{(y_{\text{ref}} - y)}{s} - K_P^x x - K_P^{x_{\text{ref}}} x_{\text{ref}} \quad (30.38)$$

where

$$K = \begin{pmatrix} K_I & K_P^x & K_P^{x_{\text{ref}}} \end{pmatrix} \quad (30.39)$$

In terms of the original notation, the model following LQR PI controller can be expressed as

$$\begin{cases} \delta_{\text{ail}} = K_{pI}^{\text{ail}} \frac{(p_{\text{ref}} - p)}{s} + K_{\beta I}^{\text{ail}} \frac{(\beta_{\text{ref}} - \beta)}{s} - K_{\beta}^{\text{ail}} \beta - K_p^{\text{ail}} p_s - K_r^{\text{ail}} r_s - K_{p_{\text{ref}}}^{\text{ail}} p_{\text{ref}} - K_{\beta_{\text{ref}}}^{\text{ail}} \beta_{\text{ref}} \\ \delta_{\text{rud}} = K_{pI}^{\text{rud}} \frac{(p_{\text{ref}} - p)}{s} + K_{\beta I}^{\text{rud}} \frac{(\beta_{\text{ref}} - \beta)}{s} - K_{\beta}^{\text{rud}} \beta - K_p^{\text{rud}} p_s - K_r^{\text{rud}} r_s - K_{p_{\text{ref}}}^{\text{rud}} p_{\text{ref}} - K_{\beta_{\text{ref}}}^{\text{rud}} \beta_{\text{ref}} \end{cases} \quad (30.40)$$

Comparing (30.39) and (30.40), yields the LQR PI optimal matrix gains:

$$K_I = \begin{pmatrix} K_{pI}^{\text{ail}} & K_{\beta I}^{\text{ail}} \\ K_{pI}^{\text{rud}} & K_{\beta I}^{\text{rud}} \end{pmatrix}, \quad K_P^x = \begin{pmatrix} K_{\beta}^{\text{ail}} & K_p^{\text{ail}} & K_r^{\text{ail}} \\ K_{\beta}^{\text{rud}} & K_p^{\text{rud}} & K_r^{\text{rud}} \end{pmatrix}, \quad K_P^{x_{\text{ref}}} = \begin{pmatrix} K_{p_{\text{ref}}}^{\text{ail}} & K_{\beta_{\text{ref}}}^{\text{ail}} \\ K_{p_{\text{ref}}}^{\text{rud}} & K_{\beta_{\text{ref}}}^{\text{rud}} \end{pmatrix} \quad (30.41)$$

The reader is encouraged to test this technique on a specific system of choice. Although the controller was designed to track step-input commands, its command following performance will be excellent for any bounded command, whose rate of change is within the closed-loop system bandwidth. In addition, one can and should

compute stability margins, at the plant input and output break points. These margins will be excessive, which is to be expected for any LQR-based design. In addition, the closed-loop system will be robust due to a large class of state-dependent nonlinear uncertainties (matched), confined within a sector, that may exist at the plant input. All these features make the LQR PI feedback design highly efficient in controlling aerial platforms. The next section introduces adaptive augmentation algorithms to extend robustness of an LQR PI controller, with respect to a wide class of matched uncertainties and beyond.

30.5 Model Reference Adaptive Control

The concept of model reference adaptive control (MRAC) was originally proposed in 1958 by Whitaker et al., at MIT (Whitaker et al. 1958), and later extended in (Butchart and Shackcloth 1965; Parks 1966). Current state of the art in adaptive control is well documented and can be found in textbooks (Narendra and Annaswamy 2005; Ioannou and Fidan 2006). The original intent of adaptive control was to specify the desired command-to-output performance of a servo-tracking system using a reference model that would define the ideal response of the system due to external commands. A generic block-diagram of the MRAC system is shown in Fig. 30.4.

As seen from the diagram, the controller parameter adjustments (the adaptive law) are made based on the tracking error (the difference between the system actual response and its target specified by the reference model output), an output feedback from the process, and the external command. For the sake of clarity and in order to motivate further discussions, consider MRAC design equations for a scalar system shown below:

$$\begin{array}{l}
 \text{Process : } \dot{x} = ax + bu \\
 \text{Ref. Model : } \dot{x}_{\text{ref}} = a_{\text{ref}}x_{\text{ref}} + b_{\text{ref}}r \\
 \text{Controller : } u = \hat{k}_x x + \hat{k}_r r \\
 \text{Adaptive Law : } \begin{cases} \dot{\hat{k}}_x = -\gamma_x x (x - x_{\text{ref}}) \\ \dot{\hat{k}}_r = -\gamma_r r (x - x_{\text{ref}}) \end{cases}
 \end{array} \tag{30.42}$$

where a and b are unknown constant parameters in the process dynamics with the known $sgnb > 0$. The control input u is selected such that the system state x follows the reference model state x_{ref} , driven by any bounded external command $r = r(t)$. Also in (30.42), the reference model data $a_{\text{ref}} < 0$ and b_{ref} are chosen to yield the desired speed of response and a DC gain (unity in most applications) from the reference model output $y_{\text{ref}} = x_{\text{ref}}$ to the system-regulated output $y = x$.

In this case, closed-loop system stability and global asymptotic tracking are achieved via a specific choice of the adaptive law in (30.42), with the adaptive

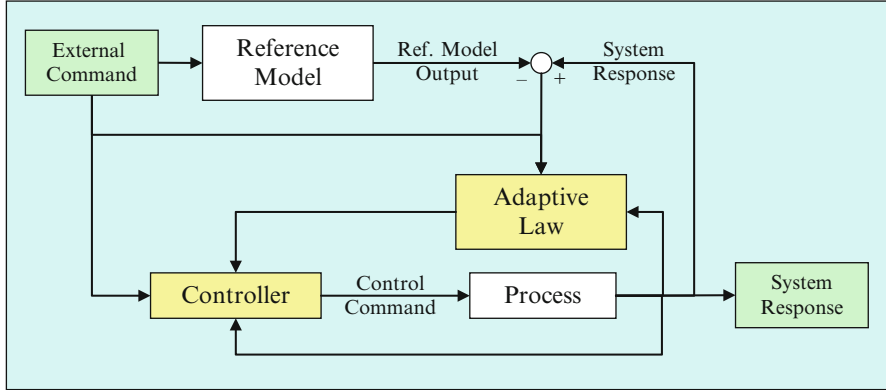

Fig. 30.4 MRAC block-diagram

gains (\hat{k}_x, \hat{k}_r) , whose dynamics are influenced by two positive constant rates of adaptation (γ_x, γ_r) . As seen from (30.42), the state tracking error

$$e = x - x_{\text{ref}} \quad (30.43)$$

drives the adaptive laws. Existence of a servo-control solution for this particular scalar dynamics is provided by the matching conditions:

$$\begin{aligned} a_{\text{ref}} &= a + b k_x \\ b_{\text{ref}} &= b k_r \end{aligned} \quad (30.44)$$

where k_x and k_r denote the ideal unknown constant parameters (gains of the ideal controller). For scalar dynamics, such as the process in (30.42), it is clear that the matching relations (30.44) always have a solution. Let,

$$\Delta k_x = \hat{k}_x - k_x, \quad \Delta k_r = \hat{k}_r - k_r \quad (30.45)$$

represent the parameter estimation errors. Substituting the matching conditions (30.44) into (30.42), one can derive the tracking error dynamics:

$$\dot{e} = a_{\text{ref}} e + b (\Delta k_x x + \Delta k_r r) \quad (30.46)$$

which indeed define transients in the corresponding closed-loop system. The tracking error dynamics and the transient dynamics are equivalent notions. If and when e becomes small (asymptotically), the system output tracks the reference model with diminishing errors. On the other hand, the transient dynamics define what happens between the start of a maneuver and the time when the error gets small. Both questions will be addressed next.

Going back to (30.46), one can employ Lyapunov arguments (Khalil 1996) to prove global asymptotic stability of the tracking error dynamics. In fact, using a radially unbounded quadratic Lyapunov function candidate in the form

$$V(e, \Delta k_x, \Delta k_r) = e^2 + \left(\frac{\Delta k_x^2}{\gamma_x} + \frac{\Delta k_r^2}{\gamma_r} \right) * b \quad (30.47)$$

it is not difficult to show that with the adaptive law (30.42), the time derivative of V , evaluated along the trajectories of the error dynamics (30.46), becomes nonpositive. This argument constitutes the inverse Lyapunov-based design. It provides (a) the adaptive law and (b) the required proof of closed-loop global asymptotic stability. As a result, one can formally show that for any initial condition, any bounded time-varying external command, and any positive rates of adaptation, the tracking error dynamics (30.46) are globally asymptotically stable:

$$\lim_{t \rightarrow \infty} |e(t)| = \lim_{t \rightarrow \infty} |x(t) - x_{\text{ref}}(t)| = 0 \quad (30.48)$$

and all signals in the corresponding closed-loop dynamics remain uniformly bounded, forward in time.

30.5.1 MRAC Design for MIMO Dynamics

The scalar MRAC design methodology generalizes to multi-input-multi-output (MIMO) systems with matched parametric uncertainties in the form

$$\dot{x} = Ax + B\Lambda(u + f(x)) \quad (30.49)$$

where $x \in R^n$ is the system state, $u \in R^m$ is the control input, and $B \in R^{n \times m}$ is the known control matrix, while $A \in R^{n \times n}$ and $\Lambda \in R^{m \times m}$ are unknown constant matrices. In addition, it is assumed that Λ is diagonal, its elements λ_i are strictly positive, and the pair $(A, B\Lambda)$ is controllable. The uncertainty in Λ is introduced to model control effectiveness failures or modeling errors. In (30.49), the unknown possibly nonlinear vector function $f(x) : R^n \rightarrow R^m$ represents the system-matched uncertainty. It is assumed that each individual component $f_i(x)$ of $f(x)$ can be written as a linear combination of N known locally Lipschitz-continuous basis functions $\phi_i(x)$, with unknown constant coefficients. So,

$$f(x) = \Theta^T \Phi(x) \quad (30.50)$$

where $\Theta \in R^{N \times m}$ is a constant matrix of the unknown coefficients and

$$\Phi(x) = (\phi_1(x) \dots \phi_N(x))^T \in R^N$$

is the known regressor vector. Of interest is the design of a MIMO state feedback adaptive control law such that the system state x globally uniformly asymptotically tracks the state $x_{\text{ref}} \in R^n$ of the reference model

$$\dot{x}_{\text{ref}} = A_{\text{ref}} x_{\text{ref}} + B_{\text{ref}} r(t) \quad (30.51)$$

where $A_{\text{ref}} \in R^{n \times n}$ is Hurwitz, $B_{\text{ref}} \in R^{n \times m}$, and $r(t) \in R^m$ is the external bounded command vector.

It is also required that during tracking, all signals in the closed-loop system remain uniformly bounded. Thus, given any bounded command $r(t)$, the control input u needs to be chosen such that the state tracking error

$$e(t) = x(t) - x_{\text{ref}}(t) \quad (30.52)$$

globally uniformly asymptotically tends to zero, that is,

$$\lim_{t \rightarrow \infty} \|x(t) - x_{\text{ref}}(t)\| = 0 \quad (30.53)$$

If matrices A and Λ were known, one could have calculated and applied the ideal fixed-gain control law:

$$u = K_x^T x + K_r^T r - \Theta^T \Phi(x) \quad (30.54)$$

and obtain the closed-loop system:

$$\dot{x} = (A + B \Lambda K_x^T) x + B \Lambda K_r^T r \quad (30.55)$$

Comparing (30.55) with the desired reference dynamics (30.51), it follows that for the existence of a controller in the form of (30.54), the ideal unknown control gains, K_x and K_r , must satisfy the matching conditions:

$$\begin{aligned} A + B \Lambda K_x^T &= A_{\text{ref}} \\ B \Lambda K_r^T &= B_{\text{ref}} \end{aligned} \quad (30.56)$$

Assuming that these matching conditions hold, it is easy to see that using (30.54) yields the closed-loop system which is exactly the same as the reference model. Consequently, for any bounded reference input signal $r(t)$, the fixed-gain controller (30.54) provides global uniform asymptotic tracking performance. Note that given a set of matrices $(A, B, \Lambda, A_{\text{ref}}, B_{\text{ref}})$, in general there is no guarantee that ideal gains K_x, K_r exist to enforce the matching conditions (30.56). In other words, the control law (30.54) may not be able to meet the design objective. However often in practice, the structure of A is known, and the reference model matrices $A_{\text{ref}}, B_{\text{ref}}$

are chosen so that the system (30.56) has at least one ideal solution pair (K_x, K_r) . Assuming that K_x, K_r in (30.56) do exist, consider the following control law:

$$u = \hat{K}_x^T x + \hat{K}_r^T r - \hat{\Theta}^T \Phi(x) \quad (30.57)$$

where $\hat{K}_x \in R^{n \times m}$, $\hat{K}_r \in R^{m \times m}$, $\hat{\Theta} \in R^{N \times n}$ are the estimates of the ideal unknown matrices K_x, K_r, Θ , respectively. These estimated parameters will be generated online through the inverse Lyapunov analysis. Substituting (30.57) into (30.49), the closed-loop system dynamics can be written as

$$\dot{x} = \left(A + B \Lambda \hat{K}_x^T \right) x + B \Lambda \left(\hat{K}_r^T r - \left(\hat{\Theta} - \Theta \right)^T \Phi(x) \right) \quad (30.58)$$

Subtracting (30.51) from (30.58), it is possible to compute the closed-loop dynamics of the n -dimensional tracking error vector $e(t) = x(t) - x_{\text{ref}}(t)$:

$$\dot{e} = \left(A + B \Lambda \hat{K}_x^T \right) x + B \Lambda \left(\hat{K}_r^T r - \left(\hat{\Theta} - \Theta \right)^T \Phi(x) \right) - A_{\text{ref}} x_{\text{ref}} - B_{\text{ref}} r \quad (30.59)$$

With the matching conditions (30.56) in place, one further gets

$$\begin{aligned} \dot{e} &= \left(A_{\text{ref}} + B \Lambda \left(\hat{K}_x - K_x \right) \right) x - A_{\text{ref}} x_{\text{ref}} + B \Lambda \left(\hat{K}_r - K_r \right) r - B \Lambda \\ &\quad \left(\hat{\Theta} - \Theta \right)^T \Phi(x) \\ &= A_{\text{ref}} e + B \Lambda \left[\left(\hat{K}_x - K_x \right)^T x + \left(\hat{K}_r - K_r \right)^T r - \left(\hat{\Theta} - \Theta \right)^T \Phi(x) \right] \end{aligned} \quad (30.60)$$

Let $\Delta K_x = \hat{K}_x - K_x$, $\Delta K_r = \hat{K}_r - K_r$, and $\Delta \Theta = \hat{\Theta} - \Theta$ represent the parameter estimation errors. In terms of the latter, the tracking error dynamics become

$$\dot{e} = A_{\text{ref}} e + B \Lambda \left[\Delta K_x^T x + \Delta K_r^T r - \Delta \Theta^T \Phi(x) \right] \quad (30.61)$$

Introduce rates of adaptation: $\Gamma_x = \Gamma_x^T > 0$, $\Gamma_r = \Gamma_r^T > 0$, $\Gamma_\Theta = \Gamma_\Theta^T > 0$. Going back to analyzing stability of the tracking error dynamics (30.61), consider a globally radially unbounded quadratic Lyapunov function candidate in the form

$$\begin{aligned} V(e, \Delta K_x, \Delta K_r, \Delta \Theta) &= e^T P e + \text{tr} \left(\left[\Delta K_x^T \Gamma_x^{-1} \Delta K_x + \Delta K_r^T \Gamma_r^{-1} \Delta K_r \right. \right. \\ &\quad \left. \left. + \Delta \Theta^T \Gamma_\Theta^{-1} \Delta \Theta \right] \Lambda \right) \end{aligned} \quad (30.62)$$

where $P = P^T > 0$ satisfies the algebraic Lyapunov equation

$$P A_{\text{ref}} + A_{\text{ref}}^T P = -Q \quad (30.63)$$

for some $Q = Q^T > 0$. Then the time derivative of V , evaluated along the trajectories of (30.61), can be calculated:

$$\begin{aligned}
 \dot{V} &= \dot{e}^T P e + e^T P \dot{e} + 2 \operatorname{tr} \left(\left[\Delta K_x^T \Gamma_x^{-1} \dot{\hat{K}}_x + \Delta K_r^T \Gamma_r^{-1} \dot{\hat{K}}_r + \Delta \Theta^T \Gamma_\Theta^{-1} \dot{\hat{\Theta}} \right] \Lambda \right) \\
 &= (A_{\text{ref}} e + B \Lambda (\Delta K_x^T x + \Delta K_r^T r - \Delta \Theta^T \Phi(x)))^T P e \\
 &\quad + e^T P (A_{\text{ref}} e + B \Lambda (\Delta K_x^T x + \Delta K_r^T r - \Delta \Theta^T \Phi(x))) \\
 &\quad + 2 \operatorname{tr} \left(\left[\Delta K_x^T \Gamma_x^{-1} \dot{\hat{K}}_x + \Delta K_r^T \Gamma_r^{-1} \dot{\hat{K}}_r + \Delta \Theta^T \Gamma_\Theta^{-1} \dot{\hat{\Theta}} \right] \Lambda \right) \\
 &= e^T (A_{\text{ref}} P + P A_{\text{ref}}) e + 2 e^T P B \Lambda (\Delta K_x^T x + \Delta K_r^T r - \Delta \Theta^T \Phi(x)) \\
 &\quad + 2 \operatorname{tr} \left(\left[\Delta K_x^T \Gamma_x^{-1} \dot{\hat{K}}_x + \Delta K_r^T \Gamma_r^{-1} \dot{\hat{K}}_r + \Delta \Theta^T \Gamma_\Theta^{-1} \dot{\hat{\Theta}} \right] \Lambda \right) \quad (30.64)
 \end{aligned}$$

Using (30.63) further yields

$$\begin{aligned}
 \dot{V} &= -e^T Q e + \left[2 e^T P B \Lambda \Delta K_x^T x + 2 \operatorname{tr} \left(\Delta K_x^T \Gamma_x^{-1} \dot{\hat{K}}_x \Lambda \right) \right] \\
 &\quad + \left[2 e^T P B \Lambda \Delta K_r^T r + 2 \operatorname{tr} \left(\Delta K_r^T \Gamma_r^{-1} \dot{\hat{K}}_r \Lambda \right) \right] \\
 &\quad + \left[-2 e^T P B \Lambda \Delta \Theta^T \Phi(x) + 2 \operatorname{tr} \left(\Delta \Theta^T \Gamma_\Theta^{-1} \dot{\hat{\Theta}} \Lambda \right) \right] \quad (30.65)
 \end{aligned}$$

Via the well-known trace identity

$$\begin{aligned}
 \underbrace{e^T P B \Lambda}_{a^T} \underbrace{\Delta K_x^T x}_b &= \operatorname{tr} \left(\underbrace{\Delta K_x^T x}_b \underbrace{e^T P B \Lambda}_{a^T} \right) \\
 \underbrace{e^T P B \Lambda}_{a^T} \underbrace{\Delta K_r^T r}_b &= \operatorname{tr} \left(\underbrace{\Delta K_r^T r}_b \underbrace{e^T P B \Lambda}_{a^T} \right) \\
 \underbrace{e^T P B \Lambda}_{a^T} \underbrace{\Delta \Theta^T \Phi(x)}_b &= \operatorname{tr} \left(\underbrace{\Delta \Theta^T \Phi(x)}_b \underbrace{e^T P B \Lambda}_{a^T} \right) \quad (30.66)
 \end{aligned}$$

Substituting (30.66) into (30.65) results in

$$\begin{aligned}
 \dot{V} &= -e^T Q e + 2 \operatorname{tr} \left(\Delta K_x^T \left[\Gamma_x^{-1} \dot{\hat{K}}_x + x e^T P B \right] \Lambda \right) \\
 &\quad + 2 \operatorname{tr} \left(\Delta K_r^T \left[\Gamma_r^{-1} \dot{\hat{K}}_r + r e^T P B \right] \Lambda \right) + 2 \operatorname{tr} \left(\Delta \Theta^T \left[\Gamma_\Theta^{-1} \dot{\hat{\Theta}} - \Phi(x) e^T P B \right] \Lambda \right) \quad (30.67)
 \end{aligned}$$

If the adaptive laws are selected as

$$\begin{aligned}\dot{\hat{K}}_x &= -\Gamma_x x e^T P B \\ \dot{\hat{K}}_r &= -\Gamma_r r(t) e^T P B \\ \dot{\hat{\Theta}} &= \Gamma_\Theta \Phi(x) e^T P B\end{aligned}\quad (30.68)$$

then the time derivative of V in (30.67) becomes globally negative semidefinite:

$$\dot{V} = -e^T Q e \leq 0 \quad (30.69)$$

Therefore, the closed-loop error dynamics are uniformly stable. Hence, the tracking error $e(t)$ as well as the parameter estimation errors $\Delta K_x(t)$, $\Delta K_r(t)$, and $\Delta \Theta(t)$ are uniformly bounded and so are the parameter estimates $\hat{K}_x(t)$, $\hat{K}_r(t)$, and $\hat{\Theta}(t)$. Since $r(t)$ is bounded and A_{ref} is Hurwitz, then $x_{\text{ref}}(t)$ and $\dot{x}_{\text{ref}}(t)$ are bounded. Consequently, the system state $x(t)$ is uniformly bounded, and the control input $u(t)$ in (30.57) is bounded as well. The latter implies that $\dot{x}(t)$ is bounded, and thus $\dot{e}(t)$ is bounded. Furthermore, the second time derivative of $V(t)$

$$\ddot{V} = -e^T Q \dot{e} = -2e^T Q \dot{e} \quad (30.70)$$

is bounded, and so $\dot{V}(t)$ is uniformly continuous. Since in addition, $V(t)$ is lower bounded and $\dot{V}(t) \leq 0$, then using Barbalat's lemma (Khalil 1996) gives $\lim_{t \rightarrow \infty} \dot{V}(t) = 0$, which implies (via (30.69))

$$\left[\lim_{t \rightarrow \infty} e^T Q e = 0 \right] \Leftrightarrow \left[\lim_{t \rightarrow \infty} \|e\| = 0 \right] \Leftrightarrow \left[\lim_{t \rightarrow \infty} \|x(t) - x_{\text{ref}}(t)\| = 0 \right] \quad (30.71)$$

It has been formally proven that the state tracking error $e(t)$ tends to the origin globally, uniformly, and asymptotically. The MIMO command tracking problem is solved, and a summary of the derived MRAC design equations is given in Table 30.1.

30.5.2 MRAC Design Modifications for Robustness

Shown in Table 30.1, the design is valid for MIMO dynamics (30.9), with a positive definite diagonal matrix Λ (control uncertainty) and a matched unknown-in-parameters function $f(x) = \Theta^T \Phi(x)$, where $\Theta \in R^{N \times m}$ represents a constant matrix of unknown parameters, $\Phi(x) \in R^N$ is the known regressor vector, and N is an integer. If components of the regressor are chosen from a certain class of approximation-capable maps (such as splines, trigonometric functions, polynomials, Gaussians, radial basis functions, sigmoidal/ridge functions), then the MIMO adaptive laws will provide semiglobal stability and command tracking for a wide class of matched uncertain functions $f(x)$ and bounded noise $\xi(t)$.

Table 30.1 MIMO MRAC laws

| | |
|-----------------------------|---|
| Open-loop plant | $\dot{x} = A x + B \Lambda (u + \Theta^T \Phi(x))$ |
| Reference model | $\dot{x}_{\text{ref}} = A_{\text{ref}} x_{\text{ref}} + B_{\text{ref}} r$ |
| Model matching conditions | $A + B \Lambda K_x^T = A_{\text{ref}}, \quad B \Lambda K_r^T = B_{\text{ref}}$ |
| Tracking error | $e = x - x_{\text{ref}}$ |
| Control input | $u = \hat{K}_x^T x + \hat{K}_r^T r - \hat{\Theta}^T \Phi(x)$ |
| Algebraic Lyapunov equation | $P A_{\text{ref}} + A_{\text{ref}}^T P = -Q$ |
| MIMO MRAC laws | $\dot{\hat{K}}_x = -\Gamma_x x e^T P B$ $\dot{\hat{K}}_r = -\Gamma_r r(t) e^T P B$ $\dot{\hat{\Theta}} = \Gamma_{\Theta} \Phi(x) e^T P B$ |

|---------------------|---|
| Dead-zone | $\dot{\hat{\Theta}} = \Gamma_{\Theta} \Phi(x) \mu(\ e\) e^T P B$ |
| σ -mod | $\dot{\hat{\Theta}} = \Gamma_{\Theta} \left(\Phi(x) e^T P B - \sigma \hat{\Theta} \right)$ |
| e mod | $\dot{\hat{\Theta}} = \Gamma_{\Theta} \left(\Phi(x) e^T P B - \sigma \ \Phi(x) e^T P B\ \hat{\Theta} \right)$ |
| Projection operator | $\dot{\hat{\Theta}} = \text{Proj} \left(\hat{\Theta}, \Gamma_{\Theta} \Phi(x) e^T P B \right)$ |

These are nonparametric uncertainties. In order to mitigate the latter, the adaptive laws must be modified to become robust (Ioannou and Fidan 2006; Narendra and Annaswamy 2005). Table 30.2 shows four robustness modifications for adaptive control of MIMO uncertain systems, with their dynamics extended to include integrated tracking errors.

Overall, an MRAC controller enforces global uniform asymptotic tracking performance of the preselected reference model dynamics, driven by a bounded time-varying command while keeping the rest of the signals in the corresponding closed-loop system uniformly bounded. Such a controller adapts to matched uncertainties, and it remains robust to nonparametric nonmatched time-varying process noise $\xi(t)$. The key feature that enables robustness of MRAC to process noise is the dead-zone modification (Fig. 30.5):

$$\mu(\|e\|) = \max \left(0, \min \left(1, \frac{\|e\| - \delta e_0}{(1 - \delta) e_0} \right) \right) \quad (30.72)$$

where $0 < \delta < 1$ is a constant.

The dead zone freezes the MRAC laws if and when the magnitude (2-norm) of the tracking error vector

$$e = x - x_{\text{ref}}$$

becomes smaller than a preset tolerance e_0 . Any realistic adaptive system must have a continuous dead-zone modification, such as (30.72), to avoid potential discontinuities in feedback connections. The “must-have” dead-zone modification will prevent adaptive parameters from drifting away due to persisting noise or other nonparametric uncertainties in the system dynamics.

Fig. 30.5 The dead-zone function

Table 30.3 The projection operator

| | |
|--|--|
| Max parameter bounds | $\ \theta\ \leq \theta^{\max}$ |
| Convex function | $f(\hat{\theta}) = \frac{(1+\varepsilon)\ \theta\ ^2 - (\theta^{\max})^2}{\varepsilon(\theta^{\max})^2}$ |
| Two convex sets | $\Omega_0 = \{\theta : f(\theta) \leq 0\} = \{\theta : \ \theta\ \leq \frac{\theta^{\max}}{\sqrt{1+\varepsilon}}\}$ $\Omega_1 = \{\theta : f(\theta) \leq 1\} = \{\theta : \ \theta\ \leq \theta^{\max}\}$ |
| Projection operator | $\text{Proj}(\theta, y) = \begin{cases} y - \frac{\Gamma \nabla f(\theta) (\nabla f(\theta))^T}{(\nabla f(\theta))^T \Gamma \nabla f(\theta)} y f(\theta), & \text{if } [f(\theta) > 0 \wedge (y^T \nabla f(\theta)) > 0] \\ y, & \text{if not} \end{cases}$ |
| Convex inequality for proof of stability | $(\theta - \theta^*)^T (\Gamma^{-1} \text{Proj}(\theta, \Gamma y) - y) \leq 0,$ $\forall \theta^* \in \Omega_0, \theta \in \Omega_1, y \in R^n$ |
| Uniform boundedness of parameters | $\dot{\theta} = \text{Proj}(\theta, \Gamma y)$ $[\theta(0) \in \Omega_0] \Rightarrow [\theta(t) \in \Omega_1, \forall t \geq 0]$ |

Also of key importance is the projection operator modification (Ioannou and Fidan 2006), shown in Table 30.3.

As defined, this modification acts on two column vectors $(\theta, \Gamma y)$. For matrices, the projection operator is applied column-wise. By design, projection-based MRAC laws will force the tracking error to become small while keeping the adaptive parameters within their prespecified bounds.

Without robustness modifications, the adaptive law dynamics are defined by integrating a nonlinear function, represented by the regressor vector $\Phi(x)$, multiplied by a linear combination of the state tracking errors $(e^T P B)$. This product is further multiplied by a constant matrix Γ_Θ (the integral gain), and finally it is integrated to yield the adaptive parameters $\hat{\Theta}(t)$ (see Fig. 30.6).

As seen from the block-diagram, there is a chain of nonlinear integrators in a feedback loop, whose output constitute the adaptive parameters. In all practical applications, feedback integrators must be “managed” in the sense that their

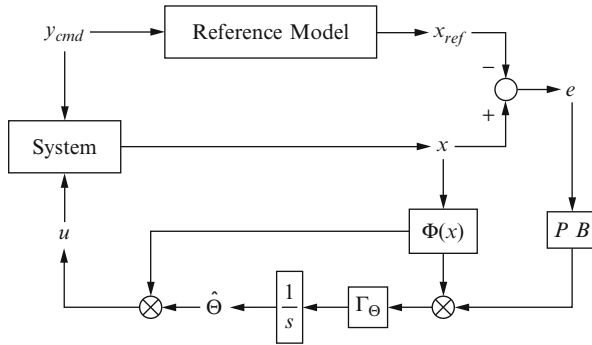

Fig. 30.6 MRAC system viewed as a nonlinear integral feedback controller

output signals (i.e., the adaptive parameters) need to be constrained. This prevents integrators against “winding up” due to nonlinear saturation functions in the control channels, where the system achievable control limits are defined and enforced. Control techniques that prevent the integrator windup problems are called the “anti-windup” methods, and the projection operator is one of them. So in practice, an MRAC architecture would consist of the smoothed dead-zone modification coupled with the projection operator. These are the two must-have modifications for enabling MRAC systems to efficiently operate in unknown environment.

30.5.3 Observer-Based MRAC Design with Transient Guarantees

Even though an adaptive controller enables command tracking asymptotically in time (as $t \rightarrow \infty$), it provides no uniformly guaranteed bounds on how large the transients might become prior to acquiring the command. In order to yield fast tracking and thus shorten transients, one needs to increase the rates of adaptation and, thus, to speed up MRAC laws. However, experience shows that if these rates grow large, unwanted transient oscillations will appear during the initial few seconds (the transient time) of operation. The balance between achieving fast tracking and avoiding undesired transients constitutes the MRAC design trade-off phenomenon. In essence, the rates of adaptation must be chosen large enough for fast tracking but not too large so that unwanted transients are precluded.

To understand the intricacies in MRAC design, reconsider the scalar design (30.42). What complicates the MRAC tuning process is the direct dependence of the transient dynamics (30.46) on (a) the external command and (b) the initial conditions for the system and the adaptive controller. These dependencies may too lead to undesirable transients. Consider the error dynamics (30.46). Using Lyapunov arguments, one can prove that the time-varying signal

$$\varphi(t) = b(\Delta k_x(t)x(t) + \Delta k_r(t)r(t)) \quad (30.73)$$

is uniformly bounded in time and that the tracking error $e(t)$ globally asymptotically tends to zero, as shown in (30.48). Still, the time constant of the transient dynamics (30.46) $\tau_e = \frac{1}{|a_{\text{ref}}|}$ is exactly the same as in the reference model (30.42). Although having the same time constant in both systems is theoretically correct, any control practitioner would want to have the transient dynamics (30.46) evolve faster than the desired reference model. In other words, the transients must die out quickly, relative to the dynamics of the reference model trajectories. This design requirement is identical to the one that takes place during the construction of asymptotic state observers, originally developed by Luenberger in his PhD thesis at Stanford (1963). Per Luenberger, the reference model in (30.42) represents an open-loop observer. So, just like in choosing the closed-loop observer dynamics, one can add an error feedback term to the reference model and arrive at the observer-like reference model:

$$\dot{x}_{\text{ref}} = a_{\text{ref}} x_{\text{ref}} + b_{\text{ref}} r + \boxed{k_e(x - x_{\text{ref}})} \quad (30.74)$$

Error Feedback Term

where $k_e > 0$ is the reference model feedback gain. The newly introduced error feedback term in (30.74) is equivalent to the output innovation feedback in a state observer. It is easy to see that in this case, the corresponding error dynamics become faster than the open-loop reference model from (30.42):

$$\dot{e} = (a_{\text{ref}} - k_e) e + b (\Delta k_x x + \Delta k_r r) \quad (30.75)$$

Once again, Lyapunov-based arguments can be easily repeated to prove (a) global asymptotic stability of the modified error dynamics (30.74) and (b) uniform boundedness of all signals in the related closed-loop system. Readers familiar with the MRAC stability proof concept should recognize that using the same Lyapunov function candidate (30.47), one needs to compute its time derivative along the trajectories of (30.75), substitute the adaptive law from (30.42), and then show that the resulting time derivative is globally nonpositive. This will prove uniform boundedness of the tracking error e and of the parameter estimation errors (30.45). Furthermore, since in the observer-like reference model (30.74), $a_{\text{ref}} < 0$ and the error feedback term is bounded, then the model state x_{ref} is bounded as well. The rest of the proof follows standard (in MRAC) stability arguments, finally arriving at (30.48).

Revised block-diagram with the observer-like reference model (30.74) is shown in Fig. 30.7.

As the reference model error feedback gain k_e is increased, the system transient dynamics become less oscillatory. In order to gain further insights into the transient behavior, choose $k_0 > 0$, a small positive parameter ε , and redefine the reference model feedback gain:

$$k_e = \frac{k_0}{\varepsilon} \quad (30.76)$$

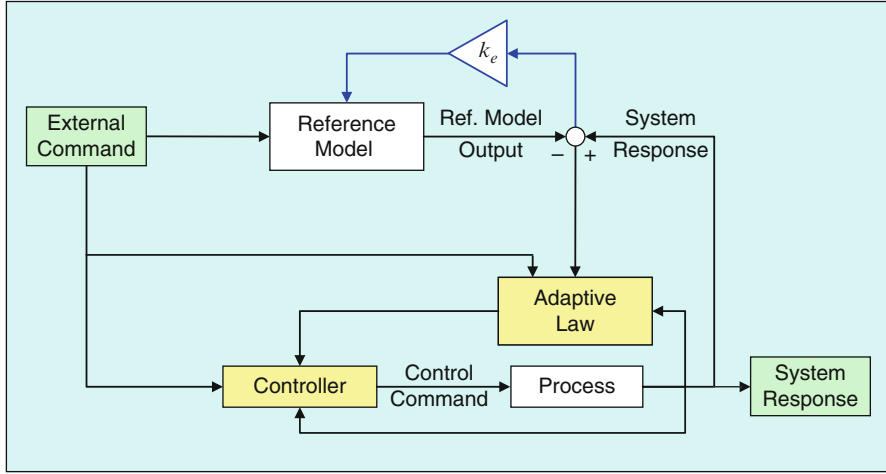

Fig. 30.7 MRAC block-diagram with observer-like reference model

Then the modified error dynamics (30.75) become

$$\varepsilon \dot{e} = (\varepsilon a_{\text{ref}} - k_0) e + \varepsilon \underbrace{[b (\Delta k_x x + \Delta k_r r)]}_{\varphi(t)} \quad (30.77)$$

Since all signals in the closed-loop system are uniformly bounded, it is not difficult to show that there exists a strictly positive finite constant $0 < \varphi_{\max} < \infty$ such that for any $\varepsilon > 0$, the upper bound $|\varphi(t)| \leq \varphi_{\max}$ holds uniformly in time and ε . Furthermore, starting from an initial condition $e(0) = e_0$, the solution of (30.77) can be written explicitly:

$$e(t) = e^{(a_{\text{ref}} - \frac{k_0}{\varepsilon})t} e(0) + \int_0^t e^{(a_{\text{ref}} - \frac{k_0}{\varepsilon})(t-\tau)} \varphi(\tau) d\tau \quad (30.78)$$

and one can compute an upper bound for this signal:

$$|e(t)| \leq e^{-k_0 \frac{t}{\varepsilon}} |e_0| + \frac{\varphi_{\max}}{k_0} \varepsilon \quad (30.79)$$

This relation is valid for any fixed $\varepsilon > 0$ uniformly in time. So, the system state $x(t)$ converges within $\left(\pm \frac{\varphi_{\max}}{k_0} \varepsilon\right)$ of the reference model state $x_{\text{ref}}(t)$ exponentially fast and at the rate no slower than $e^{-k_0 \frac{t}{\varepsilon}}$. This term gives an upper-bound quantification for the decay rate of the MRAC transient dynamics due to initial conditions mismatch $x(0) \neq x_{\text{ref}}(0)$. Otherwise, the system transients would remain within

ε -dependent bounds $\left(\pm \frac{\varphi_{\max}}{k_0} \varepsilon\right)$. Consequently, the system transients are reduced by decreasing ε , which according to (30.76) corresponds to increasing the reference model feedback gain k_e . Being able to influence and shape the MRAC transient dynamics constitutes the essential benefit of the Luenberger-like reference model modification (30.74)–(30.76). Relation (30.79) can also be written as

$$x(t) = x_{\text{ref}}(t) + C e^{-k_e t} + o(1) \quad (30.80)$$

where $C > 0$ is a constant independent of k_e and $o(1)$ is the “small-O” signal (a function of time that decays to zero asymptotically, as $t \rightarrow \infty$). The second term in (30.80) defines the transient dynamics due to initial conditions. Consequently, with a large enough feedback gain k_e , MRAC transient dynamics can be quantified and forced to decay as fast as needed. Note that since k_e is inversely proportional to ε , then the obvious trade-off in the modified MRAC design would be to avoid high gain effects in the reference model.

As for standard MRAC, it is also possible to generalize the observer-based MRAC to a broad class of nonlinear MIMO uncertain dynamical systems in the form

$$\underbrace{\begin{pmatrix} \dot{e}_y \\ \dot{x}_p \end{pmatrix}}_{\dot{x}} = \underbrace{\begin{pmatrix} 0_{m \times m} & C_p \\ 0_{n_p \times m} & A_p \end{pmatrix}}_A \underbrace{\begin{pmatrix} e_y \\ x_p \end{pmatrix}}_x + \underbrace{\begin{pmatrix} 0_{m \times m} \\ B_p \end{pmatrix}}_B \Lambda \left(u + \overbrace{\Theta_d^T \Phi_d(x_p)}^{d(x_p)} \right) + \underbrace{\begin{pmatrix} -I_{m \times m} \\ 0_{n_p \times m} \end{pmatrix}}_{B_{\text{ref}}} y_{\text{cmd}} \quad (30.81)$$

$$y = \underbrace{\begin{pmatrix} 0_{m \times m} & C_p \end{pmatrix}}_C x$$

These dynamics incorporate an n_p -dimensional open-loop system with m control inputs u - and m - regulated outputs y . This is the original plant, whose state is $x_p \in R^{n_p}$. The plant is augmented by the m -dimensional integrated output tracking error dynamics $\dot{e}_y = C_p x_p - y_{\text{cmd}}$, where $C_p \in R^{m \times n_p}$ is a known constant matrix. The order of the complete system (30.81) is $n = n_p + m$. In addition, $x \in R^n$ is the system state vector, $u \in R^m$ is the control input, $y \in R^p$ is the regulated output, $y_{\text{cmd}} \in R^m$ is the commanded signal for y to follow, $d(x_p) = \Theta_d^T \Phi_d(x_p) \in R^m$ is a nonlinear state-dependent matched parametric uncertainty, $\Theta_d \in R^{N \times m}$ is the matrix of unknown constant “true” parameters, and $\Phi_d(x_p) \in R^N$ is the known N -dimensional regressor vector, whose components are locally Lipschitz continuous in x , that is, there exists a finite positive known constant $0 < L_{\Phi_d} < \infty$ such that for any $(x_1, x_2) \in R^{n_p}$ from a bounded neighborhood of the origin, the following inequality holds

$$\|\Phi_d(x_1) - \Phi_d(x_2)\| \leq L_{\Phi_d} \|x_1 - x_2\| \quad (30.82)$$

Also in (30.81), $A \in R^{n \times n}$, $B \in R^{n \times m}$, $B_{\text{ref}} \in R^{n \times m}$, and $C \in R^{m \times n}$ are constant known matrices, while $\Lambda \in R^{m \times m}$ is a constant diagonal unknown matrix with strictly positive diagonal elements.

Consideration of the process dynamics (30.81) is largely motivated by aerospace applications, where x_p models the 6-DoF motion of an airborne platform and $d(x_p)$ represents uncertainties in the vehicle aerodynamic moments. By definition, the moment uncertainties appear together with the system control inputs, thus enforcing the matching conditions needed to justify mere existence of a control solution. Moreover, control actuator uncertainties, control effectiveness reduction, and other control failures are modeled by an unknown constant matrix Λ . Finally, inclusion of the integrated output tracking error $\dot{e}_{yI} = C_p x_p - y_{\text{cmd}}$ into the open-loop system leads to the extended system formulation (30.81). This inclusion is optional, yet it allows the designer to explicitly account for baseline controllers with integral feedback, and it also allows to avoid feedforward terms in a control solution. Other dynamics, such as structural notch filters, sensors, and actuators, can also be added in the formulation of the extended open-loop system.

In order to control a dynamical system such as (30.81), one needs the nominal system (no uncertainties) to be controllable. It is well known that controllability of (A_p, B_p) , coupled with the rank condition,

$$\text{rank} \begin{pmatrix} A_p & B_p \\ C_p & 0_{p \times m} \end{pmatrix} = n_p + m = n \quad (30.83)$$

ensures controllability of the extended pair (A, B) . Disregarding the system uncertainties, it is straightforward to form the ideal reference model dynamics:

$$\dot{x}_{\text{ref ideal}} = A_{\text{ref}} x_{\text{ref ideal}} + B_{\text{ref}} y_{\text{cmd}} \quad (30.84)$$

where

$$A_{\text{ref}} = A - B \underbrace{(R_{\text{ref}}^{-1} B^T P_{\text{ref}})}_{K_{\text{lqr}}^T} \quad (30.85)$$

is Hurwitz, K_{lqr} is the baseline LQR feedback gain, P_{ref} is the unique symmetric positive definite solution of the ARE,

$$P_{\text{ref}} A + A^T P_{\text{ref}} - P_{\text{ref}} B R_{\text{ref}}^{-1} B^T P_{\text{ref}} + Q_{\text{ref}} = 0 \quad (30.86)$$

and $(Q_{\text{ref}}, R_{\text{ref}})$ are some appropriately chosen symmetric positive definite matrices. Using the LQR design is the preferred way to formulate reference model dynamics and to embed basic performance of an LQR PI controller into system specifications. Due to inclusion of the integrated tracking error in (30.81), the DC gain of the reference model (30.84) is unity. Consequently, if $\Lambda = I_{m \times m}$ and $d(x) = 0_{m \times 1}$, then the baseline LQR PI linear state feedback control $u_{\text{lqr}} = -K_{\text{lqr}}^T x$ enforces global exponential stability of the reference model (30.84), and it makes the regulated output $y(t)$ track any bounded command $y_{\text{cmd}}(t)$, with bounded errors. For a step-input command, the LQR PI controller provides global exponential tracking with zero steady-state errors. Also, it is easy to see that such a choice of the reference model enforces the model matching conditions, whereby given a

Hurwitz matrix A_{ref} and an unknown constant positive definite diagonal matrix Λ , there exists a constant possibly unknown gain matrix K_x such that

$$A_{\text{ref}} = A - B \Lambda K_x^T \quad (30.87)$$

It is important to understand that in this case, existence of K_x is guaranteed for any controllable pair (A, B) and for any nonsingular matrix Λ . In particular, relations (30.85) and (30.87) imply

$$K_x = K_{\text{lqr}} \Lambda^{-1} \quad (30.88)$$

Using (30.87), it is convenient to rewrite the system dynamics (30.81) in the form

$$\begin{aligned} \dot{x} = A_{\text{ref}} x + B \Lambda \left(u + \underbrace{\left[K_x^T x + \Theta_d^T \Phi_d(x_p) \right]}_{\Theta^T} \right) + B_{\text{ref}} y_{\text{cmd}} \quad (30.89) \\ \underbrace{\left(K_x^T \Theta_d^T \right)}_{\Theta^T} \underbrace{\begin{pmatrix} x \\ \Phi_d(x_p) \end{pmatrix}}_{\Phi(x)} \end{aligned}$$

and then get

$$\dot{x} = A_{\text{ref}} x + B \Lambda \left(u + \Theta^T \Phi(x) \right) + B_{\text{ref}} y_{\text{cmd}} \quad (30.90)$$

The control goal of interest is bounded tracking of y_{cmd} in the presence of the system parametric uncertainties $\{\Lambda, \Theta\}$. Specifically, one needs to find a control input u such that the regulated output $y = C x \in R^m$ tracks any bounded time-varying command $y_{\text{cmd}}(t) \in R^m$ with bounded errors, while the rest of the signals in the corresponding closed-loop system remain bounded. In addition, it is desirable to have smooth and quantifiable transient characteristics in the closed-loop dynamics. Using Lyapunov-based arguments (Khalil 1996), coupled with asymptotic analysis (Kevorkian and Cole 1996), one can derive MRAC systems with quantifiable transient performance.

Similar to (30.74) and for the system dynamics (30.90), consider a Luenberger-like reference model in the form

$$\dot{x}_{\text{ref}} = A_{\text{ref}} x_{\text{ref}} + \underbrace{\left[L_v(x - x_{\text{ref}}) \right]}_{\text{Error Feedback Term}} + B_{\text{ref}} y_{\text{cmd}} \quad (30.91)$$

where $\hat{x} \in R^n$ is the reference model state and $L_v \in R^{n \times n}$ is the error feedback gain, parameterized by a positive scalar $v > 0$ (to be defined). The system control input u is selected as

$$u = -\hat{\Theta}^T \Phi(x) \quad (30.92)$$

Substituting (30.92) into the system dynamics (30.90) gives

$$\dot{x} = A_{\text{ref}} x - B \Lambda \underbrace{\left(\hat{\Theta} - \Theta^T \right)}_{\Delta \Theta} \Phi(x) + B_{\text{ref}} y_{\text{cmd}} \quad (30.93)$$

where $\Delta \Theta \in R^{N \times m}$ denotes the matrix of parameter estimation errors.

In what follows, the pair $(L_v, \hat{\Theta})$ will be selected such that the system state x globally asymptotically tracks x_{ref} – the state of the observer-like reference model (30.91), and so $y \xrightarrow{t \rightarrow \infty} y_{\text{ref}}$. Also, one can show that x_{ref} tracks $x_{\text{ref ideal}}$, which in turn implies that $y_{\text{ref}} \xrightarrow{t \rightarrow \infty} y_{\text{ref ideal}}$. Furthermore, since the output of the ideal reference model (30.84) follows its command $y_{\text{ref ideal}} \rightarrow y_{\text{cmd}}$, with bounded errors, and $y \xrightarrow{t \rightarrow \infty} y_{\text{ref}} \xrightarrow{t \rightarrow \infty} y_{\text{ref ideal}}$, then the system-regulated output y will also track y_{cmd} with bounded errors. This argument constitutes the proposed design strategy.

Begin by choosing adaptive laws for $\hat{\Theta}$ so that x globally asymptotically tracks x_{ref} , in the presence of the system uncertainties. Let,

$$e = x - x_{\text{ref}} \quad (30.94)$$

denote the state tracking error. Subtracting (30.91) from (30.93), gives the system transient dynamics:

$$\dot{e} = (A_{\text{ref}} - L_v) e - B \wedge \Delta \Theta^T \Phi(x) \quad (30.95)$$

Choose the error feedback gain L_v as

$$L_v = P_v R_v^{-1} \quad (30.96)$$

where $P_v = P_v^T > 0$ is the unique solution of the following ARE,

$$P_v A_{\text{ref}}^T + A_{\text{ref}} P_v - P_v R_v^{-1} P_v + Q_v = 0 \quad (30.97)$$

with the ARE weight matrices (Q_v, R_v) selected as

$$Q_v = Q_0 + \left(\frac{\nu + 1}{\nu} \right) I_{n \times n}, \quad R_v = \frac{\nu}{\nu + 1} I_{n \times n} \quad (30.98)$$

using a constant parameter $\nu > 0$. This constant will eventually become the design “tuning knob,” where small values of ν yield better MRAC transients. However, the corresponding feedback gain L_v will increase at the rate of $\frac{1}{\nu}$. In fact, as ν tends to zero, the error feedback gain tends to infinity:

$$L_v = \left(1 + \frac{1}{\nu} \right) P_v = O\left(\frac{1}{\nu}\right) \quad (30.99)$$

while the solution P_v of the ARE (30.97) tends to a constant positive definite symmetric matrix P_0 . It is easy to verify that the ARE (30.97) possesses the unique symmetric positive definite solution P_v . Furthermore, because of (30.97), the observer closed-loop matrix

$$A_v = A_{\text{ref}} - L_v = A_{\text{ref}} - P_v R_v^{-1} = A_{\text{ref}} - P_v \left(1 + \frac{1}{v}\right) \quad (30.100)$$

satisfies

$$P_v \underbrace{\left(A_{\text{ref}} - \underbrace{P_v R_v^{-1}}_{L_v} \right)^T}_{A_v} + \underbrace{\left(A_{\text{ref}} - \underbrace{P_v R_v^{-1}}_{L_v} \right)}_{A_v} P_v + P_v R_v^{-1} P_v + Q_v = 0 \quad (30.101)$$

or equivalently

$$P_v A_v^T + A_v P_v = -P_v R_v^{-1} P_v - Q_v < 0 \quad (30.102)$$

and therefore, A_v is Hurwitz for any $v > 0$.

Since P_v is the unique symmetric positive definite solution of the ARE (30.97), then the matrix inverse $\tilde{P}_v = P_v^{-1}$ exists for any $v \geq 0$ and the following relation takes place:

$$A_v^T \tilde{P}_v + \tilde{P}_v A_v = -R_v^{-1} - \tilde{P}_v Q_v \tilde{P}_v < 0 \quad (30.103)$$

The design task is to choose adaptive laws for $\hat{\Theta}$ so that the tracking error e globally asymptotically tends to the origin. Toward that end, consider the following Lyapunov function candidate:

$$V(e, \Delta\Theta) = e^T \tilde{P}_v e + \text{trace}(\Lambda \Delta\Theta^T \Gamma_{\Theta}^{-1} \Delta\Theta) \quad (30.104)$$

where $\Gamma_{\Theta} = \Gamma_{\Theta}^T > 0$ is the adaptation rate. The time derivative of V , along the trajectories of the error dynamics (30.95), can be computed as

$$\begin{aligned} \dot{V}(e, \Delta\Theta) &= e^T \tilde{P}_v \dot{e} + \dot{e}^T \tilde{P}_v e + 2 \text{trace}(\Lambda \Delta\Theta^T \Gamma_{\Theta}^{-1} \dot{\hat{\Theta}}) \\ &= e^T \tilde{P}_v (A_v e - B \Lambda \Delta\Theta^T \Phi(x)) + (A_v e - B \Lambda \Delta\Theta^T \Phi(x))^T \tilde{P}_v e \\ &\quad + 2 \text{trace}(\Lambda \Delta\Theta^T \Gamma_{\Theta}^{-1} \dot{\hat{\Theta}}) \\ &= e^T (\tilde{P}_v A_v + A_v^T \tilde{P}_v) e - 2e^T \tilde{P}_v B \Lambda \Delta\Theta^T \Phi(x) \\ &\quad + 2 \text{trace}(\Lambda \Delta\Theta^T \Gamma_{\Theta}^{-1} \dot{\hat{\Theta}}) \end{aligned} \quad (30.105)$$

Because of (30.102) and using the properties of the matrix trace operator,

$$\dot{V}(e, \Delta\Theta) = -e^T (R_v^{-1} + \tilde{P}_v Q_v \tilde{P}_v) e + 2 \text{trace}(\Lambda \Delta\Theta^T (\Gamma_{\Theta}^{-1} \dot{\hat{\Theta}} - \Phi(x) e^T \tilde{P}_v B)) \quad (30.106)$$

If the adaptive laws are chosen as

$$\dot{\hat{\Theta}} = \Gamma_{\Theta} \Phi(x) e^T \tilde{P}_v B \quad (30.107)$$

then

$$\dot{V}(e, \Delta\Theta) = -e^T (R_v^{-1} + \tilde{P}_v Q_v \tilde{P}_v) e \leq 0 \quad (30.108)$$

and, hence, $V(e, \Delta\Theta)$ is the Lyapunov function for the error dynamics (30.95). For this reason, the tracking error signal e as well as the parameter error matrix $\Delta\Theta$ are uniformly bounded in time, that is, $(e, \Delta\Theta) \in L_\infty$. Since A_{ref} in (30.91) is Hurwitz by design and $(e, y_{\text{cmd}}) \in L_\infty$, then $(x_{\text{ref}}, \dot{x}_{\text{ref}}) \in L_\infty$ and consequently $x \in L_\infty$. Since the unknown parameters Θ are constant and $\Delta\Theta \in L_\infty$ then $\hat{\Theta} \in L_\infty$. The regressor vector $\Phi(x_p)$ is Lipschitz continuous and $(x, \hat{\Theta}) \in L_\infty$. Therefore, from definition (30.92) it follows that $u \in L_\infty$ and consequently $\dot{x} \in L_\infty$. Also, since $\dot{x}_{\text{ref}} \in L_\infty$, then $\dot{e} \in L_\infty$. Using (30.108) yields

$$\ddot{V}(e, \Delta\Theta) = -2e^T (R_v^{-1} + \tilde{P}_v Q_v \tilde{P}_v) \dot{e} \in L_\infty \quad (30.109)$$

The function V from (30.104) is lower bounded and has a nonincreasing time derivative as in (30.108). Thus, V tends to a limit, as $t \rightarrow \infty$. Also the function's second time derivative is uniformly bounded. Therefore, \dot{V} is a uniformly continuous function of time. Using Barbalat's lemma (Khalil 1996) implies that $\dot{V}(t)$ tends to zero, as $t \rightarrow \infty$. Finally, and due to (30.108),

$$\lim_{t \rightarrow \infty} \|e(t)\| = 0 \quad (30.110)$$

which proves global asymptotic stability of the tracking error, attained by the adaptive controller (30.92), the adaptive laws (30.107), and the observer-like reference model (30.91).

In order to show that x_{ref} asymptotically tracks $x_{\text{ref ideal}}$, it is sufficient to subtract (30.84) from (30.91) and write the dynamics of the reference model error $e_{\text{ref}} = x_{\text{ref}} - x_{\text{ref ideal}}$:

$$\dot{e}_{\text{ref}} = A_{\text{ref}} e_{\text{ref}} + L_v \underbrace{e(t)}_{o(1)} \quad (30.111)$$

Then,

$$e_{\text{ref}}(t) = \exp(A_{\text{ref}} t) e_{\text{ref}}(0) + \int_0^t \exp(A_{\text{ref}}(t - \tau)) L_v \underbrace{e(\tau)}_{o(1)} d\tau = o(1) \xrightarrow{t \rightarrow \infty} 0 \quad (30.112)$$

So $x \xrightarrow{t \rightarrow \infty} x_{\text{ref}} \xrightarrow{t \rightarrow \infty} x_{\text{ref ideal}}$, and hence,

$$(y = C x) \xrightarrow{t \rightarrow \infty} (y_{\text{ref}} = C x_{\text{ref}}) \xrightarrow{t \rightarrow \infty} (y_{\text{ref ideal}} = C x_{\text{ref ideal}}) \rightarrow y_{\text{cmd}}(t) \quad (30.113)$$

In other words, the system-regulated output y asymptotically tracks its ideal reference command $y_{\text{ref ideal}}$, and y also tracks its original command y_{cmd} with bounded errors.

Table 30.4 Observer-based MRAC design summary

| | |
|------------------------------------|---|
| Open-loop plant | $\dot{x} = A_{\text{ref}} x + B \Lambda (u + \Theta^T \Phi(x)) + B_{\text{ref}} y_{\text{cmd}}$ |
| Observer-like reference model | $\dot{x}_{\text{ref}} = A_{\text{ref}} x_{\text{ref}} + L_v (x - x_{\text{ref}}) + B_{\text{ref}} y_{\text{cmd}}$ |
| State tracking error | $e = x - x_{\text{ref}}$ |
| Riccati equation for adaptive laws | $P_v A_{\text{ref}}^T + A_{\text{ref}} P_v - P_v R_v^{-1} P_v + Q_v = 0$ |
| ARE weight matrices | $Q_v = Q_0 + \left(\frac{v+1}{v}\right) I_{n \times n}, \quad R_v = \frac{v}{v+1} I_{n \times n}$ |
| Observer gain | $L_v = P_v R_v^{-1}$ |
| Total control input | $u = -\hat{\Theta}^T \Phi(x)$ |
| MRAC laws | $\dot{\hat{\Theta}} = \Gamma_{\Theta} \Phi(x) e^T P_v^{-1} B$ |

The design summary is given in Table 30.4.

In order to analyze the transient dynamics (30.95), substitute (30.96) into (30.95) and write the transient error dynamics as

$$\dot{e} = \underbrace{(A_{\text{ref}} - P_v R_v^{-1})}_{\text{Hurwitz Matrix}} e - \underbrace{B \Lambda \Delta \Theta(t)^T \Phi(x(t))}_{\varphi(t) = \text{Uniformly Bounded Function of Time}} \quad (30.114)$$

Using (30.98) gives

$$\dot{e} = \left(A_{\text{ref}} - \left(1 + \frac{1}{v} \right) P_v \right) e - \varphi(t) \quad (30.115)$$

In (Lavretsky 2011), it is shown that the asymptotic relation

$$P_v = P_0 + O(v), \quad \text{as } v \rightarrow 0 \quad (30.116)$$

holds with a constant positive definite symmetric matrix P_0 . Then,

$$\dot{e} = \left(A_{\text{ref}} - \left(1 + \frac{1}{v} \right) (P_0 + O(v)) \right) e - \varphi(t) \quad (30.117)$$

or equivalently

$$v \dot{e} = (v A_{\text{ref}} - (v+1) (P_0 + O(v))) e - v \varphi(t) \quad (30.118)$$

Rewrite (30.118) as

$$\begin{aligned} v \dot{e} &= (v A_{\text{ref}} - (v+1) (P_0 + O(v))) e - v \varphi(t) \\ &= \left(-P_0 + \underbrace{(v A_{\text{ref}} - v (P_0 + O(v)) - O(v))}_{O(v)} \right) e + v \varphi(t) \\ &= (-P_0 + O(v)) e + v \varphi(t) \end{aligned} \quad (30.119)$$

or, equivalently,

$$\dot{e} = \frac{1}{\nu} (-P_0 + O(\nu)) e + \varphi(t) \quad (30.120)$$

It is not difficult to show (by direct integration), that solutions of (30.120) satisfy the following asymptotics

$$e(t) = O\left(e^{-\gamma \frac{t}{\nu}}\right) + O(\nu), \quad (\nu \rightarrow 0) \quad (30.121)$$

uniformly in time, with a positive constant γ and for all sufficiently small $\nu > 0$. So, the transient dynamics exponentially decay to a neighborhood of the origin, no slower than $O\left(e^{-\gamma \frac{t}{\nu}}\right)$. Moreover, the “diameter” of the convergence set can be made arbitrarily small, by choosing ν to be sufficiently small. This argument formally proves and quantifies transient dynamics improvements in MIMO MRAC systems with observer-like reference models.

There is also an alternative way to analyze the transient dynamics in (30.118). This system can be viewed as singularly perturbed, where ν plays the role of a small parameter. To understand the intricacies of the system behavior, one can employ the singular perturbation arguments (Khalil 1996; Kevorkian and Cole 1996). Setting $\nu = 0$ gives the isolated root $e = 0$ for the corresponding reduced system, which describes asymptotic behavior as $t \rightarrow \infty$, that is, for a sufficiently small $\nu > 0$, the error trajectories converge to a small neighborhood of the manifold $e \equiv 0$ and will evolve near this manifold thereafter. Next, the boundary-layer system is formed to quantify and characterize the transient dynamics. These dynamics are derived by “stretching” the time

$$\tau = \frac{t}{\nu} \quad (30.122)$$

rewriting (30.118) in the “fast” time scale τ , and then setting $\nu = 0$. The resulting boundary-layer dynamics

$$\frac{d e}{d \tau} = -P_0 e \quad (30.123)$$

are globally exponentially stable, since P_0 is symmetric and positive definite (Kevorkian and Cole 1996). In this case, one can claim (Khalil 1996) that for a sufficiently small $\nu > 0$, while starting from an initial time $t_0 \geq 0$, the singular perturbation system (30.118) has a unique solution $e(t, \nu)$, defined on an infinite interval $[t_0, \infty)$, and the asymptotic relation

$$e(t, \nu) = \bar{e}\left(\frac{t}{\nu}\right) + O(\nu) \quad (30.124)$$

holds uniformly on $[t_0, \infty)$, where $\bar{e}\left(\frac{t}{\nu}\right)$ is the solution of the boundary-layer system (30.123) and $t_0 > 0$ is the initial time instant. Since,

$$\bar{e}\left(\frac{t}{\nu}\right) = \exp(-P_0(t - t_0)) \bar{e}(0) \quad (30.125)$$

then substituting (30.125) into (30.124) results in

$$e(t, v) = \exp\left(-P_0 \left(\frac{t-t_0}{v}\right)\right) (x(t_0) - x_{\text{ref}}(t_0)) + O(v) \quad (30.126)$$

This asymptotic relation is conservative. In fact, it has been already proven that the tracking error $e(t, v)$ asymptotically converges to the origin, starting from any initial condition. Consequently,

$$\varphi(t) = B \Lambda \underbrace{\left[\Delta \Theta(t)^T \Phi(x(t)) \right]}_{o(1)} = o(1), \quad (t \rightarrow \infty) \quad (30.127)$$

and so, (30.126) can be rewritten as

$$x(t, v) = \underbrace{\exp\left(-P_0 \left(\frac{t-t_0}{v}\right)\right) (x(t_0) - x_{\text{ref}}(t_0))}_{\text{Transient Dynamics}} + \underbrace{x_{\text{ref}}(t) + O(v)o(1)}_{\text{Global Asymptotic Stability}} \quad (30.128)$$

where P_0 is a constant symmetric positive definite matrix, $o(1)$ is a function of time with $\lim_{t \rightarrow \infty} o(1) = 0$, and $O(v)$ decays to zero no slower than v . Design details and stability proofs can be found in (Lavretsky 2011).

The asymptotic expansion (30.128) quantifies the MRAC transient dynamics. Indeed, for a sufficiently small $v > 0$, the transients, described by the first term in (30.128), decay exponentially fast, while the second term defines asymptotic behavior of the tracking error, as $t \rightarrow \infty$. This constitutes the main benefit of using the error feedback in an observer-based reference model. Essentially, with a sufficiently small parameter $v > 0$, one ensures quantifiable transient characteristics, and the latter are given by the first term in (30.128). The observer-based MRAC design method represents a numerically efficient technique of reducing unwanted transient oscillations in state feedback/feedforward MRAC systems.

The plant dynamics (30.81) and the corresponding control problem formulations can be modified to include nonparametric uncertainties, such as matched uncertainty approximation errors and bounded possibly nonmatched process noise. In that case, one can use known robustification techniques (i.e., σ -modification, e -modification, and the projection operator) to prove bounded tracking performance and then establish transient characteristics. Also, the state feedback MRAC design, with an observer-like reference model, can be extended to adaptive output feedback controllers (Lavretsky 2012).

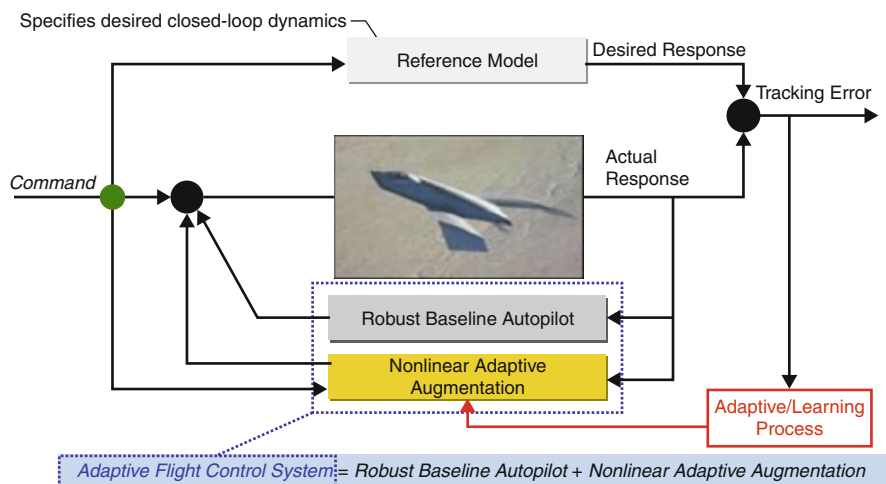

Fig. 30.8 (Robust + adaptive) flight control system

30.6 Conclusion

Robust and adaptive methods can be seamlessly combined to construct resilient controllers, applicable to a wide range of systems, including aerial platforms. A notional block-diagram is shown in Fig. 30.8.

This system is designed to track and execute external commands, provided by a pilot, a guidance logic, or an autonomous mission planner. The architecture embeds a robust baseline controller (LQR PI feedback). The reference model represents the baseline closed-loop dynamics that would be achieved under the baseline controller and without uncertainties. The adaptive control acts as an augmentation to the baseline. Its purpose is to recover the desired baseline performance while operating in the presence of “unknown unknowns” in the system dynamics and operational environment. As depicted in the figure, this control architecture was designed and flown on various vehicles at the Boeing Company. Some are in production today, and yet others were designed to test and verify extreme capabilities and resilience of aerial platforms equipped with robust and adaptive flight controllers.

Section VII

UAV Communication Issues

Eric W. Frew

Kimon P. Valavanis and George J. Vachtsevanos

The absence of a pilot onboard an unmanned aircraft necessitates the development and application of robust, effective, and secure communication technologies that will enable unmanned aircraft to unmanned aircraft, unmanned aircraft to ground or mother ship communications, and unmanned aircraft to air traffic controller communications. Unmanned aircraft control and communication issues are tightly coupled and they are treated as such, since the “*Achilles heel*” of UAVs is controlling them when they are out of range.

► **Problem of UAV Communications** by Heppe summarizes the current consensus view (as of the end of 2012) regarding critical data flows for UAS, control link performance requirements, potential frequency bands that can satisfy the relevant technical as well as regulatory constraints, challenges that must be overcome to ensure reliable operation, and possible data link design principles that could lead to a safe and workable implementation. Both line-of-sight and beyond-line-of-sight data links are addressed. It is shown that the challenges to be faced and overcome are significant, but a safe and workable implementation appears to be achievable through data link diversity and other error correction and error recovery techniques.

► **Cognitive Networking for UAV Swarms** by Brown, McHenry, and Jaroonvanichkul examines the enabling role of cognitive radio technologies for UAS to access more spectrum needed for flight operations. After requirements are set, different architecture choices available to the UAS cognitive radio designer

are presented, including the communication architecture, the spectrum awareness techniques for assessing what spectrum is available, and the spectrum access techniques for deciding which available spectrum to use. Information in this chapter is relevant for the development of future UAS rules and standards.

► **Layered Approach to Networked Command and Control of Complex UAS** by Elston, Stachura, Dixon, Agrow, and Frew discusses different networking hardware, protocols, and sensors that when combined, they create a diverse and complex UAS through a layered design approach with modular supporting software. It is shown that critical software components, such as service discovery, simplify the inclusion of a diverse set of subsystems and sensors. Maintaining the modularity of these software components ensures that the system can be expanded while requiring minimal software changes. A detailed description of a system is presented, which enabled flight operations of a multi-vehicle unmanned aircraft system for performing targeted, in situ sampling of supercell thunderstorms during the 2010 VORTEX2 field campaign.

► **Cognitive Radio Architectures for Unmanned Aircraft Systems** by Wietfeld and Daniel discusses challenges and solution approaches with respect to self-organized and robust multi-UAV systems. The focus is on designing novel service-oriented system architecture to achieve a flexible deployment of UAS. The design aspects of mobility control algorithms addressing the competing requirements of communication reliability and spatial distribution of UAV swarms are demonstrated using aerial sensor networks and ad hoc aerial relay networks. Solution approaches rely on agent-based control of UAV swarms operating autonomously in dynamically changing environments. Different communication-aware algorithms for microscopic as well as macroscopic mobility control are presented, such as Cluster Breathing, Smart Cube, Potential Fields, and Role-Based Connectivity Management. The chapter also discusses how the network and application task-specific performance requirements are met with the proposed mobility control algorithms even in the cases of temporarily unavailable communication links. The self-healing capabilities therefore allow for reliable networking and control of aerial robot swarms in diverse use cases, such as emergency response, environmental monitoring, and ad hoc network provisioning.

Collectively, this section addresses current and future trends and challenges in single and networked UAV communication issues, also highlighting UAV integration issues and communication and networking requirements as dictated by air traffic organizations.

Abstract

Unmanned aircraft have been phenomenally successful in military operations, but have yet to achieve widespread civilian use. This is chiefly due to a concern that unmanned aircraft would pose a danger to other aircraft in the air (including manned aircraft) as well as humans and property on the ground. In order to address this concern and ensure an adequate level of safety, the communication link between the unmanned aircraft and the ground-based pilot – the control link – must carry certain safety-critical data and must be extremely robust and reliable. This chapter summarizes the current consensus view (2012) regarding critical data flows for unmanned aircraft systems, control link performance requirements, potential frequency bands that can satisfy the relevant technical as well as regulatory constraints, challenges that must be overcome to ensure reliable operation, and possible data link design principles that could lead to a safe and workable implementation. Both line-of-sight and beyond-line-of-sight (i.e., satellite based) data links are addressed. It will be seen that the

challenges are significant, but a safe and workable implementation appears to be achievable through data link diversity and other error correction and error recovery techniques.

32.1 Introduction and Scope of Communications Challenge

In principle, an unmanned aircraft (UA) or unmanned air vehicle (UAV) can operate in several modes:

- (a) *Man-in-the-loop*. The pilot on the ground has direct real-time control of all aircraft systems including engine and aerodynamic control surfaces. This is the typical mode of operation for radio-controlled (RC) aircraft operated by the hobbyist.
- (b) *Man-on-the-loop (sometimes called “semi-autonomous”)*. Onboard automation, such as an autopilot, ensures stable and controlled flight in accordance with flight plans and other directives (including real-time flight commands) received from a pilot on the ground.
- (c) *Autonomous*. The aircraft operates without direct real-time human control and responds automatically to changes in its operating environment or aircraft state (although a human may optionally monitor aircraft operations in real time).

Of course, a single aircraft might be capable of all three modes of operation. For example, the nominal operating mode for most of a flight might be “man-on-the-loop,” but with the capability for “man-in-the-loop” for launch and recovery, and “autonomous return to base” in the event of control link failure.

While an aircraft capable of fully autonomous operation from launch to recovery might be a desirable *theoretical* goal, the practical reality is that the aviation industry – and society at large – does not yet trust the state of the art in automation to allow fully autonomous operation as a normal matter. The operating assumption is that, in the general fault-free case, a certified human pilot will have responsibility for the UA while it is operating (RTCA 2007, p. 11). This phrasing allows for at least two modes of operation: (a) man-in-the-loop (direct real-time control of the aircraft flight trajectory by the pilot); and (b) man-on-the-loop (semi-autonomous with the UA autopilot executing a flight plan previously commanded by the pilot). Of course, with the pilot not physically on the aircraft, a communications link must be provided. In addition, an autonomous mode will be needed for the (extremely rare) event of a control link failure. It should also be noted that policy guidance for very small UA (micro UA) might be less stringent but is yet to be established.

This chapter will generally refer to a UA, which is synonymous with a UAV, as part of an “unmanned aircraft system” (UAS) as shown in Fig. 32.1. The UAS consists of the UA and the pilot. These two elements are tied together by control link interactions that provide telemetry and status on the “return link” (UA to pilot) and telecommands on the “forward link” (pilot to UA). For a line-of-sight (LOS) system, the return link and forward link are synonymous with “downlink” and “uplink,” respectively. In a beyond-line-of-sight (BLOS) system, both the return link and the forward link comprise an uplink and downlink to/from a satellite. For example, the

Fig. 32.1 Internal data flows for an unmanned aircraft system (UAS)

forward link comprises a satellite uplink from the pilot control station (or some other ground-based satellite gateway terminal to which the control station is connected) to the satellite, and a downlink from the satellite to the UA.

The UA and its pilot must solve all the problems of a more traditional (manned) aircraft. Specifically, the UAS as a whole must be able to “aviate, navigate, and communicate” – three verbs that are drilled into every pilot. The first, *aviate*, refers to managing and controlling the aircraft, ensuring stable flight and avoiding obstacles both in the air and on the ground. The second, *navigate*, refers to knowing one’s current position and flight plan. The third, *communicate*, refers to voice and data communication with air traffic control, other aircraft in the airspace (which may or may not be actively coordinating with the UA), and associated systems on the ground. In a traditional manned aircraft, only the last required a “technical” means of communication – typically a radio, although light signals and even hand signals have been used in the past. The first two (*aviate* and *navigate*) involved “communication” only in the sense of a pilot observing his or her instruments, making adjustments to those instruments, and manually controlling the aircraft itself (either directly, or indirectly via the autopilot). In the case of a UA, all three activities now involve technical means of communication since the intimate connection between the pilot and his or her UA must now be extended over longer distances – from hundreds of meters to thousands of kilometers. These new communications links must be highly reliable and exhibit very high levels of integrity in order to provide the same level of positive control that is achieved by a pilot actually flying in a plane. In order to quantify the levels of performance required, the aviation community relies on a paradigm called “required communications performance” (RCP) which consists of four performance metrics (ICAO 2008):

1. *Availability*. The probability that an operational communication transaction can be initiated when needed.
2. *Continuity*. The probability that an operational communication transaction can be completed within the communication transaction time.
3. *Integrity*. The probability that communications transactions are completed within the communication transaction time with undetected error.
4. *Latency and communication transaction time*. Latency is the maximum time to deliver a one-way message (or a two-way message plus response) for a given communications system. Communications transaction time is the time for completion of the operational communication transaction (including human response time) after which the initiator should revert to an alternative procedure.

“Availability” is simply the long-term average probability that a communications link exists and is able to support a needed communication transaction, at an arbitrary instant of time when a human (or automated system) attempts to send a message. If there is a single radio link connecting the pilot and UA, “availability” would be the probability that both the ground radio and airborne radio are in working order; that the radio link is not corrupted by rain, foliage, jamming, or airframe blockage; and that the radio channel is not over-subscribed by other users. Note that random bit errors on an otherwise fault-free channel are excluded from this definition. “Continuity” is a conditional probability that a communication transaction can be completed (within the necessary time limit), given that the communications facility was “available” at the start of the transaction. Continuity is typically affected by short-term “soft failures” such as multipath fading and airframe blockage. If one ignores the case where a communications link is “failed” at the start of a transaction but “recovers” and successfully delivers a message within the required timeframe, then the probability of actually delivering an arbitrary message is $\Pr\{\text{delivery}\} = (\text{availability}) (\text{continuity})$. Values from 0.9 to 0.999 are typical. Particular requirements for UA communications are identified below. The general term “reliability” can be used as a shorthand term encompassing both availability and continuity.

Integrity is the probability of an undetected error in a message (sometimes defined as the probability of experiencing an undetected error in any message over a defined span of time, such as an hour). Typical values range from 10^{-5} to 10^{-10} or even lower. This definition actually quantifies a “loss of integrity,” but it is easier to cite a single exponent than a large number of nines (e.g., either 5 nines or 10 nines, or even more).

Transaction expiration time is the time allowed to complete a transaction before an unsafe condition would result. Typical values have traditionally fallen in the range of seconds to hundreds of seconds. However, for linking a pilot to a UA for real-time perception of the airborne environment and real-time control, more stringent values are needed (fractions of a second to seconds). For one-way transactions such as delivery of telemetry, transaction expiration time is equivalent to the end-to-end latency of the data link. For two-way transactions, such as the delivery of a particular telemetry message indicating a potential collision threat, plus an uplink command executing an avoidance maneuver, transaction expiration time includes the two-way latency of the data link plus the pilot response time.

Before detailing the numerical requirements for communications performance, and engineering methods to achieve that performance, it is useful to review the types of communication that must be supported. Figure 32.2 illustrates electromagnetic (radio and radar) interactions between the UAS (the UA and its pilot) and external entities. Some of these have an obvious impact on UAS communications. For example, in the navigation domain, many UA will have GPS and VOR receivers (as examples). These must be controlled and managed by the pilot via the telecommand forward link, and their output data must be delivered to the pilot by the telemetry return link. These data flows are generally low bandwidth (i.e., only limited amounts of data per second) and repetitive (thus, occasional message losses are not critical). Similarly, ATC ground surveillance involves various airborne subsystems which

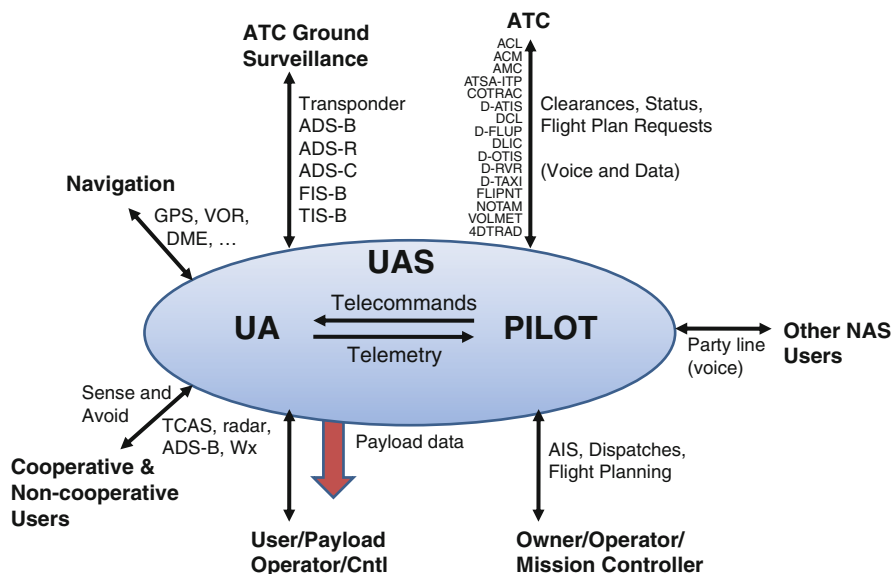

Fig. 32.2 UAS external interactions

must be controlled by the pilot (e.g., the radar transponder and automatic dependent surveillance – broadcast transmitter), and in some cases their output must be returned to the pilot as well (e.g., traffic information service – broadcast (TIS-B) receivers). It should be noted that some data can flow directly to or from the pilot without passing through the UA.

The sense and avoid data streams (for cooperative and non-cooperative targets) are some of the most critical since aircraft move quickly and pilots generally have only a few seconds to make key decisions when things go wrong. These data streams place stringent constraints on the availability, continuity, latency, and integrity of the telecommand and telemetry data links of medium and large UA. Typical airborne equipment in this domain includes traffic alert and collision avoidance (TCAS), the ADS-B receiver, traffic radar, and weather radar. The data from these sensors must flow down to the pilot as telemetry data with very high reliability and integrity, and very low latency. Pilot telecommand responses to the aircraft, necessary to control the aircraft trajectory, avoid obstacles, and ensure safety of flight, must be returned to the aircraft with similar levels of reliability, integrity, and latency.

The “air traffic control” (ATC) data flows comprise the traditional voice and data interactions between a pilot and the air traffic control system. The end-points of these interactions are the pilot on one side and the air traffic controller (or other ATC system element) on the other side. Typically for a manned aircraft, a radio on the aircraft would communicate with a radio at the desired ATC facility (such as an airport tower or en route center) or alternatively with a remote radio facility that was networked through ground infrastructure to ATC. This is shown graphically as the radio communications links labeled “A” and “B” in Fig. 32.3. These links

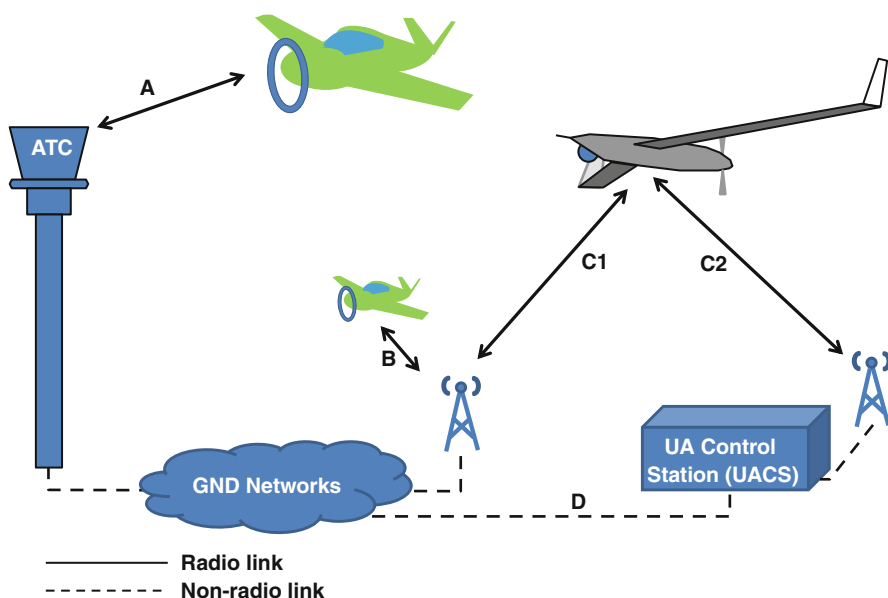

Fig. 32.3 Data link options for ATC communications

are usually shared on a party-line basis by many aircraft in a single ATC sector. For a UA, one could insist that ATC communications continue to be routed to (through) the aircraft as indicated by the links labeled “C1” and “C2” in the figure. This has the advantage that ATC deals with a UA just as it deals with a manned aircraft; the link C1 is equivalent to the link A or B from the standpoint of ATC. This would also maintain the party-line nature of the ATC/UA link since manned aircraft in the vicinity would be able to hear both the ATC and the relayed UA pilot’s transmissions. However, the voice (or data) on the aircraft must be routed to/from the pilot which requires a second radio link C2 in a different frequency band (i.e., to prevent cosite interference caused by simultaneous transmission and reception). C2 could be the same radio link used for UA telecommand and telemetry or a different link. Either way, the tandem combination of C1 and C2 will have lower end-to-end link availability, continuity, integrity, and worse latency, than either C1 or C2 alone. Furthermore, since there is no way for the UA to determine autonomously when a voice signal is coming from ATC and intended for its pilot, versus being transmitted by (or to) another pilot, the link C2 must actually carry *all* the traffic on link C1 – even though only a small fraction of this traffic is intended for the UA and its pilot. Hence, the bandwidth penalty is significant – each UA would effectively consume the equivalent spectrum of an entire ATC radio channel (albeit in a different band), instead of only a small fraction of a channel as is typical today.

An alternative is to recognize that the UA pilot is actually on the ground and potentially could be accessed without any reliance on radio at all. This is indicated by landline “D” in the figure. Since landlines and other forms of terrestrial communication can be made more robust compared to radio links, this approach has advantages in terms of end-to-end availability, continuity, integrity, and latency (in addition to the savings in terms of bandwidth). However, this so-called “wired ATC network” approach requires an enhancement to the switching and networking capability of the ATC system.

A third possibility is to rely on a radio link between ATC (or a remote radio tower) and the pilot in the UA control station (i.e., from one radio tower to another in the figure), thereby avoiding any change to the ATC switching system but nevertheless bypassing the UA itself, thereby avoiding the need for a relay. This approach is particularly convenient when the UA control station (the UACS) is in the same geographic area as, and has line-of-sight visibility to, the ATC facility or its remote radio tower.

In reality, all three approaches should be accommodated in a mature architecture since some missions may not allow the pilot control station to easily access terrestrial infrastructure (e.g., disaster relief, remote/oceanic operations, etc.). However, the “wired ATC network” approach should be emphasized due to its benefits in terms of availability, continuity, integrity, latency, and spectrum utilization efficiency.

Returning to Fig. 32.2, the party-line (voice) communication to other NAS users refers to the current situational awareness afforded by each pilot listening to the voice interaction between ATC and other aircraft in the vicinity. This may become less important in the future as ATC shifts to data link instead of voice, but party-line voice communications can be maintained (to the extent used) by suitable voice-activated switching capability between landlines and radios.

All of the external data flows addressed so far, in relation to Fig. 32.2, involve communications related to the safety of flight. These external data flows, along with the internal telecommand and telemetry data flows, are jointly identified as “control and non-payload communications” (CNPC). To the extent that radios are used for these flows (recall that ATC voice and data would ideally rely on landlines), the frequency channels used must be protected from a regulatory standpoint and reside in “aeronautical safety spectrum.” This is addressed further below.

The owner, operator, and mission controller data flows, in Fig. 32.2, connect the pilot to the aircraft owner/operator or mission commander and do not normally involve radio communication in protected aeronautical spectrum.

Finally, payload data (and control and status of the payload) must be addressed in the context of a complete system. However, this is a special category of communication since it does not involve safety of flight. Certain payloads, for example, video cameras, can involve very large data rates and bandwidths but must be handled outside of “aeronautical safety spectrum” if they are used as a mission payload. However, if used for ensuring safety of flight (e.g., for separation assurance or takeoff and landing support), they would fall within the CNPC “safety of flight” domain.

32.2 Detailed CNPC Performance Requirements

The international community has been working for several years to estimate the future bandwidth and performance requirements of UA CNPC. This work has proceeded within the RTCA (a not-for-profit corporation that functions as a Federal Advisory Committee for the U.S. Federal Aviation Administration), EUROCAE (a European body also dedicated to aviation standardization), the International Civil Aviation Organization (ICAO), and the International Telecommunications Union (ITU). As of this writing (2012), a consensus is beginning to emerge. This consensus can be understood in terms of the bandwidth needs of an individual UA, the aggregate bandwidth needs of all UA in the airspace (requiring additional assumptions on the number, type, and deployment of UAS), and the RCP performance parameters needed to ensure safety of flight.

Bandwidth Requirements for a Single Large UA. The key CNPC data flows illustrated previously in Fig. 32.2, which must be supported in aviation-protected spectrum, can be grouped into three broad categories: (1) command and control, (2) relay of ATC voice and data, and (3) sense and avoid. These involve forward link as well as return link communications which vary as a function of phase of flight and type of flight control employed (manual control, with the pilot directly commanding the control surfaces in real time, versus “automatic” (man-on-the-loop) with the pilot directing an onboard autopilot in terms of, for example, speed, climb rate, turn rate, heading, or a detailed flight plan). The estimated data throughput requirements (bits per second) are tabulated in Fig. 32.4 for a large,

| PHASE OF FLIGHT AND OPERATING MODE (MANUAL OR AUTOMATIC) | COMMAND AND CONTROL | | | | ATC RELAY | | | SENSE AND AVOID | | |
|--|---------------------|------------------|---------|------|-------------|------------|----|------------------|------------------------------|---------|
| | CONTROL | | NAVAIDS | | VOICE RELAY | DATA RELAY | | TARGET TRACKS | AIRBORNE WEATHER RADAR | VIDEO |
| | UPLINK (UL) | DOWNLINK (DL) | UL | DL | UL and DL | UL | DL | DL | DL | DL |
| | | | | | | | | | | |
| MAXIMUM FOR ANY PHASE OF FLIGHT [1] | 4600 | 7600 | 670 | 1100 | 4800 | 50 | 60 | 9100 | 28 000 | 270 000 |
| AVERAGE FOR MANUAL OPERATION | 1700 | 3200 | 670 | 870 | 4800 | 24 | 31 | 9100 | 8700 | 270 000 |
| AVERAGE FOR AUTOMATIC OPERATION | 440 | 650 | 140 | 190 | 4800 | 24 | 31 | 9100 | 8700 | 270 000 |
| OVERALL AVERAGE | 690 | 1200 | 250 | 330 | 4800 | 24 | 31 | 9100 | 8700 | 270 000 |

| NOTES: | | | | | | | | | | |
| 1. Flight phases include departure, en route, and arrival. Pre-flight and post-flight phases are excluded. | | | | | | | | | | |
| 2. Data throughput values include overhead and are rounded to two significant figures. | | | | | | | | | | |
| 3. Target tracks assumes 60 targets in local environment of the UA. | | | | | | | | | | |
| 4. Video is only needed intermittently, for some aircraft. | | | | | | | | | | |
| 5. Overall average assumes 80% of aircraft are operating automatically in each flight phase; 20% operating manually. | | | | | | | | | | |

Fig. 32.4 Estimated peak and average non-payload throughput requirements (bps) for a typical large UA over a 4 h flight

well-equipped UA (smaller UA might not support all listed data flows). Note: The “uplink” and “downlink” terminology of Fig. 32.4 can be converted to “forward link” and “return link,” respectively, in order to generalize for both LOS and BLOS communication architectures. The bottom row indicates average requirements for a large UA assuming 80 % of such aircraft are operated “automatically” (man-on-the-loop). All values include link overhead for network control, error correction, and authentication.

Examining Fig. 32.4, the peak uplink (forward link) data throughput requirement is roughly 10 kbps (summing the uplink contributions in the top row), and the average data throughput requirement is roughly 5.8 kbps (summing the uplink contributions in the bottom row). A significant element in both of these values is ATC voice relay (4.8 kbps) which, as noted earlier, might be handled via landline without any RF spectrum impact at all – for at least some users. As a consequence, the future CNPC data link must be able to accommodate an uplink (forward link) data throughput of at least 10 kbps per UA (this might be required for some UA for some periods of time), but careful design might allow a large number of UA to share the spectrum resource with each UA consuming on average only 5.8 kbps of system capacity if the UA is used to relay ATC voice communication or only 1 kbps of system capacity if a “wired ATC network” is employed to connect ATC directly with the pilot, bypassing the UA.

Similarly, for the downlink (return link), the peak requirement is roughly 320 kbps (again driven by the terminal area approach phase), and the average is about 290 kbps. These are large numbers, but several caveats are important:

- (a) The 270 kbps for “sense-and-avoid video” (intended to enhance situational awareness) is assumed to represent an intermittent requirement. It is not clear, at this time, if video is intermittently *required* for some or all classes of UA or only *desirable*. Some UA might not have this subsystem, and the associated data burden, at all.
- (b) Weather radar is also a significant data load (the two values in the table reflect compressed versus uncompressed data depending on phase of flight) but might only be installed on a small fraction of the medium and larger UA. It seems likely that a pilot in a ground-based UA control station could access real-time weather products via landline or satellite broadcast, without requiring a dedicated data stream from his or her own UA.
- (c) Target tracks (sense-and-avoid downlink indications of nearby traffic, including potential “intruders” that represent a risk of collision) are arguably one of the most critical data flows in the entire system. The data volume of this component is estimated at roughly 9.1 kbps. It is imperative that the pilot have a complete and accurate understanding of nearby traffic. However, even here, there is a potential for capacity savings through, for example, “reporting by exception” as suggested at the end of this chapter.
- (d) As with the uplink assessment, a portion of the downlink is based on relay of ATC voice (4.8 kbps) which, as noted earlier, might be handled via landline without any RF spectrum impact at all – for at least some users.

As a result of these considerations, the future CNPC data link(s) must be able to accommodate up to 320 kbps per UA on the return link; however, some UA, some of the time, may require as little as 1.5–2 kbps if they do not use video for sense and avoid, do not have a weather radar installed and operational, rely on target reporting by exception, and rely on a wired ATC network for ATC voice to/from the pilot.

Because of the wide range of data throughput requirements for a single UA, it is imperative that a multi-access sharing system be implemented which minimizes wasted spectrum and allows for efficient allocation of radio channel resources to individual UA.

Bandwidth Requirements for a Regional Population of UA. The international community is currently attempting to allocate RF spectrum for UA CNPC data links. This requires an assessment of aggregate bandwidth requirements considering the needs of individual UA; the extent to which small, medium, and large UA participate in the data flows indicated above; the population distribution of small, medium, and large UA; the number of UA that might be operational at any one time; and the spatial distribution of these UA both geographically and in altitude (this affects the number of UAS that are mutually visible to one another as well as their associated ground stations). Furthermore, the total bandwidth required for a regional population of UA depends on whether the aircraft are supported by (a) line-of-sight (LOS) radios between the UA and the pilot as illustrated in Fig. 32.3 or (b) beyond-line-of-sight (BLOS) radios using satellite relay.

As a first step, the participating members of ITU-R Working Party 5B estimated the peak areal density of UA in the 2030 timeframe. Two methods were used. The first method estimated areal density for all aircraft and then assumed that 10 % of these would be UA. A second method attempted a bottom-up analysis by projecting the number and types of UA missions (military and civilian, governmental, and commercial) that could be implemented by 2030, assuming regulatory guidelines were in place. These two methods resulted in expected areal densities of between 8.6 and 10.4 UA per 10,000 km² (ITU-R 2009, Tables 5 and 7). This is equivalent to 0.00086–0.00104 UA/km². These are average densities which do not account for variations associated with human population density or particular mission requirements (military or otherwise).

The total expected population of UA was also subdivided into three broad aircraft classes: small, medium, and large. These three classes were assigned certain operational characteristics, such as typical operating altitude and avionics equipment and typical operating regime. Working from the more conservative (larger) areal density noted above, the consensus view is that, for a uniform geographic distribution, small UA operating below 300-m altitude can be expected to represent an areal density of ~ 0.0008 UA/km², medium UA operating between 300 and 5,500 m can be expected to represent an areal density of ~ 0.0002 UA/km², and large UA operating above 5,500 m can be expected to represent an areal density of ~ 0.00004 UA/km². The altitude range affects channel sharing and frequency reuse across geographic domains, and avionic equipment affects flight operations. For example, small UA were assumed to operate only in daylight at low altitude, within visual range of the pilot (and the UACS), and have only the most basic

flight controls and sensors and therefore have only limited need for data transfer in aviation-protected spectrum.

ITU-R WP5B also considered the impact of nonuniform geographic distribution of UA – for example, due to disaster relief such as floods and hurricanes and normal geographic asymmetries due to airport operations. While these factors can lead to a localized increase in areal density by as much as a factor of 10, the group determined that such nonuniformities could be accommodated by relying on spectrum resources in neighboring areas. Thus, total spectrum requirements could be based on the uniform distribution.

Based on the analyses performed, ITU-R WP5B concluded (ITU-R 2009) that the total aviation-protected spectrum requirements for UA CNPC data links are:

- 34 MHz for a terrestrial LOS system supporting all UA
- 56 MHz for a regional-beam satellite BLOS system supporting medium and larger UA only (small UA are assumed to be too small to support the antenna needed for a satellite BLOS system)

The satellite-based system requires more spectrum, despite supporting only a subset of the UA, because it is comparatively less able to rely on frequency reuse. Within a terrestrial LOS system, bandwidth requirements would be split between uplink and downlink with UACS to UA data flows consuming 4.6 MHz and UA to UACS data flows consuming 29.4 MHz. Within a satellite-based BLOS system comprising multiple satellites and a degree of frequency reuse, the forward links from the UACS to the satellite, and from the satellite to the UA, each consume 4.1 MHz and the return links from the UA to the satellite, and from the satellite back down to the UACS, each consume 24.05 MHz.

RCP Thresholds for CNPC Data Flows. In addition to the individual and aggregate bandwidth requirements, which affect user channelization and total system capacity, it is important to understand the required communications performance in terms of availability, continuity, integrity, and transaction expiration time (including latency). Figure 32.5 provides guidance on the RCP levels recommended for pilot-to-controller voice and data communications, based on ICAO (2008). This provides

| RCP Type | Transaction Time (sec) | Continuity (per flight hr) | Availability (per flight hr) | Integrity* (per flight hr) | Usage |
|----------|------------------------|----------------------------|------------------------------|----------------------------|--|
| RCP 10 | 10 | 0.999 | 0.99998 | 10 ⁻⁵ | Controller voice intervention supporting separation assurance in a 5 nmi radius environment |
| RCP 60 | 60 | 0.999 | 0.9999 | 10 ⁻⁵ | Controller routine communication in a 5 nmi radius environment – data |
| RCP 120 | 120 | 0.999 | 0.9999 | 10 ⁻⁵ | Controller voice intervention supporting separation assurance in a 15 nmi radius environment |
| RCP 240 | 240 | 0.999 | 0.999 | 10 ⁻⁵ | Controller voice intervention supporting separation assurance in a 30/50 nmi radius environment |
| RCP 400 | 400 | 0.999 | 0.999 | 10 ⁻⁵ | Controller voice intervention supporting separation assurance outside a 30/50 nmi radius environment |

*This is actually the probability of a loss of integrity during an arbitrary flight hour.

Fig. 32.5 ICAO guidance on RCP for controller/pilot voice and data communication

information related to some, but not all, of the data flows associated with UA CNPC. The reader may note that continuity and availability levels are relatively high (typically 0.999–0.9999 and even 0.99998 for voice availability in an RCP 10 environment associated with a 10-s transaction expiration time) but that the transaction times are on the order of tens to hundreds of seconds. This implicitly allows for some “soft failures” where a link may be interrupted or interfered with for a period of time but then recovers.

RTCA Special Committee 203 (RTCA/SC-203) has been working to identify additional requirements, beyond those identified by ICAO, specifically necessary to support UA CNPC data links. Final consensus has not been achieved, but some preliminary results are available in working papers within the committee and can be reported here. Readers are cautioned that further refinement may occur.

With regard to controller/pilot voice and data communications for UA, RTCA/SC-203 Working Group 2 has tentatively determined that the technically achievable round-trip latency for UA is likely to be up to a second longer than the technically achievable round-trip latency for manned aircraft. For ATC *voice communications*, the current capability for manned aircraft is about 770 ms (95 %) according to RTCA (2003). An additional second of delay for UA will still easily satisfy the ICAO guidance summarized above in Fig. 32.5. However, the situation for ATC *data communications* is less clear. In 1995, the FAA produced a report entitled Air Ground Data Link VHF ACARS Preliminary Test Report (Rehmann and Mestre 1995). The report concluded that the average round-trip message delay associated with ACARS (an existing air/ground data link system used by airlines and ATC) fell within the range of 10–20 s, with 5 out of approximately 2,300 messages lost. While the authors noted that Aeronautical Radio Inc. (ARINC), the operator of the ACARS, did not endorse the tests performed, these results would fall short of the most stringent ICAO guidance for data communications, even without an additional second of delay. Luckily, it is possible to improve the observed performance of ACARS with an enhanced (or a new) data link system. The working group has recommended further analysis to validate the ability to meet controller/pilot data link requirements for future UA operations.

While controller/pilot data link communications represent an obvious issue for future UA operations, the real driving consideration for RCP, in the context of UAS, appears to be the interaction between a pilot and his or her UA in a time-critical safety-related scenario – specifically, a loss of separation between two aircraft flying in opposite directions on a collision course (see Fig. 32.6).

In the case of an unmanned aircraft flying beyond visual range of the UACS and without the benefit of an autonomous collision avoidance system, the UA must sense the intruder, alert the pilot through a reliable return link, and respond to pilot forward link commands in order to avoid the collision. The detection of an intruding aircraft, and determination of a collision threat, could be based on TCAS, ADS-B, TIS-B, radar, or even visual detection with a suitable processor and software. The critical data flows are the telemetry containing the target track for the intruding aircraft and the telecommand containing the pilot's command for the avoidance maneuver.

Fig. 32.6 Collision avoidance scenario (RTCA 2011)

The entire timeline for this collision avoidance scenario spans only a few tens of seconds. This places high demands on communications link availability, continuity, and latency. RTCA/SC-203 has addressed this scenario with a two-pronged analytic approach:

- (a) First, identify RCP performance levels that appear adequate to achieve the same levels of safety as demonstrated by manned aircraft today.
 - (b) Second, develop a strawman communications architecture, with sufficient engineering detail, to verify that these performance levels can be achieved in practice.
- As a preliminary matter, the working group recognized that the short timeline for the collision avoidance scenario places a stringent upper limit on communication latency. Simulations indicate that round-trip delays beyond a few seconds (exclusive of pilot reaction time) can adversely affect the outcome. Furthermore, the working group has recognized that the round-trip communication transaction time cannot be less than roughly 500 ms for a LOS communications system, or 1,100 ms for a BLOS communications system, due to the inherent message assembly and transmission times and propagation delays (RTCA 2009a). Hence, there is a strong incentive to deliver each message reliably on the first attempt. While message repetition (multiple transmissions separated in time) is not precluded as a viable communications technique, it should not be the primary means employed to achieve the necessary levels of link reliability. A precise latency requirement has not been identified, but the working group is proceeding under the assumption that the round-trip latency requirement for 95 % of the transactions must be on the order of 2 s or less.

Turning to availability and continuity, two methods were used to identify total probability of message delivery, which could then be used to derive RCP performance levels for availability and continuity (RTCA 2011). Method #1 relied on historical midair accident rates for general aviation (Part 91) and transport category aircraft (Part 121). It then applied assumptions relating to the likelihood of experiencing a potential midair collision scenario and the likelihood that a pilot could avoid a collision by observation and piloting. The UA CNPC data link must

have sufficient performance to not significantly degrade the pilot's ability to avoid the collision. Method #2 relied on the probability of catastrophic failures noted in FAA/AC 23.1309 for Class I and Class III aircraft. Class I (single reciprocating engine, gross weight <6,000 pounds) was used as a surrogate for smaller UA (Part 91 equivalent operations in Method #1). Class III (single or multiengine, reciprocating or turbine, gross weight >6,000 pounds) was used as a surrogate for large UA (Part 121 equivalent operation in Method #1). These two methods resulted in comparable performance values for total probability of message delivery: 99.8 % for smaller and medium UA equivalent to general aviation aircraft operating under Part 91 and 99.999 % for larger UA equivalent to transport category aircraft (Part 121 operations). These are stringent values for a radio communication link – not easily achieved without careful engineering. Furthermore, the reader's attention is drawn to the fact that larger UA have substantially more challenging requirements than smaller UA.

The RCP performance parameters of availability and continuity may be traded off against one another to some degree but must be set so as to jointly satisfy the required overall delivery probability for a particular class of aircraft (either 99.8 or 99.999 %), keeping in mind that

$$\text{Pr}\{\text{delivery}\} = (\text{availability}) (\text{continuity}).$$

With regard to message integrity, ICAO has already identified a target level for ATC/pilot voice and data communications as noted above in Fig. 32.5. This level is no more than one undetected message error per 10^5 flight hours. This can be converted to a per-message probability of undetected error (an undetected message error rate, or UMER) by considering the maximum number of messages that can be delivered over a span of time. For example, if the eventual UA CNPC data link supports 25 messages per second, there would be the potential for 90,000 messages per hour and required UMER = $1.1 \times 10^{-10} \sim 10^{-10}$. This level of integrity may also apply to relatively noncritical pilot/UA control interactions such as routine telemetry and some classes of telecommand which do not have an immediate impact on flight operations. However, this conjecture requires validation.

There is also the question of integrity for pilot/UA interactions that are associated with extremely time-critical safety messages (such as track reports for potential intruder aircraft) and uplink commands that affect aircraft trajectory (such as avoidance maneuvers) or changes to flight plans stored in the UA. These have not been addressed by ICAO, but the RTCA/SC-203 has associated these messages with a potential catastrophic loss in the event of an undetected message error and tentatively assigned a required integrity level of no more than one undetected message error per 10^9 flight hours for larger UA. This is based on the historical midair collision rate of 2.5×10^{-9} per flight hour for Part 121 operations, the threshold level of catastrophic failure for Class III aircraft of 10^{-8} per flight hour from FAA AC 23/25.1309, and the likelihood of a catastrophic hazard (10^{-9}) as listed in FAA (2008). As with the integrity level for ATC voice and data communications, this can be converted to a UMER by considering the number of

message opportunities per hour. If the eventual UA CNPC data link supports 25 messages per second, the derived UMER = 10^{-14} .

It should be noted that the analytic framework and RCP performance values and bounds described above are tentative and have not yet been validated by any regulatory body. The ITU based its analysis of bandwidth needs on three classes of UA (small, medium, and large), and these bandwidth requirements are currently being used to identify suitable RF spectrum resources. In slight contrast, the RTCA has tended to analyze RCP performance requirements relative to just two classes – a class of “smaller” UA which is somewhat related to the small UA of the ITU but is more directly associated with performance requirements derived from those of general aviation (Part 91 operations) and a class of “larger” UA which is somewhat related to the medium and large UA of the ITU but is more directly associated with performance requirements derived from those of transport category aircraft (Part 121 operations). The ultimate classification of UA and UAS operations, for regulatory purposes, will be agreed within ICAO based on consensus among the world’s civil aviation authorities; this work has yet to be completed. The performance requirements noted above should be viewed as *likely representative* of the range of requirements that may ultimately be applied to various classes of UA, recognizing that the specific classifications, breakpoints between classes, and associated requirements are subject to refinement and validation.

32.3 Frequency Bands for CNPC Communications

As noted in ITU-R (2010), current UAS use a wide range of frequency bands for control of the UA in segregated airspace. Systems operate on frequencies ranging from VHF (72 MHz) up to Ku-band (15 GHz) for both line-of-sight (LOS) and beyond-line-of-sight (BLOS). The factors driving the choice of frequency are related to limiting the size, weight, and power of the airborne data link equipment – particularly antennas and power amplifiers – as well as satisfying the data rates required. Many LOS systems operate in frequency bands allocated to the mobile service, or the aeronautical mobile service, but are not accorded extra protection as a safety service such as bands allocated to the aeronautical mobile (route) service (AM(R)S) or the aeronautical mobile satellite (route) service (AMS(R)S). Furthermore, many LOS and BLOS systems share the control link and the payload return link on a common carrier. This is desirable from the standpoint of minimizing radio size, weight, and power but mixes different data types in a way that would not be allowed in safety spectrum.

In the future, considering that UA will operate in civil nonsegregated airspace, and that the UA CNPC data link will help ensure the safety of life and property, the RF spectrum employed for CNPC will need to be designated as a safety service. Figure 32.7 lists some existing aeronautical bands, between 100 and 5,150 MHz, which were examined by RTCA/SC-203 for UAS. Other aeronautical or aeronautical-related bands exist but were excluded from this list because either (a)

| Frequency Band | Allocated Use (typical systems) |
|-------------------|---|
| 108 - 112 MHz | ARNS (ILS LOC) |
| 112 - 117.975 MHz | ARNS (VOR, GBAS) |
| 117.975 - 137 MHz | AM(R)S (VHF voice and data) |
| 960 - 1215 MHz | ARNS (DME, TACAN, Radar Transponders) |
| 1525 - 1559 MHz | AMS(R)S |
| 1610 - 1660 MHz | AMS(R)S |
| 2900 - 3100 MHz | Radiolocation, Radionavigation |
| 5000 - 5150 MHz | ARNS (MLS), Radionavigation Satellite, AMS(R)S, FSS (but limited to MSS feeder links) |

Fig. 32.7 Potential aeronautical or aeronautical related bands for UA CNPC data links

they are already allocated to systems which would not be suitable for sharing with UAS or (b) they are at frequencies inappropriate for UAS use. After considering numerous factors including existing congestion in each band, potential for sharing, available bandwidth, link range, capacity, propagation characteristics, and air and ground cosite compatibility (among others), the list was narrowed to two candidates: portions of the 960–1,024-MHz ARNS band for a LOS system; and the 5,030–5,091-MHz band for either a LOS or BLOS system (or both) (RTCA 2009b). While the 960–1,024-MHz subband currently lacks an AM(R)S allocation as would be required for a LOS system, this was viewed as achievable from a regulatory standpoint. As for the 5,030–5,091 MHz band, the only incumbent user is the microwave landing system (MLS) which is deployed in very limited numbers. Technical analyses indicated that both LOS and BLOS (satellite) CNPC systems could effectively share the band with MLS.

While other candidate bands could potentially be used on a case-by-case basis, they would not be suitable for meeting any significant portion of the projected bandwidth requirements of the UAS community (34 MHz of terrestrial spectrum and 54 MHz of satellite spectrum).

In a similar vein, the ITU-R has identified portions of the 960–1,164 and 5,030–5,091-MHz bands as good candidates to support control links for UAS without causing harmful interference to incumbent services and systems (ITU-R 2010). As noted by the ITU, the 960–1,164-MHz band is highly favorable for UAS control links. Rain losses are negligible and free-space path losses are low enough to permit reliable long-range LOS communication between relatively low-power radios using omnidirectional and medium-gain antennas. While much of the band is heavily used, substantial subbands (960–976 and 1,151–1,156 MHz) are not used by airborne NAVAID transmitters and contain no fixed ground-based assignments in some countries. In such countries, 10.4 MHz of spectrum could be made available, which would furnish small UA with badly needed access to protected spectrum and provide

UA of all types with band diversity that is essential for reliable UA CNPC. While the identified spectrum (10.4 MHz) is less than the 34 MHz identified as needed for terrestrial/LOS links, it “would suffice to meet all UAS CNPC requirements except for backup links, video, and downlinking of airborne weather-radar data in some countries.”

RTCA/SC-203 has also noted (RTCA 2009b) that Inmarsat and Iridium (satellite systems operating in the 1.5-/1.6-GHz bands) could be considered as existing BLOS systems able to support UA CNPC links. Inmarsat operates in a band with a clear AMS(R)S allocation, has a total bandwidth of 14 MHz available on a worldwide basis, and is suitable for BLOS UA CNPC. Iridium also operates in an aeronautical band and has been used for BLOS UA CNPC by at least one UAS. But its first-generation system has rather limited per-channel bandwidth which limits its suitability for the full range of UAS (however, this may be overcome in its second-generation system).

RTCA/SC-203 has also considered the potential for a new AMS(R)S allocation at either Ku-band or Ka-band that could support BLOS UA CNPC with a wide-band geostationary satellite system. At Ku-band, the 12/14 GHz commercial fixed satellite service (FSS) band and the 13.25–13.4 and 15.4–15.7-GHz bands are all attractive. The latter two bands are allocated to the aeronautical radio navigation service (ARNS) on a primary basis, although the lower band is limited to Doppler navigation systems and both bands have other coprimary allocations. Nevertheless, the existing ARNS allocation indicates the potential to add another aeronautical safety service such as AMS(R)S. Similarly, the 19.7–20.2 and 29.5–30.0-GHz bands (Ka-band) appear potentially suitable for UAS BLOS CNPC links, with the upper 50 MHz of each of these bands appearing to be particularly attractive given other existing users, allocations, and interference considerations. SC-203 noted that “The close proximity between these bands and those used by Ka Band equipped military UAS makes it possible for the military to use the same equipment in both segregated and non-segregated airspace by just tuning to different frequencies without the need to change antennas or modems. This is a very attractive feature of the proposed K/Ka band segments” (RTCA 2009b).

As is clear from the preceding discussion, it is challenging but not impossible to assemble the necessary spectrum resources for UAS CNPC data links. Of course, a single UAS could operate within the currently allocated bands using less than a MHz of spectrum, and the first several UAS deployed would not perceive any bandwidth constraints. However, uncontrolled or uncoordinated proliferation of UAS with differing CNPC data link formats, protocols, and waveforms could lead to relatively inefficient use of the spectrum and the potential for unsafe conditions brought about by interference. Therefore, there is a strong incentive to define a common data link standard that could efficiently support the entire community. The work of defining such a standard is likely to take place initially in various advisory bodies such as RTCA and EUROCAE, with an eventual standard being finalized by consensus within the International Civil Aviation Organization (ICAO).

32.4 Technical Challenges for CNPC Communications

As noted previously, the required communications performance (RCP) thresholds for UA CNPC data links are stringent. The information flows for sense-and-avoid and pilot control, in particular, must be extremely reliable, have low latency, and have very high integrity, in order to ensure safety of flight. While numerical requirements have not yet been formally adopted, the emerging consensus at RTCA indicates that availability and continuity must satisfy message delivery probabilities on the order of 99.8–99.999 %, latency must be on the order of 1–2 s, and undetected message error rates (integrity) for at least some information flows (for some UA) must be on the order of 10^{-10} – 10^{-14} per message. In order to meet these requirements, the system designer must address hardware failures that could permanently disable a link. Hardware failures primarily affect link availability and continuity (not latency or message integrity) and can be mitigated through careful design and system redundancy using well-understood techniques. These will not be further discussed. In addition, the system designer must address “soft failures” such as airframe shadowing, multipath fading, rain attenuation, and random bit errors introduced on the channel, which lead to short-term outages and potential undetected errors. These short-term outages are actually the dominant concern for the most stringent RCP thresholds identified. For example, airframe shadowing or excess rain attenuation, which persists for several seconds, could prevent a pilot from recognizing a safety threat and taking appropriate and timely action. The key impairments, of interest to the UA system designer, are addressed below in the context of the “link budget” which provides a quantitative framework for understanding link performance.

The Link Budget as a Framework for Understanding Soft Failure Issues. All radio communication links operate by transmitting energy in a particular physical format (e.g., a “waveform”) from the transmitter to the receiver. Generally, for digital data links, one or more particular parameters of a sinusoidal radio wave are adjusted among a finite number of possibilities from one transmitted symbol to another. For example, the amplitude, frequency, or phase of the sinusoid might be adjusted. These alternatives generally go by the names of amplitude shift keying (ASK), frequency shift keying (FSK) and phase shift keying (PSK). The number of different symbols that can be sent is usually a power of 2; for example, a system with two possible phase states is called binary PSK or BPSK. A system with eight possible frequencies is called 8ary FSK or 8-FSK. Literally scores of different waveforms have been invented over the years. However, all of them involve the transmission of energy from a transmitter to a receiver. The desired signal is generally received at a very low signal level (picowatts, or even less) and in the presence of natural and man-made RF noise from the environment, as well as RF noise generated internal to the receiver itself. This RF noise tends to corrupt the desired signal and prevent accurate decision-making as to the symbol or symbols actually sent by the transmitter. Hence, a primary task of the communications engineer is to ensure that the amount of received energy in the desired signal, during a given symbol

interval or set of symbol intervals, is sufficient to allow accurate reception of the vast majority of transmitted messages.

The analytic framework used to predict reliable reception is called the “link budget.” A link budget is similar to a household financial budget, where one starts with monthly take-home pay or revenue, subtracts known fixed expenses as well as an allowance for variable expenses, and checks to see if everything can be covered – hopefully with a little extra “margin” that can be saved for a rainy day (i.e., when variable expenses turn out to be larger than expected). In the case of an RF link budget, one starts with the power transmitted by the transmitter, accounts for known fixed losses as well as an allowance for variable losses, and checks to see if there is sufficient power at the receiver (or, in other words, sufficient energy in each received symbol or set of symbols) to allow reliable reception given the expected RF noise – hopefully with a little extra “margin” that can be used if losses are greater than expected or the transmitter is somewhat weaker than expected.

| Parameter | Units | Uplink | Downlink |
|--|-------|--------|----------|
| Transmit power | dBm | 40 | 40 |
| Transmit antenna gain ¹ | dBi | 8 | 0 |
| Cable and filtering loss | dB | 1 | 1 |
| Transmit EIRP | dBm | 47 | 39 |
| FSPL (1 GHz, 75 nmi) | dB | 135 | 135 |
| Additional losses ² | dB | 23 | 23 |
| Receive antenna gain ¹ | dBi | 0 | 8 |
| Cable and filtering loss | dB | 1 | 1 |
| Received signal power | dBm | -112 | -112 |
| Receiver noise power | dBm | -126 | -126 |
| Available Carrier-to-noise ratio (C/N) | dB | 14 | 14 |
| Theoretical C/N | dB | 6 | 6 |
| Implementation losses | dB | 2 | 2 |
| Safety margin | dB | 6 | 6 |
| Required C/N | dB | 14 | 14 |
| Excess margin ³ | dB | 0 | 0 |

¹Variability of UA antenna gain due to airframe blockage or reflections is taken into account in the airframe loss part of the “additional losses” row.

²Additional losses comprise atmospheric losses, airframe losses and multipath losses. These are convolved together and the quoted value provides for 99.8% link availability (0 dB margin, 99.8% of the time).

³With double or triple ground diversity, the excess margin could increase by 9 to 14 dB.

Fig. 32.8 Simplified link budget for line-of-sight UA CNPC data link at L-band (Based on RTCA (2011) and Wilson (2011))

A simplified sample link budget, showing the major categories of fixed and variable losses that must be considered for a LOS UA CNPC link, is illustrated in Fig. 32.8. This link budget is used here only as an example – many of the values are particular to the specific design and assumed operating scenario; other assumptions as to operating band, waveform, and operating scenario, would lead to different numbers. Also, a BLOS link budget must consider four links instead of just two (the UA uplink and downlink to the satellite and the ground station uplink and downlink to the satellite). Finally, the reader should note that the various gains and losses are multiplicative, but the link budget converts everything to a scaled logarithm called a “decibel” (dB). This allows the gains and losses to be added and subtracted as in a financial budget.

Looking to the figure, the first line is the actual transmitter power in dB (milliwatts) or dBm. The numerical value of 40 dBm is equivalent to a 10 Watt transmitter. This link budget assumes that both the ground-based radio (for the uplink) and the airborne radio (for the downlink) have the same transmitter power. The second line is the antenna gain. The ground antenna is assumed to have a moderately directive antenna (8 dB relative to isotropic, or 8 dBi) which “focuses” the RF energy into a beam with roughly 8 dB more power than if the energy were radiated equally in all directions (8 dB is roughly a factor of 6:1). The airborne antenna is assumed to be nominally isotropic, so it has no directive gain relative to an isotropic antenna. However, the airborne antenna is mounted on the aircraft and can easily be shadowed by the airframe. As a result, the actual gain experienced from one moment to the next can vary significantly from this value. Generally it will be worse. This is accounted for in the “additional losses” line below. The third line accounts for transmitter cable and filtering losses. Finally, the fourth line accumulates the first three into a “figure of merit” for the transmitter – its “effective isotropic radiated power” (EIRP). This is used for the subsequent calculations.

The free-space path loss (FSPL) row accounts for the weakening of the RF signal as it propagates from the transmitter to the receiver. For a radio link at roughly 1-GHz (L-band), and a 75-nmi path, the loss is 135 dB. This is a nominal value assuming no big obstructions and no refractive losses. Further data and calculation methods are provided in ITU-R (2007). For UA operating at long range and low altitude (expected to be a common scenario), the design engineer should specifically account for diffraction losses which can add on the order of 15–20 dB of loss for an aircraft close to the radio horizon (ITU-R 2007; CCIR 1991).

The “Additional losses” row accounts for several time-varying effects which are critical to an understanding of the UA CNPC data link design. These include airframe shadowing, antenna variability, multipath fading, and atmospheric and rain attenuation (especially relevant at 5 GHz and higher). Since these different effects are physically independent, a statistical analysis is needed to determine the “allowance” that must be provided in order to guarantee a given level of performance. For the sample link budget provided here and based on other data and design assumptions as discussed below (including at least two antennas on the aircraft but a single ground antenna), a convolution of the probability distributions indicated that the combined losses would be no worse than 23 dB, 99.8 % of the

time. Thus, a CNPC data link attempting to achieve an availability of 99.8 %, with these assumptions, should allow for 23 dB of variable losses.

The next three lines account for the receive antenna gain, cable and filtering losses at the receiver, and final received power level (dBm) at the input to the first-stage amplifier, assuming the variable losses noted above were at the threshold value. The aircraft antenna gain (0 dBi) is again a nominal value that does not account for the expected variation already handled in the “additional losses” row. The assessed received signal power is -112 dBm (6×10^{-15} W).

The “receiver noise power” line accounts for ambient and receiver-internal RF noise across the channel bandwidth of the receiver. This is usually based on measured data for the environment and measured or predicted data for the receiver equipment chain including the antenna, cables, filters, mixers, and first-stage amplifier (at least), referenced to the same reference point as the received carrier power (in this case, the input to the first-stage amplifier). The sample link budget indicates an equivalent noise power of -126 dBm.

The difference between the received signal power, or carrier power (C), and the receiver noise power (N) is the “carrier-to-noise power ratio” (C/N). This value (14 dB for the sample link budget) must be large enough to allow for reliable operation, allowing the messages to be received without error (at least most of the time). Note that C/N refers to the integrated power (for the desired signal and the noise) over the receiver channel bandwidth. Another important metric is ratio of the energy in a single transmitted symbol or bit (abbreviated E_s or E_b) and the noise power density per Hz of bandwidth (abbreviated N_0), called E_s/N_0 or E_b/N_0 , respectively. All of these metrics represent a “signal-to-noise ratio” (SNR), but because of the definitional differences, any reference to “SNR” should be precisely defined as one of these particular metrics for a particular application or calculation.

The “theoretical C/N ” is the C/N for a particular waveform and data link protocol (with its synchronization features, authentication, and forward error correction) needed to achieve the desired message error rate, before accounting for implementation losses (hardware imperfections). For the waveform and forward-error-correction coding scheme assumed here, this value is 6 dB. To this theoretical C/N value, it is necessary to account for the receiver implementation losses (such as improper timing, inaccurate carrier tracking, amplifier nonlinearities, filter distortion) and also allow for a “safety margin” accounting for all additional effects and link impairments beyond the ability of the engineering team to predict. In this case, the combination of the theoretical C/N , implementation losses, and safety margin ($6 + 2 + 6 = 14$ dB) exactly matches the available C/N assuming variable link losses at the 99.8 % availability level. Hence, the link closes 99.8 % of the time as required, taking into account all the known variables (the engineering team could say they succeeded in the link design), but there is no “excess margin” beyond the safety margin.

Considering the link budget as a whole, it is clear that the “additional losses” line is a key driver. The primary physical factors contained in this line are now addressed.

Fig. 32.9 Typical top-mounted antenna performance on a mid-sized aircraft (RTCA 2011) (Ref: Colby et al. 1996)

Airframe Shadowing and Installed Antenna Performance. It is convenient – but not accurate – to assume that an omnidirectional antenna mounted on an aircraft will actually deliver uniform gain in all directions (or even uniform gain over one hemisphere, such as an upper hemisphere for a top-mounted antenna or a lower hemisphere for a bottom-mounted antenna). Figure 32.9 illustrates typical performance for a mid-sized manned aircraft with a top-mounted, nominally omnidirectional L-band antenna (either horizontal, vertical, or right-hand circular polarized) operating at 1,575.42 MHz, relatively close to the potential new AM(R)S allocation around 1 GHz currently being considered for UAS CNPC data links.

The left-hand panel of Fig. 32.9 indicates significant gain variation within 15° of the local horizontal plane and very poor performance (as much as 25 dB below nominal) below the aircraft. For an aircraft that is a significant lateral distance from the serving ground station, any bank “away from” the ground station would expose the bottom of the aircraft to the ground station and create a significant drop in antenna performance. The right-hand panel (measured at a 7° depression angle roughly associated with long-range communications to a ground station, for an aircraft in straight-and-level flight) indicates that typical gain is roughly -5 dB but typically varies by several dB for different azimuth angles relative to the aircraft centerline. Furthermore, more than 5 % of the azimuthal pattern exhibits an additional 5 dB loss, and there are narrow nulls (e.g., exactly off the tail) where antenna gain is as much as 10 dB worse than nominal (if “nominal” is taken to be -5 dB relative to an ideal isotropic antenna). Clearly, these variations must be accounted for if the system is intended to achieve 99.8 % or greater link availability.

The loss in performance (as much as 25 dB in this case) can be partially mitigated by installing, and relying on, two or more CNPC data link antennas strategically placed on the UA. For example, top, and bottom-mounted antennas, or antennas located at each wingtip, can be used to ensure that the worst-case losses are never

experienced simultaneously by both (or all) antennas. Multiple antennas on the ground can also be used – particularly if the UA CNPC architecture relies on a shared nationwide infrastructure with multiple radio cells (sectors) each with its own antenna. For three widely separated ground antennas surrounding a UA, spanning more than 180° of arc as perceived by the UA, at least one ground antenna will always have a nominally unobstructed view to at least one antenna on the aircraft. These techniques are both called “antenna diversity” or “space diversity” (because one node or “station” has two or more antennas at different locations in space). The improvement due to antenna diversity is illustrated in Fig. 32.10 for a particular UAV with a carbon composite body and a 3-m wingspan. The upper panel is for a single L-band antenna installed in a winglet (i.e., at the end of a wing, in an RF-transparent housing). The five traces are for different elevation or depression angles relative to the local horizontal, but the key point of this plot is the worst-case performance for a single antenna, experienced at any angle, at roughly -28 dBi. This would imply a required link margin of at least 28 dB, just for this impairment alone, relative to a link designed for a nominal 0-dBi antenna.

The lower panel indicates that diversity antennas can reduce the required margin to about 13 dB.

If multiple antennas are available on the ground as well, arranged so as to avoid a condition where all of them are on a “line of symmetry” relative to the airborne antennas, or all of them can view only one of the airborne antennas (this requires at least three widely separated ground antennas surrounding the aircraft and spanning more than 180° of arc as seen from the UA), the margin requirement can likely be reduced to roughly 10 dB or less (RTCA 2011). This is an 18-dB improvement over the no-diversity case.

Multipath Fading. Multipath refers to portions of the transmitted signal which are reflected off of objects or terrain in the environment and which arrive at the receiving antenna nearly “out-of-phase” relative to the direct signal. This can significantly reduce the received signal strength. Close to complete cancellation (fading) can occur for short periods of time. Figure 32.11 illustrates typical fading on an L-band air/ground data link for an aircraft flying at 500 m, communicating with a ground station antenna 25 m above ground level.

The large-scale lobing evident in Fig. 32.11, with signal strength varying by 10–20 dB, is due to so-called ground-bounce multipath and is relatively predictable for a particular environment and flight profile (as indicated by the red trace which is a mathematical model) (ICAO 1999). The fine-scale fading is due to other effects such as reflections off of individual terrain features, buildings, small bodies of water, and the airframe itself. As with the antenna effects illustrated earlier, these multipath fades must be accounted for if the system is intended to achieve 99.8 % link availability or greater. ITU-R (2007) provides a general method to estimate the probability of fade depth for multipath fading, but does not provide any framework to assess correlation time (the time that the fade depth is relatively constant). This turns out to be a significant factor for CNPC link availability and continuity. Also, while there is a fair amount of experimental data for air/ground data links at VHF, there is relatively little experimental data for air/ground data links (on flight

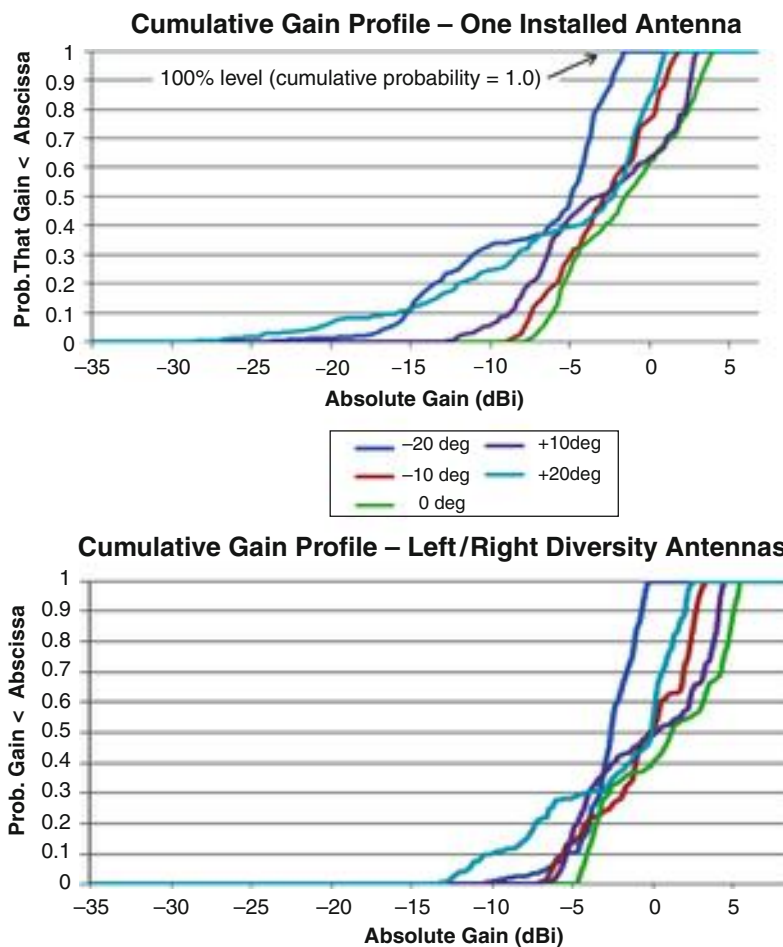

Fig. 32.10 Antenna performance with and without diversity

profiles that would be representative of typical UA operations) at L-band and above. While some estimates of expected UA CNPC link performance can be made by extrapolating from lower frequencies and compensating for known differences at the higher frequencies, further work is needed in this area.

Lacking precise information on the correlation time of multipath fading for typical UA operating scenarios at the expected operating frequencies, one can nevertheless make a first estimate of required fade margin by calculating the cumulative fade distribution for a given environment, using approved techniques as described, for example, in ITU-R (2007). Typical values at L-band are 18 dB of fading (at the 99.8 % availability level) for an aircraft at 75-nmi range and 10,000-ft altitude, and a ground antenna at 100 ft, and 22 dB of fading (for 99.8 % availability) if the aircraft is at 5,000-ft altitude. At shorter range, for example, 30 nmi, multipath

fading may be on the order of 10 dB less severe – but this is still a significant impairment.

As with airframe and antenna variation, multipath effects can be partially mitigated by multiple data link antennas on the aircraft or on the ground (or both). Widely separated ground antennas can partially mitigate ground-bounce multipath (the large-scale variation in Fig. 32.11), and antenna diversity on the ground as well as the aircraft can partially mitigate the short-term fluctuations simply because the reflected signals are unlikely to arrive at all the available antennas with the same relationship of amplitudes and phase shifts. For example, with two data link paths exhibiting uncorrelated statistics, the pair will deliver 99.8 % link availability if each individual link is engineered to provide roughly 95 % link availability. At long range and low altitude, this can reduce necessary fade margins by roughly 10 dB (e.g., to the range of 7–10 dB). Additional diversity paths provide additional gain, although improvements quickly become marginal.

Furthermore, if multiple messages are sent in quick succession (i.e., within the correlation time of the fading, so that several messages in succession might be corrupted), a change in channel operating frequency from one message to the next can frequently provide for independent fading statistics. This can be beneficial in systems that rely on selective retransmission (or even multiple transmissions for all messages) to enhance overall link availability. Preliminary evidence and analysis indicate that a slow frequency-hopping system operating within the contiguous bandwidth expected for a LOS system (i.e., on the order of 10 MHz or greater) will provide the necessary statistical independence from one message to the next.

Atmospheric and Rain Attenuation. All radio signals are attenuated by atmospheric gases, water vapor, and liquid rain. At L-band and below, this attenuation is generally very small and can be ignored or compensated by a relatively modest margin allowance. However, at 5 GHz and above and especially at Ku- and Ka-band

Fig. 32.11 Typical multipath fading (See also ICAO 1999 for a comparison of measured and modeled fading on typical air-ground VHF data links)

frequencies currently under consideration for at least some BLOS links, both clear sky and rain attenuation can be significant. Of course, it does not rain all the time (the worldwide average is only about 5 % at a random location), and some aircraft might actually fly above the rain layer for most of their mission. But for aircraft flying in the rain (e.g., during takeoff and landing and for low-altitude operations) and using a data link frequency of 5 GHz or higher for safety communications, link outages caused by rain must be explicitly considered. There are several widely used models for attenuation caused by atmospheric gases, water vapor, and rain. ITU-R (2007) offers a good starting point; this ITU recommendation draws on several other ITU recommendations and provides a good road map for analysis. Generally speaking, atmospheric gases contribute a fairly predictable and constant attenuation for a given operational scenario, whereas the rain models provide a statistical understanding of the percentage of time that a particular attenuation level is exceeded. This directly affects the assessment of link availability. Surprisingly, it turns out that continuity (the problem of a link failing *during* a message transmission period) can be substantially ignored at the availability levels (and probability of message delivery) relevant to UA CNPC. This is because rain fades tend to persist for tens of seconds or longer, with fade levels changing significantly only over seconds (not milliseconds) as a consequence of the physics of rain. Specifically, the volume of space, through which the RF signal travels, can be thought of as an extended tube or ellipsoid which is partially filled and emptied by the rain. An intense rain burst will tend to “fill” the radio path with water, whereas a lull in the rain will tend to allow the radio path to empty out. Because raindrops fall at a characteristic rate and because the radio path has a significant length and girth, it takes a finite amount of time (typically measured in seconds) to significantly change the amount of liquid water contained in the tube or ellipsoid.

Antenna diversity (space diversity) is generally not as effective at combating rain attenuation on BLOS links since the rain fade on two data links supported by a single aircraft tends to be correlated, even if multiple satellites are used for these two data links (i.e., two antennas on the UA pointing to different satellites).

Convolution of Time-Varying Effects. As noted earlier, once the characteristics of antenna performance, airframe shadowing, multipath fading, and rain attenuation are understood for a particular LOS or BLOS CNPC architecture and operational scenario, the four effects should be treated as statistically independent and convolved to derive an aggregate distribution of fade probability, to avoid an overly conservative link design. For the case of a typical L-band CNPC data link operating an LOS path over 75 nmi, intended to achieve an overall availability of 99.8 % with dual-link diversity, these separate effects would have a combined margin requirement in excess of 30 dB. In contrast, a proper statistical analysis indicates that the actual requirement is only 23 dB. The reader is cautioned that these numbers are illustrative, and particular UA operating scenarios should be separately validated to ensure that required link performance can be achieved.

Lost-Link Considerations. Despite all the engineers’ best efforts, there is always a possibility that the CNPC data link (including all its diversity paths) will be

permanently lost. This could affect the telemetry link or the telecommand link or both. Potential causes are: hardware failures on the UA, hardware failures at the UACS, hardware failures in the ground infrastructure, widespread jamming or interference, and pilot error (e.g., commanding the UA to fly beyond communications coverage). If ATC voice and data communications were being routed through the UA at the time of failure (instead of being routed directly between ATC and the UA control station through a wired ground network), the ATC data flows would be affected as well (note: this is another reason to favor the wired ground network, and only rely on ATC data flows relayed through the UA when no other alternative exists).

When a lost-link event occurs, procedural methods must be in place to ensure safety of flight for the affected UA, safety of flight for other aircraft in the airspace, and safety for people and property on the ground. There is as yet no worldwide consensus on how to handle a UA with a lost CNPC link. However, several reasonable procedures can be identified now based on currently available technology and operational procedures:

- First, “heartbeat messages” on uplink and downlink can be used to track link performance and quickly identify a lost-link event when it occurs (time out thresholds are currently TBD). If found to be operationally beneficial, summary statistics could even be echoed back to the other node (e.g., the UA could transmit down to the UACS, as part of its telemetry stream, the statistics of the heartbeat messages it observed on the uplink).
- If the UA detects a failed CNPC data link, it could autonomously set a unique radar transponder code which would serve to alert ATC, as well as other aircraft in the airspace, that it was suffering a lost link. This would be similar to the existing procedure for radio failure on a manned aircraft. A lost forward link is directly observable by the UA. A lost return link, which leaves the forward link intact, is also possible although less likely. This can be detected if the UACS is echoing back return link heartbeat statistics or if the UACS has the ability to send a dedicated command indicating a lost return link. Hence, it is always possible for the UA transponder to be properly set. Suitable transponder codes remain to be defined but are currently being considered. Special messages could also be broadcast via future (or upgraded) ADS-B systems.
- If controller-pilot communications are supported with a wired ground network, these data flows will likely remain intact even if the UA CNPC RF data link fails. Therefore, the pilot can inform ATC that the UA has suffered a lost link. Similarly, if the UA has reset the transponder code, this will be apparent to ATC, and the controller could then contact the pilot.
- The UA should have a default flight plan, stored in its onboard computer, which will be autonomously executed in the event of a lost CNPC data link. This flight plan might be updated from time to time during a particular flight but should in any case comprise standardized procedures (following guidelines preapproved by aviation regulatory authorities). For example, this might involve a short period following its current flight plan while broadcasting its condition via its

radar transponder and ADS-B transmitter (this allows ATC to clear the airspace immediately around the UA), followed by a climb to a preapproved altitude, followed by execution of a new flight plan such as “circle for X minutes waiting for link to be reestablished” or “return to base” or “fly to alternate recovery site” or “fly to previously identified remote area and self-destruct.” If the UA is equipped with ADS-B, the flight plan being executed could potentially be broadcasted via this medium so that ATC, and surrounding aircraft, would be aware of the UA’s intent. It should be noted that some UA operational today already implement such a lost-link flight plan strategy as part of their standard operational doctrine (absent the broadcast via ADS-B).

32.5 A Strawman Architecture for CNPC Communications

Potential architectures for UA CNPC communications have evolved within RTCA, the ITU-R, and other groups. The strawman architecture described in this section (the “strawman”) is one such solution based on the work in RTCA and is presented here simply to illustrate the types of solutions that could be envisioned for a future system. Other options are certainly possible and will need to be explored before a final conclusion can be developed into a consensus standard for the UAS industry to adopt.

With regard to frequency bands, the strawman incorporates LOS links at L-band and C-band and BLOS links at C-band and either Ku-band or Ka-band (or both). Precise band edges are TBD, but current international efforts indicate that it will be possible to assemble at least 34 MHz of LOS spectrum and 56 MHz of BLOS spectrum by relying on this approach. Note that C-band is shared between LOS and BLOS; the strawman assumes that the BLOS system will operate with uplink and downlink channels at the edges of the allocated C-band spectrum (likely the 5,031–5,090-MHz band) with a central gap between the two. This central gap is necessary to avoid self-interference by BLOS users who will be transmitting and receiving simultaneously. The gap is then filled with the C-band portion of the LOS subsystem. The exact split between the LOS and BLOS spectrum at C-band is TBD and could potentially vary from one geographic region to another. Alternative bands may also be used by individual UAS – for example, VHF for LOS connectivity and L-band (using either Inmarsat or Iridium) for BLOS connectivity. But the strawman concept does not focus on these alternatives.

The LOS subsystem is assumed to rely on airborne antennas which are nominally omnidirectional. However, as noted above, each airborne antenna is assumed to suffer significant shadowing and nulling due to its interaction with the airframe. Thus, at least two antennas and radios are assumed for even the smallest UA.

The transmitters on the aircraft, and the transmitters and antennas at the ground stations, must be sized to provide sufficient transmit power and antenna gain to close the link against the expected fixed and variable impairments as discussed above. Engineering trade-offs among these elements (i.e., the airborne and ground transmitters and the ground antennas) are expected within the framework of the

strawman design and the associated link budget analyses. Phased-array or “smart antenna” technology, with signal detection and characterization and multichannel beam-forming capability, is expected to be used in the ground stations in order to track and provide sufficient ground antenna gain to multiple UA at arbitrary locations in a given coverage sector. An additional advantage of this technology is that multipath fading on the downlink could potentially be eliminated or reduced to very small levels.

Diversity techniques are heavily used in order to meet anticipated (but not yet validated) RCP requirements. The UA population is assumed to be sub-divided into two groups based primarily on size but possibly including other factors such as speed and operating regime. The first group is comprised of “smaller” UA which must satisfy a message delivery probability of 99.8 % within 1–2 s in order to satisfy presumed safety requirements. The second group is comprised of “larger” UA which must satisfy a message delivery probability of 99.999 % within 1–2 s. The first group is expected to have relatively small CNPC data throughput requirements, is not expected to operate BLOS because of their small size, and may rely almost exclusively on L-band LOS links. At least two antennas and radios are assumed to exist on each of these smaller UA in order to provide support for the necessary level of diversity to achieve 99.8 % message delivery probability with feasible transmit power and omnidirectional airborne antennas (but even more antennas and radios may be installed, if required). The second group is expected to have larger CNPC data throughput requirements as well as more stringent RCP requirements will use either LOS or BLOS (or both) and will rely on a dual-band system offering at least four-way diversity. For example, a larger UA could rely on L-band and C-band for LOS links, with at least two antennas and radios in each band (a total of at least four antennas and radios), or some combination of C-band, Ku-band, or Ka-band BLOS links (for aircraft that are so equipped), so as to provide connectivity to at least two satellites simultaneously with each satellite link engineered to deliver at least 99.8 % message delivery probability (thereby achieving 99.999 % delivery probability for the diversity pair). Larger UA with BLOS capability are also expected to support LOS capability for short-range and low-altitude operation where terrestrial infrastructure exists to support them. This also partially mitigates the problem of overcoming rain attenuation at low altitude (i.e., for takeoff and landing operations), where the satellite link (if used) might encounter a significant amount of rain attenuation along the radio path.

With regard to LOS ground stations, a regional or nationwide deployment is assumed in order to provide basic coverage (similar to VHF voice radio and ATC radar today) as well as to provide adequate space diversity to meet expected RCP requirements. A notional deployment is illustrated in Fig. 32.12. In this concept, 12 frequency subbands are assigned to nominally hexagonal sectors and reassigned such that co-channel interference between sectors using the same subband is minimized (note: this is for sectors that have relatively high-altitude limits; a dedicated frequency plan for smaller UA might use a “four-color mapping” instead of a “twelve-color mapping”). Within the strawman concept, the total number of ground stations is equal to the total number of sectors (an actual deployment could

ground station pilot signals, the UA will associate itself with a particular sector and ground station (this could also be commanded by the ground system in some cases). This access process involves authentication of the UA in the system and assignment of a low-rate or high-rate channel (or subset of a channel) based on UA data link requirements. When a smaller UA is required to transmit, it selects the antenna/radio that has recently exhibited the best uplink performance from *any* of the ground stations in view, and transmits through this antenna/radio pair *on its assigned channel* (i.e., the one associated with its “primary” CNPC data link).

In a similar vein, each ground station monitors all traffic channels in the system – not only its “assigned subset.” This is a little different from cellular systems today, but a receiver bank is relatively inexpensive, and the benefits are enormous (as will now be explained). When a ground station receives a message on a channel outside its primary responsibility, it reads the header and routes the message to the primary ground station to which it was addressed (or a suitable concentrator node that communicates with a regional grouping of ground stations). In this way, each ground station acts as a potential “diversity receiver” for each UA downlink transmission, thereby achieving the diversity goals of the system without increasing spectrum utilization (spectrum is expensive; receivers are cheap). The primary ground station (or a suitable concentrator node – which in the limit could even be the UA control station) merges the return link messages from each UA into a correlated stream by selecting the first copy of each message received and discarding later copies. The correlated stream is routed to the UACS (if the concentrator node is not the UACS itself).

Return link message reception statistics are gathered at each ground station for each UA and shared among the regional ground stations or merged at a concentrator/controller node (which could be the UACS if this is the concentrator node for downlink traffic). In principle, this sharing or merging of data allows for optimum selection of a ground station for forward link transmissions to each UA (i.e., the ground station with greatest probability of message delivery). The selection algorithm has not been defined or agreed, but options include (a) deterministic use of the “primary” until a handoff is executed (this either fails to optimize message delivery probability or requires frequent handoffs which incurs its own overhead penalty), (b) selection of an optimum ground station with uplink transmission on the UA’s preassigned frequency (this requires the non-primary ground station to transmit on the primary’s channel, while the primary remains quiet) or (c) selection of an optimum ground station with uplink transmission on a channel associated with the selected ground station (this requires additional control traffic and a time delay to alert the UA that an unexpected frequency channel should be monitored for an imminent message). Each of these options has advantages and disadvantages that are yet to be assessed and traded off.

For larger UA that operate at both L-band and C-band in order to achieve 99.999% message delivery probability within the LOS subsystem, critical messages are duplicated at L-band and C-band, and parallel processes to those described above are implemented at C-band. Hence, there will be a minimum of two message transmissions (one in each frequency band) and nominally four or more received

copies. It is assumed that each ground station location will host both an L-band and a C-band subsystem. But even though the ground stations host dual-frequency systems, multipath will be statistically independent between the two frequencies. UA manufacturers can also strive for statistical independence of antenna/airframe directive gain patterns as well (although the extent to which this can be achieved in practice is TBD).

For wideband and less critical traffic, such as video to enhance situational awareness, and weather radar, and some low-rate control traffic, only the C-band subsystem is used by the larger UA's. The achieved message delivery probability for these information flows is 99.8 %. By limiting video and weather radar traffic to C-band, the relatively scarce spectrum resource at L-band is conserved.

The waveform and message format are assumed to include forward-error-correction coding which both improves message delivery probability at a given transmitter power level and offers a degree of integrity (i.e., protection against undetected error). As noted earlier and depending on RCP requirements ultimately assessed, the inherent level of integrity offered by the system can be augmented with additional CRC checks, message cross-checks, and selective message repeats (and cross-checks) in order to meet RCP requirements. A selective message repeat can be achieved in less than 500 ms, thereby preserving low latency, and slow frequency hopping from message to message will mitigate multipath fading with statistically independent fade statistics on the repeated message.

Overall, the strawman architecture serves as an existence proof that stringent RCP requirements potentially levied on future UAS CNPC data links will be achievable with existing technology at acceptable cost. Excursions from this strawman, and other CNPC architectures entirely, could be considered and compared on the basis of performance and cost, as the community moves toward a consensus on a preferred approach.

With regard to the BLOS subsystem that could be used by some larger UA, the strawman architecture is somewhat less complete due to uncertainty regarding eventual frequency band support. However, it is clear that 99.8 % message delivery probability on each individual satcom link can be achieved within reasonable design guidelines, for flight above certain threshold altitudes that are dependent on regional rain statistics and time of year. Hence, it is clear that larger UA could operate "at altitude" using a BLOS system for critical CNPC data. A message delivery probability of 99.8 % can be achieved with a single BLOS link, and 99.999 % can be achieved with two BLOS links (one operating at Ku- or Ka-band and the other operating at L- or C-band). Another possibility is to operate with a single BLOS system plus a LOS subsystem in high-density domestic airspace, in order to achieve 99.999 % message delivery probability in this airspace and revert to the single BLOS system in remote areas where a lower RCP requirement could be justified.

It should be noted that even in domestic airspace, a hybrid LOS and BLOS system could prove beneficial for certain users. For example, a suitably designed BLOS subsystem could support CNPC data flows in a protected frequency band (AMS(R)S), along with high-data-rate payload data flows in a neighboring

frequency band without special protection. Such a system, combined with an L-band or C-band LOS link for critical CNPC data flows, could prove to be particularly cost effective.

Reducing Downlink Data Load: Reporting by Exception. It is desirable to minimize the data load associated with each UA – if it can be done safely – since this allows for a greater number of UA to share a given spectrum resource. As noted earlier, in many cases, the sense-and-avoid downlink data – the target tracks for potentially threatening nearby aircraft – dominate the bandwidth used. In the most basic case, each UA transmits a track report on every aircraft it can “sense,” and most of these aircraft are reported by a large number of UA. Hence, there is redundancy on the return link, and the system engineer should consider ways to minimize this redundancy. With this thought in mind, assume that the ATC ground infrastructure broadcasts a local or regional correlated surveillance picture on a “traffic information service-broadcast” (TIS-B) forward link, accessible by all UA in the airspace, and also makes this information available to all UA pilots via terrestrial means (i.e., an authenticated internet stream via the “wired ATC network”). This is a single data flow which requires much less bandwidth than the aggregate of all the sense-and-avoid return links of all the UA in the airspace. The pilot could indicate to the UA that he or she is receiving this data feed – such an indication requires only one very short forward link message every second. The UA can compare its own target track data to that contained in the correlated surveillance picture received from ATC via the TIS-B forward link. If they match within predefined accuracy bounds, for aircraft within a suitable “range of interest” from the UA, and if the UA knows that the pilot has also received this same picture, no return link reporting is necessary (except for a small heartbeat message indicating that the system is operational). If there is a discrepancy, either in an estimated target position or in the detection of a target not reported by ATC, only these differences need to be reported. Of course, if the UA fails to receive the TIS-B forward link or fails to receive an indication that the pilot has received it, the full target list would be reported. This would be a normal event in remote areas where no ground network exists. Of course, in remote areas, there are few aircraft in the airspace and little competition for spectrum resources.

As may be seen, reporting by exception can significantly reduce bandwidth requirements for the system without any loss in safety (i.e., since the fallback modes are fully functional) but at the expense of greater ground system complexity.

32.6 Conclusion

In order to ensure an adequate level of safety for unmanned aircraft operating in shared airspace, the communication link between the unmanned aircraft and the ground-based pilot must carry certain safety-critical data and must be extremely robust and reliable. Initial estimates of channel loading and required communications performance have been developed, and candidate frequency bands for control and non-payload communications have been identified. While further work is needed to fully characterize the communications channel and achieve international consensus

on frequency allocations and other regulatory aspects, the current consensus view is that a safe and workable implementation appears likely to be achievable through a combination of data link diversity and other error correction and error recovery techniques. The precise set of techniques that will be employed, and the extent to which those techniques will be mandated in the system and subsystem performance standards remains to be worked out.

Abstract

A new generation of lightweight and small Unmanned Aerial Vehicles (UAVs) enables the design of networked aerial robotic systems for a wide range of applications. In this book chapter challenges and solution approaches with respect to self-organized and robust multi-UAV systems are discussed. In order to achieve a flexible deployment of Unmanned Aerial Systems (UAS), a novel service-oriented system architecture is introduced. The design aspects of mobility control algorithms addressing the competing requirements of communication reliability and spatial distribution of UAV swarms are demonstrated using two reference scenarios with diverging requirements: aerial sensor networks and ad-hoc aerial relay networks. The novel solution approaches presented in this chapter rely on agent-based control of UAV swarms operating autonomously in dynamically changing environments. Different communication-aware algorithms for microscopic as well as macroscopic mobility control are presented, such as Cluster Breathing, Smart Cube, Potential Fields, and Role-Based Connectivity Management. For the positioning of UAV relays, the Interference-Aware Positioning of Aerial Relays (IPAR) algorithm is introduced. The system design and optimization of cognitive networking for UAS requires a dedicated multi-scale simulation environment, which includes a detailed physical channel model and real-world experiments. The chapter discusses how the network and application task-specific performance requirements are met with the proposed mobility control algorithms even in the cases of temporarily unavailable communication links. The self-healing capabilities therefore allow for reliable networking and control of aerial robot swarms in diverse use cases, such as emergency response, environmental monitoring, and ad-hoc network provisioning.

33.1 Introduction and Related Work

The advances in embedded systems technologies have enabled broad research and first deployments of networked sensors/actors to fulfill monitoring and control tasks (Akyildiz et al. 2002). While many of these cyber-physical systems incorporate mobile components and therefore rely on wireless communications, they are typically ground-based. Hence, they are limited in their scope of operation and movement. The research in the area of networked aerial robotic systems focuses on enabling teams of communicating UAVs (Michael et al. 2006; Frew et al. 2008) to autonomously fulfill a given task (How et al. 2009; Chung et al. 2011), such as the exploration of chemical or nuclear plumes (Spears et al. 2009; White et al. 2008; Daniel et al. 2009; Corrigan et al. 2008). In addition to exploration tasks, teams of flying robots may also provide an ad hoc relay network to serve ground-based users in case of network overload or outage situations (Cheng et al. 2008; Pengcheng et al. 2011).

In contrast to many ground-based networking applications in which the mobility of the communication nodes is mandated by the application scenario, the mobility of aerial robot swarms can be actively influenced. These controlled mobility algorithms aim to meet both application task requirements and communication-related performance indicators (Wang et al. 2006; Rooker et al. 2007; Stump et al. 2008; Akkaya et al. 2010; Ghaffarkhah et al. 2011). While exploration tasks may, for example, suggest spreading out in different directions, the need for continuous data transfer may rather demand for a behavior that keeps the swarm close together. Given a known and static environment, it is possible to steer the swarm with preplanned schemes, which fulfill the competing goals. However, in many real-life scenarios, the swarm needs to be prepared for the unexpected, in particular when disaster management applications or component failures need to be considered. To enhance the robustness and flexibility of the robot swarm, current research seeks to distribute the control intelligence across the different platforms, leading to an autonomous swarm behavior controlled by software agents implemented on each UAV (How et al. 2009; Chung et al. 2011).

This book chapter provides an insight into promising new solution approaches for cognitive networking capabilities to solve the trade-off between application task- and communication-related goals. As a specific contribution of this book chapter, cognitive networking algorithms are discussed as part of a generic service platform concept supporting diverging UAS application services. In the following chapter, the key design challenges in terms of building blocks, reference scenarios, and key performance indicators are presented. Then a new modular service platform for UASs is presented, which leverages embedded Web services technologies to allow for the flexible deployment of multipurpose UAV swarms. Before cognitive networking algorithms are discussed in detail, a model-based development approach, which encompasses analytical modeling, multi-scale system simulation as well as experiments, is introduced. Finally, various new communication-aware mobility steering are presented and discussed based on performance evaluation results.

33.2 Design Challenges

33.2.1 Key Building Blocks

The generic design of a swarm-based aerial robotic system considered in this book chapter (cf. Fig. 33.1) consists of UAVs that are equipped with sensors/actors and act as mobile communication nodes at the same time. Depending on the use case, the aerial robotic swarm connects via base stations to ground-based devices, such as mission control entities, databases, and network gateways. In this chapter the focus lies on the air-to-ground (A2G), air-to-air (A2A), and air-to-user (A2U) links, while the choice of the back-end ground connections is left out of scope. Different communication technologies for A2G, A2A, and A2U links can be considered:

- Local area networks (in particular IEEE 802.11a/b/g/n, p and s)
- Cellular networks such as HSPA, IEEE 802.16e, and LTE

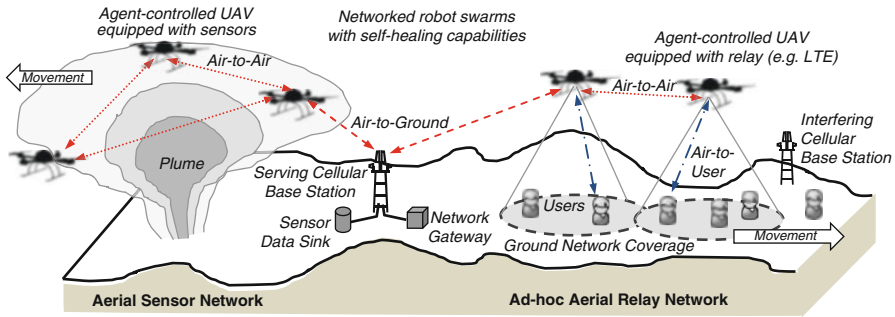

Fig. 33.1 Architecture and reference tasks for networked aerial robot swarm

The primary task of the communication network is to transfer application task-related data, namely, sensor data or user data. At the same time, the swarm control data required to steer the members of the swarm are communicated via the network. To achieve maximum robustness, aerial communication nodes may act as relays in order to provide multiple hop connections and meshing capabilities, as described in Lloyd et al. (2007) and Jung et al. (2010).

33.2.2 Basic Principles of Context-Aware UAV Swarm Control

Due to the dynamically changing, unpredictable system environment leading to potentially unreliable wireless communication links, an autonomous behavior of the swarm is desired. The agent-based control of the robot swarm proposed in this book chapter can be distinguished in two main steering types:

- The microscopic steering controls the behavior of the individual UAV so that a coherent, interconnected swarm is maintained (also called cluster). At the same time, the members of the swarm should not interfere with each other and achieve a maximum impact related to the given swarm task. The microscopic steering is of high importance for the A2A links, as it will self-configure and determine the availability of communication links within the swarm.
- The macroscopic steering controls the swarm according to a given task through a larger-scale scenario, namely, to explore an unknown area or to move from point A to point B. The macroscopic steering will typically be the main influencing factor for the availability of A2G and A2U links.

The key contribution of this book chapter is that both steering types are combined by an autonomous, agent-based decision process on each UAV. Thereby the robot swarm can perform its application task independently of a central ground station. Self-healing capabilities allow that UAVs, which are cut off from the swarm due to obstacles and channel impairments, will automatically reintegrate into the swarm.

33.2.3 Reference Scenarios and Key Performance Indicators (KPIs)

To illustrate the concrete challenges and performance indicators of cognitive networking in aerial robot swarms, two application areas are introduced: the exploration of tropospheric plumes as an example for a monitoring task and the ad hoc network provisioning for outage compensation in terrestrial networks (cf. Fig. 33.1).

33.2.3.1 Scenario 1: Plume Exploration

In the case of a chemical or nuclear accident, disaster managers require information about the current and future development of a plume to decide on potential counter measures for protecting inhabitants and rescue personnel. The aerial sensor system should provide as fast as possible, but not necessarily in real-time, accurate information about the concentration of harmful substances.

This chapter discusses in particular the following key performance indicators:

- **Spatial Exploration Ratio (SER):** The SER is determined by dividing the scenario in a regular spaced grid. If a grid element is accessed by a UAV and once the information was successfully transferred to the data sink, this grid element is counted as being covered. The sum of all covered grid elements divided through the total number of grid elements delivers the SER value.
- **Cluster Separation Ratio (CSR):** Among the variety of communication-related parameters to be considered, the CSR value serves as an indicator to assess the communication performance: the time span, in which one or more UAVs are not connected to the main part of the swarm (the so-called cluster), is determined and related it to the overall mission time.

The key challenge for the control of the aerial robot swarm in this scenario is to allow for continuous communication within the swarm by meeting a minimum CSR target (e.g., $CSR < 1\%$) while at the same time as much space as possible is explored (indicated by a high SER value).

33.2.3.2 Scenario 2: Ad-Hoc Aerial Relay Network

The handling of temporary network outages or overload situations is a major challenge for network operators. Aerial network provisioning is a very interesting option to quickly provide ad hoc network coverage, even if parts of the ground-based infrastructure are not operational or overloaded.

The considered key success criteria for the networked swarm are:

- **Ground Network Coverage (COV):** The COV is determined by cumulating all coverage areas of each individual UAV excluding overlaps, obstacles, and isolated UAVs that are not connected to the swarm.
- **Throughput (TP):** The amount of communication traffic handled by the system in terms of TP is determined by summing up the raw data rates of all individual A2U communication connections within the swarm.

Table 33.1 Overview of challenges and proposed solution approaches

| Scenario | Challenges and design considerations | New channel-aware swarm control algorithms | |
|-----------------------------|--|--|--|
| | | <i>Microscopic</i> | <i>Macroscopic</i> |
| Aerial sensor network | Trade-off between CSR and SER: loose connectivity among the UAVs leads to a high SER, but at the same time the CSR may grow too high | <i>Cluster Breathing (CB), Smart Cube (SC), C.-A. Potential Fields (CAPF)</i> | <i>Cluster Repelling Walk (CRW), Role-Based Connectivity, Return and Release</i> |
| Ad-hoc aerial relay network | Trade-off between TP and COV: a stable TP can be achieved by reducing the COV to adapt to bad channel conditions | <i>Communication-aware Potential Fields (CAPF)</i> <i>Interference-aware positioning of relays (IPAR)</i> | |

The scenario-specific challenge will typically be to achieve a minimum throughput to match the requirements of specific communication service (e.g., $TP > 5 \text{ Mbit/s}$) while at the same time the COV value should be maximized to serve as many users as possible.

Table 33.1 summarizes the challenges and design considerations addressed in this book chapter. It provides an outlook of the corresponding solution approaches discussed later on. Before the proposed swarm control algorithms are discussed, the overall system architecture is introduced in the next section.

33.3 Modular Service Platform for Unmanned Aerial Systems

The research for context-aware communication within Unmanned Aerial Systems (UAS) has focused not only on the mobility control algorithms (see in subsequent sections) but also on the development of a generic and modular service architecture, which supports heterogeneous, multipurpose UAS. In the following section the requirements and solution approach for a generic UAS service platform are introduced.

33.3.1 Requirements for a Flexible UAS Service Architecture

In order to serve different use cases, an Unmanned Aerial System should build on a flexible software and communication architecture. Several architecture approaches have been presented and implemented to address multi-sensor, multi-network-technology and multi-vehicle systems for unmanned autonomous systems (Tisdale et al. 2006; Dias et al. 2008; Love et al. 2009; Elston et al. 2009, 2011). As an

evolution and alternative to these approaches, in this chapter an architecture building on embedded Web services technologies to ease the integration of highly diverse services beyond sensor tasks is introduced.

While service-oriented architectures (SoA) are state of the art for IT services, in the embedded and real-time control systems area, SoA architectures are still an emerging topic. The key benefit of adopting the SoA concept for embedded systems is that the complexity and heterogeneity of different hardware and software components is hidden by well-defined Web Services and clearly structured XML data formats. This allows for the reuse of software components and flexible integration of new components. Recent developments have overcome the concern regarding the overhead introduced by SoA for resource-constraint systems. Prominent examples for the adoption of SoA concepts for embedded systems are the Device Profiles for Web services (DPWS) (Discroll et al. 2009) as well as Efficient XML (EXI) (Schneider et al. 2011). Research projects such as the European MORE project (Wolff et al. 2007) have shown the feasibility of using DPWS for geo-monitoring services and remote control of embedded devices. Other areas, in which SoA-based embedded Web services gain importance, are distributed energy systems and Smart Grid control (Wietfeld et al. 2011).

The design of a future-proof UAS service platform should therefore leverage the concept of a service-oriented architecture while at the same time the real-time constraints of Unmanned Aerial Systems shall be taken into account. The service architecture should be flexible to support diverse aerial services ranging from sensor-based monitoring to communication relaying. Furthermore, different types of Unmanned Aerial Vehicles (quadcopters, fixed wing, tiltwing) as well as different wireless networking technologies (ranging from Wi-Fi to public cellular networks) have to be taken into account for the system architecture design. Appropriate system capabilities are required to allow for autonomous operation in unknown environments and for providing robustness against component and node failures. End users shall be able to operate the system with minimum training, allowing them to focus on the application task to be fulfilled. Therefore, automatic self-configuration and health management shall be supported. Finally, the implementation needs to comply with real-time, safety and security requirements. Hence, state-of-the-art, highly efficient Web services-based concepts, such as optimized IP transport, DPWS, and EXI, are considered to meet the resource constraints of embedded HW/SW platforms.

Within the research project AVIGLE (Rohde et al. 2010), an example UAS service platform fulfilling these requirements has been designed, implemented, and validated by real-life experiments. Key building blocks addressing these requirements are introduced in the next section.

33.3.2 Key Building Blocks of the Service Architecture

As a proof of concept of the flexibility of the architecture, two diverging UAS use cases are considered in the following: a 3D Visual Exploration Service (as an

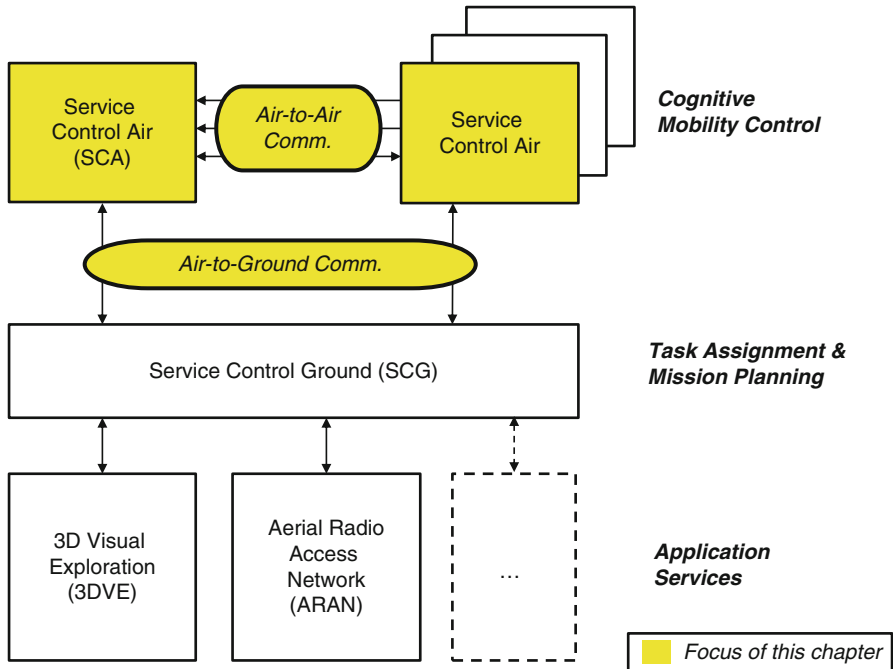

Fig. 33.2 Key components of UAS service platform

example for a generic Sensor Exploration Service) and an Aerial Radio Access Network Service. These reference application services are linked with two core UAS control services groups: the Service Control Ground (SCG) and the Service Control Air (SCA); see Fig. 33.2. The core services provide the generic control functionality to operate the UAS independent of a specific application task, such as navigation services. In addition, communication services are an essential part of the system architecture: on one hand local buses provide onboard communication (e.g., intra-SCA), while wide-area wireless communication services allow for the inter-UAV communication as well as the link between UAVs and the ground-based functionalities.

It should be mentioned at this stage that the architecture is worked out in this chapter in great detail for Unmanned Aerial Systems, but it is flexible enough to cater also other types of autonomous vehicles, such as ground-based or underwater vehicles. In the following, the key services of a UAS are introduced in detail.

33.3.2.1 Service Control Air (SCA)

The Service Control Air (SCA) provides all functionalities to enable the operation of multiple, even heterogeneous UAVs within a UAS. A basic assumption is that each UAV has implemented specific flight control mechanisms, which allows it to be steered by the SCA to a specific position. Therefore, the detailed local control

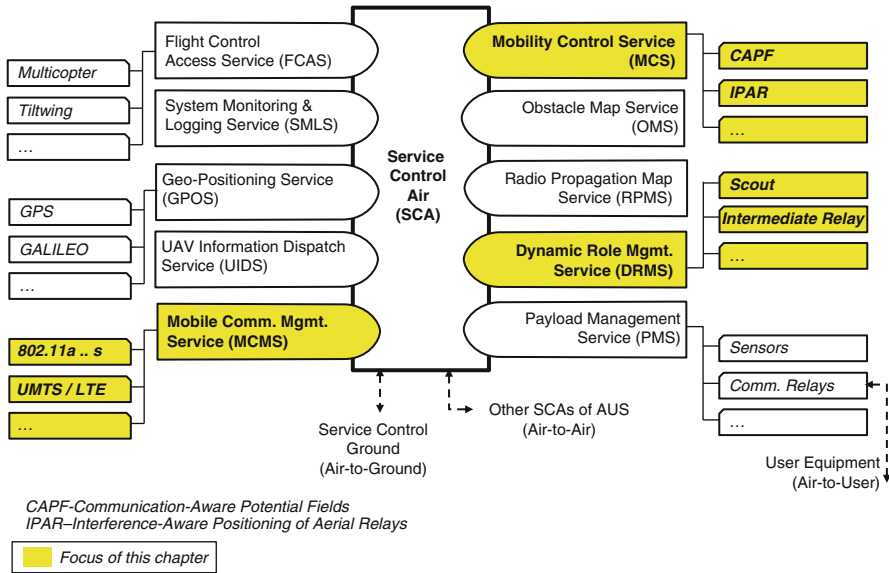

Fig. 33.3 Overview of *Service Control Air (SCA)*

algorithms and components, such as the individual control of the UAV engines, are out of scope for the SCA. The following services are essential parts of the SCA (cf. Fig. 33.3):

- In line with the idea of service-orientation, the complexity of the UAVs' capability to stay in the air and fly into a given direction is hidden through a corresponding Flight Control Access Service (FCAS). The parameters of this service are either global geographical positions or directions.
- The main user of the FCAS is the Mobility Control Service that implements different strategies to achieve predefined performance indicators. The mobility control of a UAS is context depending, while the context is defined by the application task, the communication requirements within the system, and the physical environment (topology, weather, etc.). The in-depth discussion of the appropriate design of the Mobility Control Service is covered in subsequent sections, as different applications task demand for specific Mobility Control Services. Example algorithms are the Communication-Aware Potential Fields (CAPF) and the Interference-Aware Positioning of Aerial Relays (IPAR).
- Another essential service is the Payload Management Service (PMS), which provides the access to different components carried by the UAV to fulfill a given application task. Example payload components are optical sensors (such as infrared cameras), environmental sensors (such as gas or radioactivity detectors), and wireless communication relays, to allow for ground coverage and provisioning of A2U links.

- Via the Payload Management Service, component-specific software libraries are integrated. The modular approach allows for the integration of future payloads, such as new sensor types or robotic components.
- The Geo-Positioning Service (GPOS) provides accurate information about the current position of the UAV. This information is required both for mobility control as well as for application services, which link sensor data with geo-positions. This function will typically leverage satellite-based positioning technologies, such as GPS, GALILEO, and combinations thereof. The accuracy of the positioning information provided by the existing Global Positioning System (GPS) as well as the future GALILEO system is typically in the range of several meters which is sufficient for most application scenarios (Niehöfer et al. 2011). Due to the inaccuracies of satellite-based positioning, additional sense-and-avoid capabilities are required to reliably avoid collisions with obstacles and within the swarm. If needed, additional positioning technologies can be integrated via the GPOS (e.g., for indoor usage).
- The Dynamic Role Management Service (DRMS) manages the UAV's application task capabilities and the task assignment. Through this service available capabilities are offered to the system, while at the same time specific task assignments within the overall UAS may require the deactivation of certain components. For example, a resource-consuming sensor can be switched off, in case the UAV serves only as a communication relay at a given point in time. The Dynamic Role Management Service therefore interacts with the Payload Management Service and the Mobility Control Service.
- Finally, Mobile Communication Management Services (MCMS) are available to allow for the transmission of UAS internal control data as well as payload data, such as pictures, videos, or ground user traffic. Similarly to the Payload Management Service, different wireless communication technologies can be integrated via the service-oriented approach. The MCMS allows integrating mobility management functionality to realize handovers and dynamic mesh routing. The CMS interacts with the MCS as mobility control often needs to take into account communication-related parameters (such as Radio Signal Strength parameters). Throughout the system operation, the CMS may gain information to feed the Radio Propagation Map Service.

The Mobility Control Service is supported by additional services within the SCA, such as:

- Obstacle Map Service (OMS): provides geo-referenced information about the physical characteristics of the environment for proactive, wide-area collision avoidance, in addition to near-distance sense-and-avoid systems of the UAV. The Obstacle Map Service may use either stored map data as well as dynamically generated data gathered by the UAS during exploration tasks.
- Radio Propagation Map Service (RPLS): provides geo-referenced information about the channel characteristics of ground base stations for proactive planning to avoid communication outages between UAVs and the ground station. Similar to the above mentioned Obstacle Map Service, pre-stored data as well as dynamic data can be used.

Support functions such as a System Monitoring and Logging Service (SMLS) as well as an Information Dispatch Service (IDS) ensure the reliable operation of the system.

33.3.2.2 Service Control Ground (SCG)

The Service Control Ground (SCG, cf. Fig. 33.4) is the counterpart of the Service Control Air and therefore contains various corresponding services, such, the Mobile Communication Management Service (MCMS), System Monitoring and Logging Service (SMLS), UAS Obstacle Map Service (UOMS), UAS Radio Propagation Management Service (UPMS), and UAV Payload Management Service (UPMS). While the Service Control Air will be present in multiple instances (one per UAV), the standard system will comprise one SCG instance. The UAV Payload Management Service serves as global repository for the different service capabilities of the various UAVs within the UAS. Due to resource constraints in the UAV, the aerial instances of the map services OMS and RPLS will contain a subset of the information handled in the ground-based instance (UOMS and UPMS). For robustness, the Service Control Ground can be realized in a redundant, physically distributed way, but this consideration is out of scope in this presentation of the architecture.

There are a number of services, which are specific to the ground-based system, compared with the aerial control components:

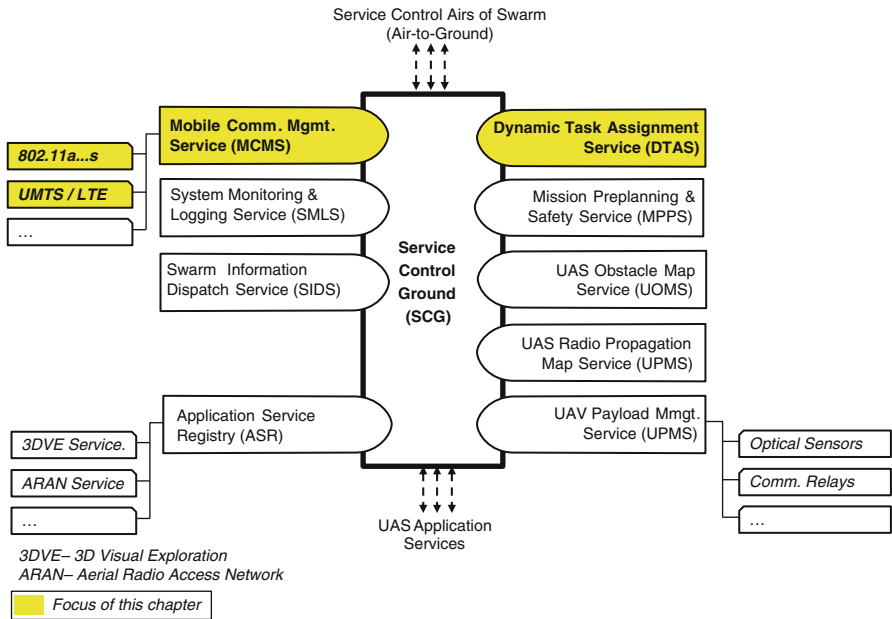

Fig. 33.4 Overview of Service Control Ground (SCG)

- The Dynamic Task Assignment Service (DTAS) provides a user interface toward the end user and allows for the specification of the application details to be fulfilled by the UAS. This service is context sensitive, that is, it must consider the payload components of the UAVs, the flight capabilities of the UAVs, the environmental conditions, etc.
- The DTAS interacts closely with the Mission Pre-Planning and Safety Service (MPPS), which will – based on the task requirements specified by the end user and the available UAV characteristics – breakdown the overall in tasks to be fulfilled by the UAVs' Mobility Control Service. The MPPS leverages information provided by OMS and RPLS.
- The Application Service Registry (ASR) manages the interaction with different application services of the UAS. Different application service will require access to different payload components and mobility control strategies. The ASR therefore interacts with the UPMS, DTAS, and MPPS in order to match the application task requirements with the available service capabilities.
- The Swarm Information Dispatcher Service (SIDS) efficiently routes any data between the ground-based services and the aerial components, may it be control information or payload data. It comprises scheduling and prioritization algorithms to master potential overload situations.

33.3.2.3 Example UAS Services

In the following, two service types in line with the reference scenarios defined in Sect. 33.2 are introduced (cf. Fig. 33.5).

3D Sensor Exploration Service (3DSE)

The 3D Sensor Exploration Service (3DSE) serves as an example for a distributed aerial sensor network application. The UAVs are equipped with sensors, such as

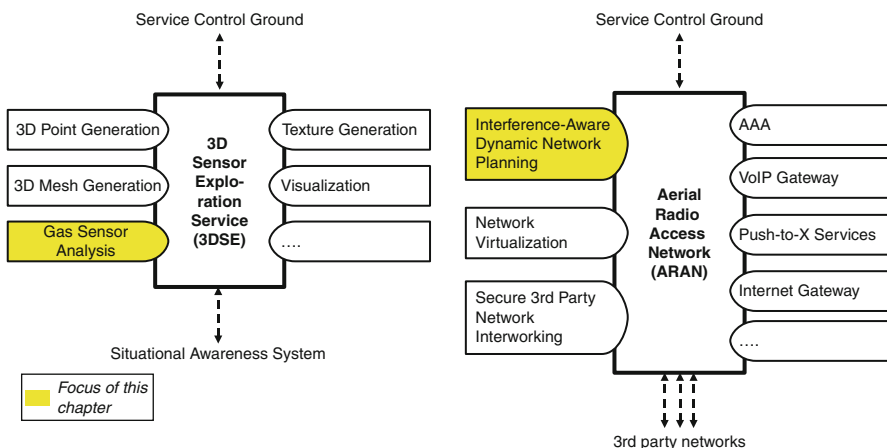

Fig. 33.5 Example application services for communication-aware UAV operations

gas sensors or cameras as a payload, and deliver geo-referenced gas sensor data or aerial photographs of the earth's surface from different perspectives. This service may comprise very specialized functionality, such as 3D point generation, 3D mesh generation, and texture generation, in order to finally visualize the results for the users of the service (visualization). A detailed description of the image processing and virtualization approach is provided by Rohde et al. (2010). An example for an aerial gas sensor application is described in Daniel et al. (2011). Potential users of the 3DSE are rescue organizations, which require detailed information of a city environment after an earthquake or after a large-scale chemical incident. Using an up-to-date 3D map as part of situational awareness systems allows efficient planning and optimization of rescue actions. But the results of this service can also be leveraged within the UAS itself, because it provides current data for the mission planning through the obstacle and radio propagation services.

Aerial Radio Access Network Service (ARAN)

The Aerial Radio Access Network Service (ARAN) provides ad-hoc ground network coverage by aerial relays. It requires communication relays as payload on the UAVs' side and specific mobility control algorithms. Examples for standard functionalities are AAA services, a VoIP gateway, and an Internet gateway.

UAS-specific service functionalities are related to:

- Interference-Aware Dynamic Network Planning which needs to take into account both coverage requirements as well as interference mitigation. This aspect is addressed in subsequent sections.
- Push-to-X services which are required to support IP-based, multimedia group communications. These services are of specific importance for ad-hoc communication of emergency response organizations (Subik et al. 2011).
- Secure Third Party Network Interworking is required to integrate the Aerial Radio Access Network with ground-based networks, such as a public cellular network, which shall be complemented with the aerial network to compensate network outages.
- Network virtualization functionalities are required in case the aerial network shall be used by multiple network operators. In this case, the available system capacity needs to be shared amongst the different networks based on service contracts. Therefore, scheduling and monitoring of Quality of Services parameters are part of this building block. The network virtualization is subject of ongoing research and out of scope for this chapter.

33.3.3 Validation and Key Learnings

The implementation of the proposed architecture has been carried out on embedded platforms (such as Vortex86DX and ARM Cortex-A8) and validated for flexibility and efficiency in experiments (see below). It has shown the embedded Web services approach is very suitable for the integration of services, such as different sensor types or communication relays. Nevertheless, in case of specialized sensors (such

as IR cameras), the implementation of software connectors to integrate proprietary drivers with the generic architecture requires significant effort. Therefore, the benefits of a Web services-based approach can be only fully leveraged, when the suppliers of the UAV payload components will provide a Web service compliant-interface off the shelf. Due to the usage of highly optimized binary EXI coding, the actual size and processing times of data messages to be exchanged within the system were similar to a comparable, non-Web services-based implementation. For real-time critical parts of the system, the data message structures have been hard-coded in order to avoid encoding delays.

In summary, the embedded Web services approach has proven to be feasible for UAS, as it provides a framework for a common, well-established formal description of service characteristics and data formats and at the same time allows to trade flexibility with efficiency by using highly efficient data encoding techniques.

33.4 Model-Based Development of Cognitive Steerings

33.4.1 Multi-scale-Simulation Environment

For the performance evaluation of cognitive UAV networks and the corresponding steering algorithms, it is essential to consider multiple system components and characteristics (cf. Fig. 33.6):

- The mobility model delivers the dynamically changing position of the UAVs.
- The wireless channel model’s output – the Radio Signal Strength – is derived from the current position of the UAV taking into account a realistically modeled

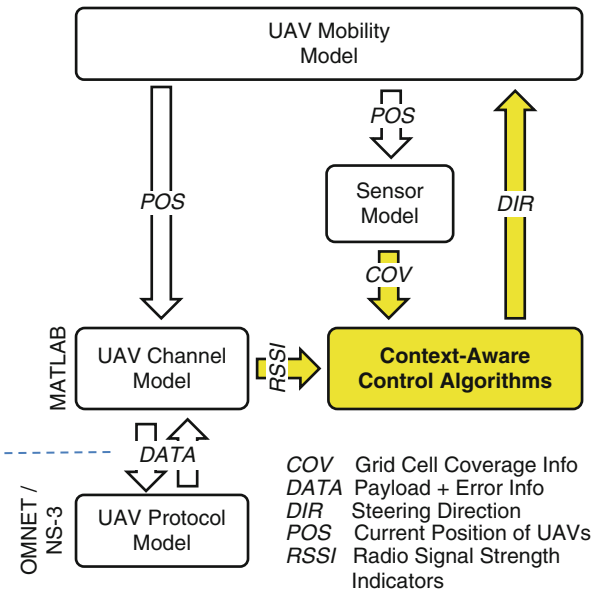

Fig. 33.6 Example information flows in multi-scale system simulation environment

system environment (topology, obstacles, interferers, antenna characteristics, etc.).

- The sensor model deployed with the UAV allows to determine the spatial coverage of the sensor based on its current position. In case of a plume exploration task, it is assumed for simplification that once the UAV has entered a grid cell, sensor measurement values for the complete grid cell are instantly available.
- The communication protocol models deliver detailed information about the timing and length of data transmissions.

To address these different system aspects, a multi-scale simulation environment is required, which combines various, specialized simulation models and real-life HW/SW implementations into a complete system model (Daniel et al. 2011). Figure 33.6 provides an overview of major information flows between the various subsystem models and the control algorithms to be investigated.

A special focus of the performance analysis is placed on the dynamic meshing capabilities, as short-life routing paths have to be reconfigured and re-established as fast as possible to avoid separations within the aerial swarm network. Subsequently, MANET and VANET protocols have been integrated into the simulation environment to allow the analysis of the interdependencies among channel, mobility, and meshing capabilities.

With regard to an appropriate trajectory calculation, a UAV-specific kinematic movement model is utilized: while the agent-based steering control algorithms mandate desired future positions of the UAV, the physical characteristics (mass, acceleration) need to be taken into account to achieve realistically modeled swarm behavior. The system component models are developed and validated based on dedicated experiments (e.g., channel measurements), which are introduced in the next section.

33.4.2 Validation by Experiments and Measurements

Although the multi-scale simulation models provide a powerful and realistically modeled environment to evaluate the system, experiments are essential to validate both dedicated system component models as well as the overall system performance.

In the research projects AirShield (Daniel et al. 2011) and AVIGLE (Goddemeier et al. 2012), different types of UAVs, ranging from multi-copter to tilt-wings and blimps, are deployed to validate mobility control algorithms. Swarm control data (telemetry) and payload-related data (gas sensor values) were successfully transmitted and routed over a Wi-Fi (A2A mesh) and UMTS-HSPA (A2G) network (cf. Fig. 33.7).

With respect to the relevance of the mesh protocol for the air-to-air links, several experiments in an EMC anechoic room have been conducted and analyzed with regard to the 802.11 performance in an interfered environment (Daniel et al. 2010). Furthermore, the impact of interferences on the reliability of air-to-ground links has also been analyzed for LTE and Mobile WiMAX by means of different network and channel emulators (e.g., R&S CMW 500, EB Prosim C8). The air-to-ground

Fig. 33.7 Example experiments carried out in the AirShield project: validation of A2G and A2A links (*left*), validation of sensor data transfer (*middle*), gas sensor and communication payload (*right*)

availability of cellular networks in higher altitudes (up to 500 m) has been surveyed with a captive balloon in urban and suburban environments. Since the channel characteristic is a crucial system property for UAV networks, results of recent studies (Goddemeier et al. 2012) are presented in the following section.

33.4.3 UAV-Specific Channel Models

The UAV channel is influenced by numerous factors such as antenna characteristics, attenuation, multipath propagation, and interference. Extensive work has been performed on ground-based wireless systems as well as satellite systems, which can be partly applied for the UAV channel. However, the UAV channel bears certain specifics due to its different geometry.

The air-to-air (A2A) channel is characterized by a dominant direct path and additional interference due to reflections from the ground (Allred et al. 2007). The characteristics of the air-to-ground (A2G) channel are highly dependent on the used communication technology in use. Leveraging publicly available cellular networks are useful to provide wide-area air-to-ground coverage without additional infrastructure. Therefore, a dedicated UAV channel model for A2G links is of specific interest for the system modeling.

Base station antennas in cellular network systems usually show directional characteristics providing reliable ground coverage for the end users.

Figure 33.8 depicts the specific characteristics of the height-dependent UAV channel, based on measurement data, ray-tracing results, and a specifically developed analytical channel model (Goddemeier et al. 2012). The channel can be characterized by 4 zones: at low heights up to 10–20 m, shadowing effects are observed (Zone I), while in heights up to approx. 50 m, a strong direct path interferes with reflections of the ground respectively the roof tops (Zone II). At heights above 50 m, the UAVs antenna leaves the main antenna lobe and a reflected path from

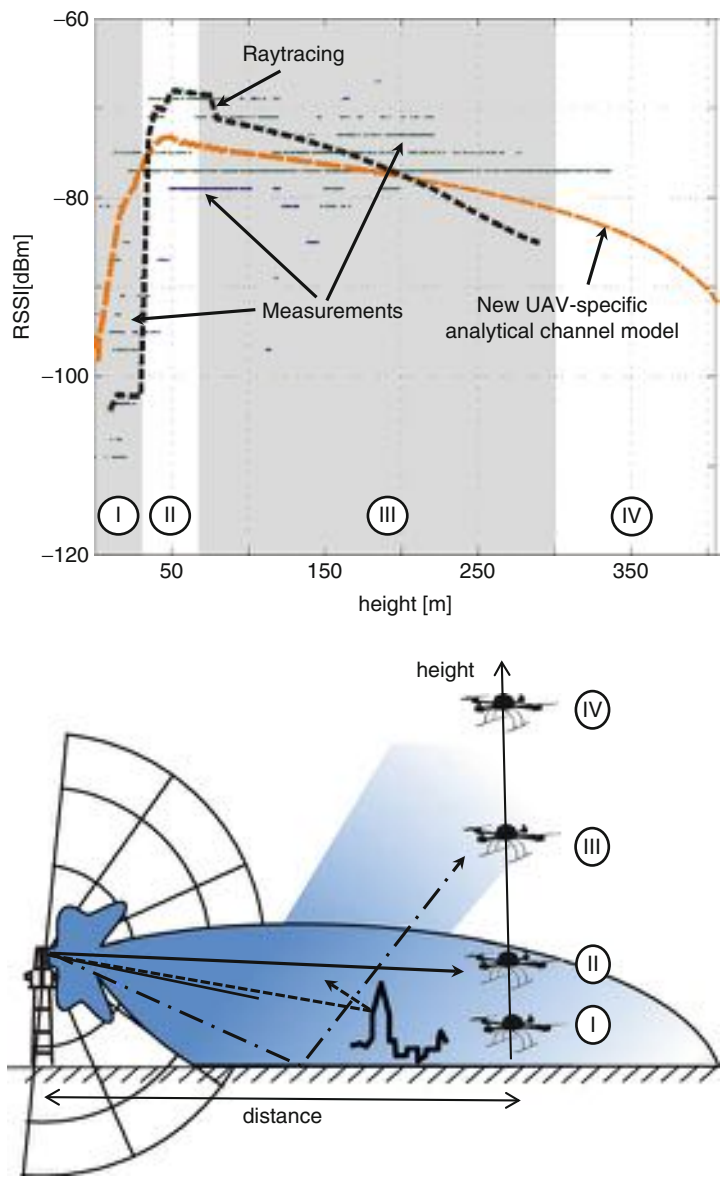

Fig. 33.8 UAV channel characteristics: air-to-ground link

the ground dominates (Zone III). Finally, for altitudes above 300 m, the received power for direct paths as well as reflected paths decreases. Consequently, no reliable communication is possible (Zone IV). The results illustrated in Fig. 33.8 have been validated with channel measurements in real-life UMTS/GSM networks in Germany

by utilizing a captive balloon ($h < 500$ m). The key conclusion from this synopsis of a far more detailed analysis (Goddemeier et al. 2012) is that the exploration at heights above approx. 250 m requires communication-aware aerial relay nodes with meshing capabilities to be able to extend the operational range by establishing multi-hop communication links.

33.5 Communication-Aware Networking Algorithms for UAV Swarms

The networked UAV systems discussed in this book chapter rely on autonomously controlled mobility. Recent research has come up with several mobility control strategies which have often been inspired by nature or found an illustrative counterpart in nature. An in-depth survey of connectivity-dependent algorithms to control the position of mobile sensor nodes is provided in (Younis et al. 2008). Examples of relevant work related to robot mobility control have been presented by Wang et al. (2006), Rooker et al. (2007), Stump et al. (2008), Elston et al. (2009), Han et al. (2009), Akkaya et al. (2010), and Ghaffarkhah et al. (2011). This chapter focuses in particular on algorithms addressing the interdependency and desired equilibrium between coverage and connectivity requirements in UAV swarm missions.

33.5.1 Inter-swarm Behavior Controlled by Microscopic Steerings

For the distributed control of a swarm, in Reynolds (1987) three basic rules are established: separation, alignment, and cohesion. Based on the physical distances between neighbors, the behavior of the swarm is controlled to avoid collisions and to ensure harmonized movements for the computer-based modeling of biological swarms and herds. This fundamental work has inspired also the research on controlled mobility for robot swarms; see, for example, Cao et al. (1997) and Ryan et al. (2004). In the context UAVs performing jointly an exploration task (see scenario 1), the coverage of the swarm shall be maximized (leading to separation) while at the same time connectivity between the UAVs needs to be preserved (leading to cohesion). In Daniel et al. (2011) a corresponding channel-quality-aware mobility control algorithm, which introduces the so-called Cluster Breathing (CB) rules, has been proposed and studied. This algorithm considers the received power from neighboring vehicles, the radio Signal Strength Indicator (RSSI) as space and time-variant communication parameter (cf. flow chart shown on top of Fig. 33.9). As the RSSI will vary due to the dynamically changing channel characteristics, the swarm will “breathe” to a certain degree. Similar to other highly dynamic control processes in mobile radio networks (such as power control or handover decisions), the impact of short-term fading must be compensated appropriately, for example, by introducing medium-term averaging of RSSI values and hysteresis. To achieve a better spreading of the UAVs when fulfilling a swarm task, such as a plume

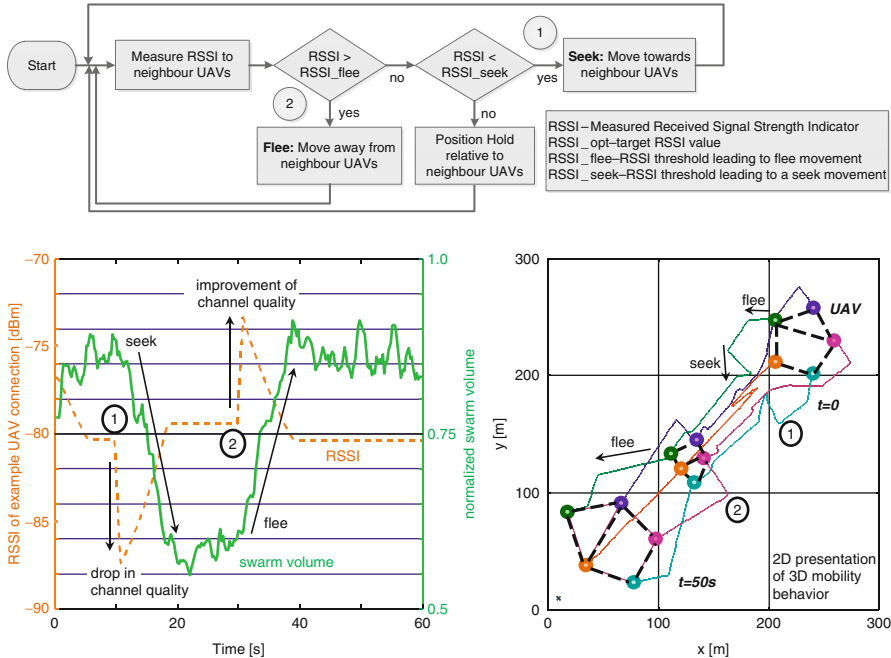

Fig. 33.9 Example of cognitive steering due to changing channel characteristics (Cluster Breathing): Flow Chart, RSSI vs. Swarm Volume Chart, Spatiotemporal 2D Chart Of Swarm Behavior

detection, the number of required neighbors can be limited, for example, to two or three.

Figure 33.9 shows an example of the behavior of an aerial robot swarm: after the robots have been separated according to the given RSSI boundaries, an area with stronger impact of fading is entered at 10 s (1), which leads automatically to a reduction of the distances between the robots respectively of the volume created by the network nodes. With improved channel quality (2), a flee movement is initiated, until the target RSSI value is reached.

Despite careful selection of the control parameters, it might nevertheless happen that the connection to one or more UAVs is completely lost. These situations require cluster-self-healing capabilities: one option is, for example, that the UAVs of the swarm move back to the position, where the connection was lost. In some cases, it might be intended to split up the swarm for a given time to fulfill the swarm task more efficiently. This special situation is discussed below in more detail (cf. Sect. 33.6.4).

The Cluster Breathing (CB) steering as described above is able to meet the communication-related goals on a microscopic level, but has the drawback that it does not exploit the full potential regarding the local exploration coverage of the swarm: the UAVs within the swarm will not or very rarely move into the edges of a cube, even if this would be possible from a communication perspective.

A static configuration can be ruled out, as it will not be possible to react on the dynamically changing physical channel characteristics. Consequently, a more advanced algorithm has been developed, namely, the Smart Cube algorithm.

The Smart Cube (SC) (Daniel et al. 2011) approach aims to optimize the 3D distribution of the UAV agents within a given cube by using Voronoi tessellation (Ammari and Das 2010) among other techniques. This algorithm provides a better local coverage in case of spatial exploration tasks. To cater for RSSI variations, the Smart Cube concept adapts the size of the cube to be covered dynamically according to current physical channel conditions. However, the performance evaluation of larger-scale scenarios has shown that the overall performance of given exploration tasks is strongly impacted by the macroscopic behavior, which might efficiently compensate for deficiencies in the local coverage of the swarm.

In order to maintain the connectivity of the UAV swarm, the maximum distances between the nodes needs to be limited. Instead of using distances the Smart Cube uses a virtual cube which size is determined by an RSSI threshold (cf. Fig. 33.10a)

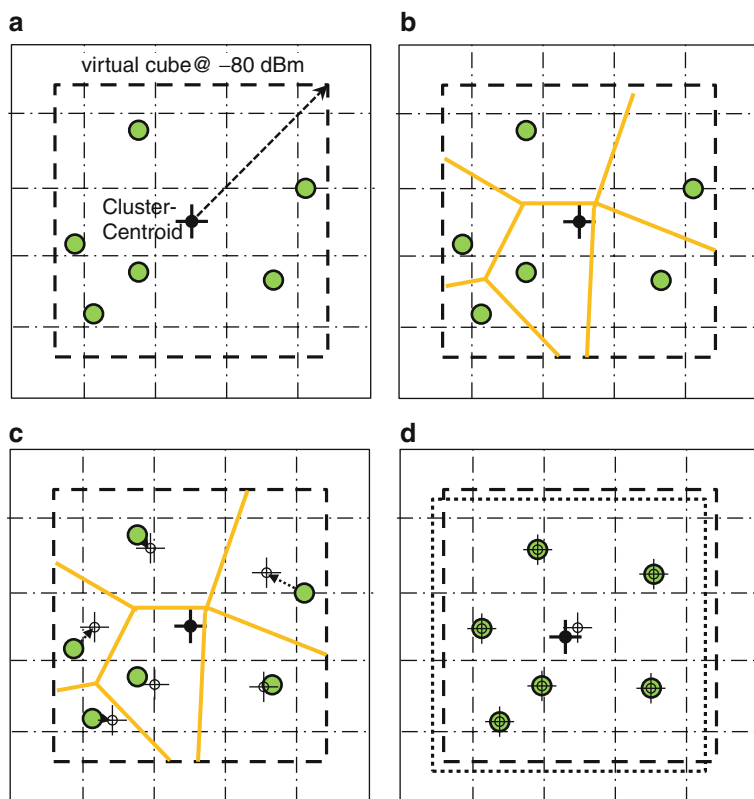

Fig. 33.10 Achieving better spatial distribution through *Smart Cube* algorithm. (a) Initial state. (b) Voronoi tessellation. (c) Lloyd movement. (d) Improved topology

for achieving communication awareness. Within this cube a Voronoi tessellation is done by each agent (cf. Fig. 33.10b). On basis of the Voronoi tessellation, the spatial volume difference between the single Voronoi cells can be evaluated. This information is utilized by each agent to iteratively increase or decrease the owned space in order to achieve an equal volume distribution (cf. Fig. 33.10c). This algorithm is known as Lloyd or k-means-algorithm (Du et al. 2006). The Lloyd algorithm itself is not communication aware. For avoiding any separation, the virtual cube restricts possible the target positions to an area where the RSSI between the nodes will be sufficient.

33.5.2 Wide-Area Mobility Controlled by Macroscopic Steerings

The macroscopic behavior of the swarm is highly dependent on the task to be fulfilled by the swarm. In case of an exploration task (see reference scenario 1), the swarm needs to move as quickly as possible through a given volume, bearing in mind the key performance indicators, in particular exploration efficiency. In completely static and homogenous scenarios, a deterministic movement of a fixed configuration of UAVs working row by row through the scenario can be considered. Such a mechanism is neither communication-aware nor would it allow for a dynamic and self-organizing adaption to complex scenarios and UAV outages. From an exploration perspective, the well-known multiple traveling salesman problem (mTSP) provides a solution approach to find the shortest path to visit all relevant grid cells within a known volume. This centralized algorithm can serve as a best-case reference in terms of exploration efficiency (Daniel et al. 2011), but it operates completely independent from communication-related boundary conditions as well as from application data gathered during the exploration. Subsequently, it is necessary to develop a situation-aware behavior, which takes an eventually dynamically changing and unknown environment into account:

- The Self-Repelling Walk (SRW) presents a known algorithm to steer the behavior of individual mobile agents, avoiding intersections with their own paths as much as possible. In its basic form, this approach can serve as a reference for an autonomous behavior of the individual UAVs within the swarm, but it takes neither communication requirements nor cooperative behavior into account.
- The Cluster Repelling Walk (CRW) applies the principles of the SRW to a complete communication cluster being superimposed by microscopic steerings at the same time. On a macroscopic level the swarm moves synchronously while being still able to compensate for changing channel environments through microscopic control algorithms (cf. Fig. 33.11).

An alternative to the combination of different microscopic and macroscopic steerings can be provided by a novel approach, namely, Communication-Aware Potential Fields (CAPF), which is described in more detail below.

Fig. 33.11 Exploration by macroscopic steering (e.g., Cluster Repelling Walk)

33.5.3 An Integrated Steering Approach Using Communication-Aware Potential Fields

The Communication-Aware Potential Fields (CAPF) algorithm expands the potential fields approach used to guide UAVs. Originally (Howard et al. 2002), the Potential Fields have been introduced to allow the mobile agents to derive attracting and repelling forces from a given environment. Thereby obstacles can be associated with a Potential Field creating repelling forces, while points of interest trigger attracting forces. The combination of potential forces with connectivity targets has been further evolved, for example, by Zou et al. (2003), Wang et al. (2005), Garetto et al. (2007) and Tan et al. (2008). In Goddemeier et al. (2011) UAVs have been associated with potential fields, thereby creating respective attracting as well as repelling forces (corresponding to low and high RSSI values when applying the Cluster Breathing method). In case of aerial sensor networks, the Communication-Aware Potential Fields (CAPF) are used for microscopic control combined with exploration-oriented macroscopic steerings. In case of the ad-hoc relay network

scenario, the CAPF approach is suited to provide both micro- as well as macroscopic steering behavior: the area to be provisioned with a wireless communication service can, for example, be associated with a potential field generating an attracting force. In addition, base stations required to ensure connectivity with other networks induce attracting forces. In case of several UAVs providing the ground-based communication service, repelling forces between the UAVs are introduced to ensure a sufficient spacing to avoid interference and allow for maximum ground coverage.

33.5.4 Interference-Aware Positioning of Aerial Relays (IPAR)

The introduction of terrestrial relays and femto-cells to increase the spectral efficiency of broadband cellular networks has gained much attention in recent years, for example, in Pabst et al. (2004) and Andrews et al. (2011). A recently proposed system concept is based on a swarm of UAVs acting as mobile relays to offload traffic to surrounding terrestrial cells with free resources (Rohde et al. 2012). Thereby cell outages as well as cell overload situations can be compensated. The optimal position of the aerial relays is highly dependent of the inter-cell interference (ICI) introduced by the mobile relays: in case that a mobile relay is operated in the vicinity too close to a ground-based station (cf. Fig. 33.1), the mobile relay will cause harmful interference resulting in reduced traffic capacity. Therefore, the specific Interference-Aware Positioning of Aerial Relays (IPAR) algorithm was introduced (Rohde et al. 2012). The IPAR algorithm's goal is thus to find positions that yield a maximized throughput of the cellular network for the aerial relays while considering interference and available traffic load. The IPAR algorithm uses an interference and load aware analytical model, inspired by Elayoubi et al. (2008), to evaluate the system performance (fitness) and iteratively improves an initial population of relaying scenarios through mutation and recombination of the relay positioning. Example results for the positioning of UAVs leveraging the IPAR algorithm are presented below (cf. Sect. 33.6.3).

33.6 Performance Comparisons of Different Steering Algorithms

In the following, the performance of different algorithms presented above is presented for the two reference scenarios: aerial sensor network and aerial relay networks.

33.6.1 Aerial Sensor Network Scenario

In this section different algorithms to address the aerial sensor network scenario are discussed. Figure 33.12 shows example results related to the Spatial Exploration Ratio (SER – percentage of grid cells visited by the swarm) and the Cluster

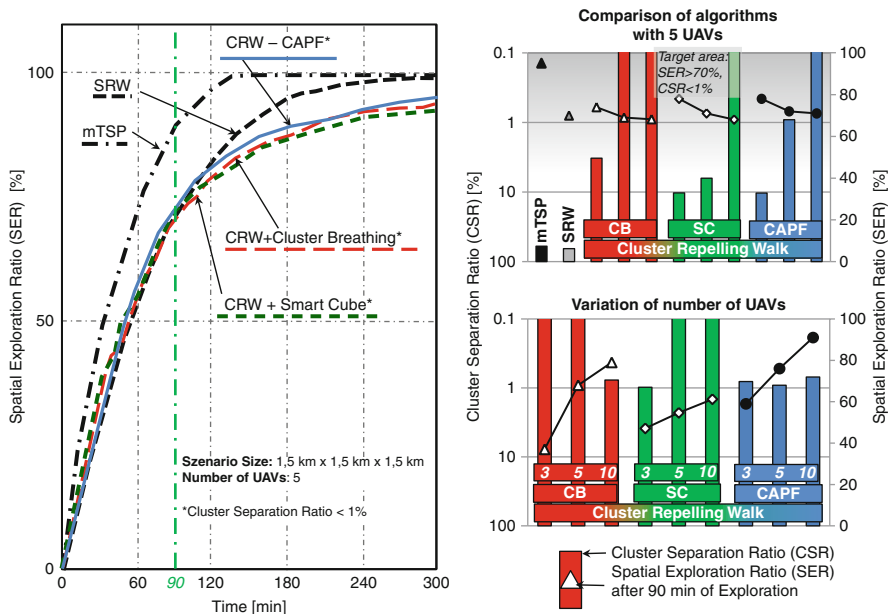

Fig. 33.12 Comparison of different steering algorithms: CRW combined with CB, SC, and CAPF for different parameterizations and swarm sizes (3, 5, and 10 UAVs)

Separation Ratio (CSR – percentage of simulation time, in which the swarm is split up in two or more communication clusters) for selected combinations of steerings corresponding to reference scenario 1. The swarm shall explore a given volume as fast as possible while maintaining stable communication links within the swarm. In order to demonstrate the dependency between inter-swarm communication and spatial exploration performance, this study focuses on the A2A connectivity (Wi-Fi at 2.4 GHz links). The top right-hand part of the figure shows selected SER and CSR after 90 min of exploration for different RSSI thresholds. The left-hand part shows the SER over time for those simulation runs, in which CSR values below 1 % were achieved. The results for a swarm with five UAVs show that the exploration task can be efficiently performed even in the presence of communication related boundary conditions. While the centrally planned reference mTSP delivers very good results for the exploration task, it shows a high number of cluster separations at the same time. The SRW without communication-awareness fulfills the exploration task with very good performance, but it also fails in terms of communication performance. The dedicated, communication-aware strategies (Cluster Repelling Walk combined with CB, SC, or CAPF) show that – given a suitable parameterization – an appropriate equilibrium between low Cluster Separation Ratio (below 1 %) and Spatial Exploration Ratio (around 70 % after 90 min of exploration) is possible. The lower-right hand part of the figure shows the results for CSR and SER for different swarm sizes, ranging from three to ten UAVs.

The selected results shown in Fig. 33.12 have been produced based on numerous simulations with different parameterizations of the algorithms, in particular by varying the RSSI thresholds as well as the weighting of macro- and microscopic mobility control. They indicate that a trade-off between communication and exploration performance is possible. The study also shows that the communication performance is much more sensitive than the exploration success: for example, the CAPF algorithm can achieve a very good communication performance ($CSR < 0.1\%$ instead of 10%) when accepting a 10% lower Spatial Exploration Ratio (SER 71% instead of 78% ; see top right-hand part of Fig. 33.11). With regard to the swarm size, the number of UAVs helps to improve the SER for all algorithms (up to 91% SER for ten UAVs; see results in Fig. 33.11, lower right-hand part). The results therefore show that the system scales well, but at the same time the SER gain per additional UAV decreases with the number of UAVs. This is an example of sub-modularity, which is a property that can be proven for most search problems; see, for example, Krause et al. (2008). One interpretation of these results is that the additional communication constraints preserve this property and limit the impact of additional UAVs on the search efficiency. For the given use case it can be concluded that already with a smaller number of UAVs (three or five) satisfactory SER values are achieved. The cost of deploying more UAVs needs to be carefully assessed against the benefit of improved exploration efficiency.

33.6.2 Ad-Hoc Aerial Relay Network Scenario Using Channel-Aware Potential Fields

With regard to the ad-hoc aerial relay network use case, the first scenario considers an emergency response scenario, in which terrestrial networks are not available anymore (Goddemeier et al. 2011). Figure 33.13 shows example results related to a network provisioning scenario for a crowd of users (e.g., firemen) which moves through an area with larger obstacles/urban canyons (cf. left part of Fig. 33.13). In this case, the channel-aware potential field algorithm controls the micro as well as macro mobility of the UAV swarm. The results (cf. right part of Fig. 33.13) show that different channel qualities lead to different ground coverage areas while at the same time allowing for constant throughput TP. The example results also demonstrate the impact of obstacles: when the distances between UAVs grow, the ground coverage is higher, but the risk for a splitting of the swarm due to obstacles also grows, leading to temporary reduction of the ground coverage area.

33.6.3 Optimal Aerial Relay Positioning Using IPAR

While the above scenario did not consider interference from other networks, the following use case focuses on the optimal positioning in the presence of a terrestrial cellular network. In the left part of Fig. 33.14, the performance of a system with a regular hexagonal layout (frequency reuse factor 1) and different numbers of aerial

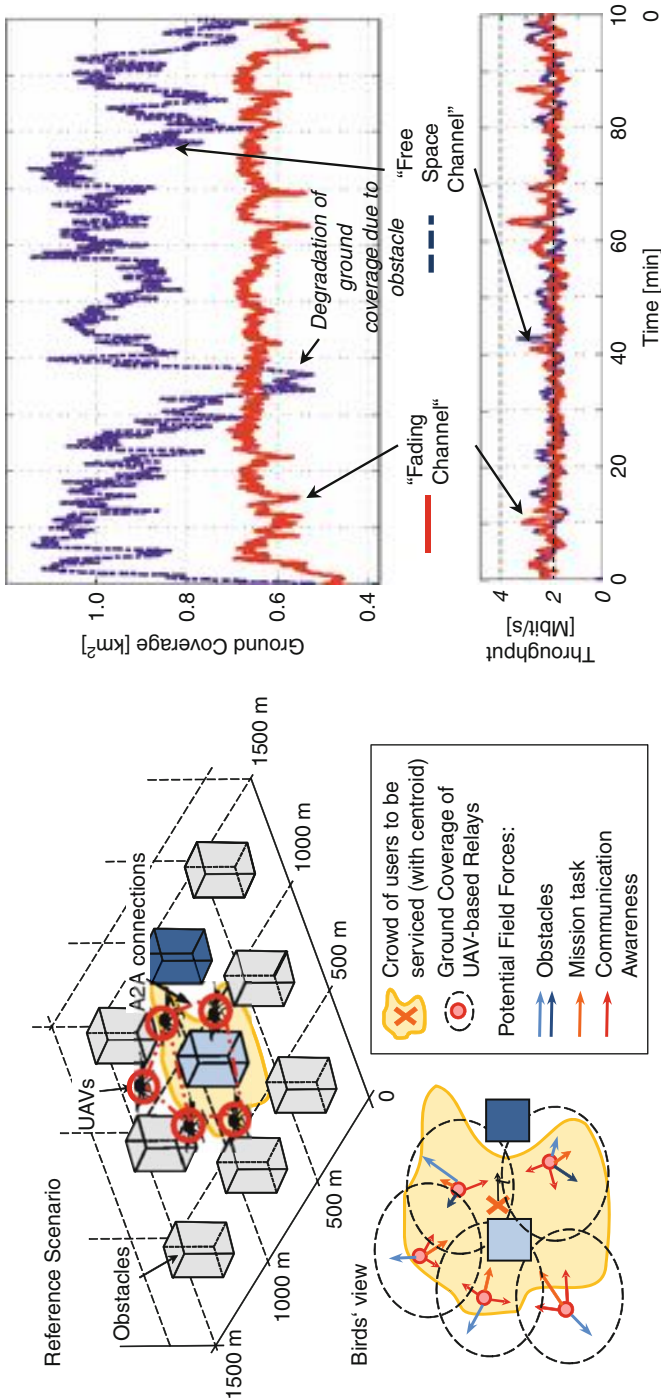

Fig. 33.13 Providing ground network coverage by aerial robot swarm (e.g., Scenario and results)

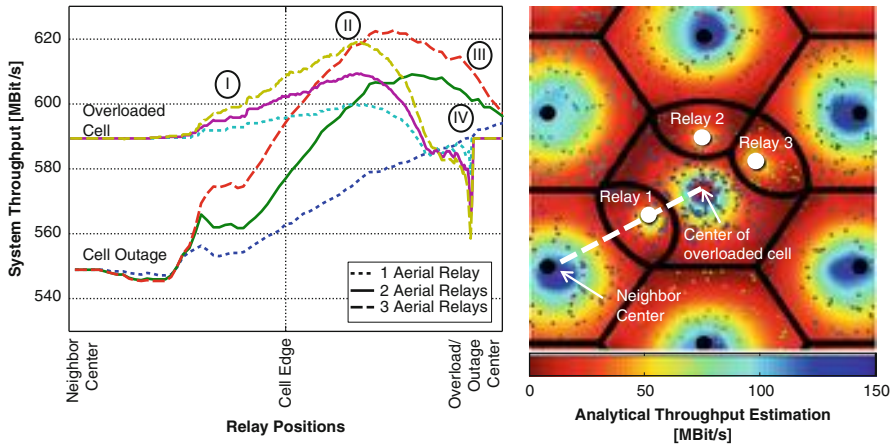

Fig. 33.14 Positioning of aerial relays based on IPAR

relays (1, 2, and 3) is shown for an overload situation as well as a complete outage of the cell. The total downlink system throughput for all connections to users within the considered scenario is shown for different relay positions. The relays move synchronously, starting from the center of the neighbor cell.

The results for the overload scenario show that with a movement of the UAV(s) toward the center of the overloaded cell (cf. (I) in Fig. 33.14), there is a slow increase in total throughput while cell overload and thus packet loss is compensated. It is visible that the method scales quite well for a small amount of relays, leading to a maximum system throughput when three relays are in use (cf. (II) in Fig. 33.14). The most important observation is that the best position of the aerial relay(s) is not at the cell edge, but at around two thirds of the distance from neighbor cell center to the center of the overloaded cell (Rohde et al. 2012). Once the UAV relay(s) further approach the center of the overloaded cell, the throughput drops significantly due to increased interference (cf. (III) in Fig. 33.14).

In case of the cell outage, the results also demonstrate the dependence of the optimal position on the level of interference. For the case of one UAV, the aerial relay (see lower dotted line, which shows a maximum throughput at the cell center; see (IV) in Fig. 33.14) is best positioned at the center of the failed and overloaded macro cell while in case of two and three aerial relays the UAVs should best be positioned in an appropriate distance from the failed macro cell. This underlines how the interference imposed by the relays and macro cells on each other strongly affects the optimal relay positioning. While the left part of Fig. 33.14 shows the full spectrum of possible relay positions and their corresponding system throughput, the right part of the figure shows an example throughput heat map for three aerial relays resulting from UAV positions determined by the IPAR optimization algorithm. The cell boundaries shown in the figure are derived by associating mobile equipment with those terrestrial cells or relays which provide the strongest RSSI (Rohde et al. 2012).

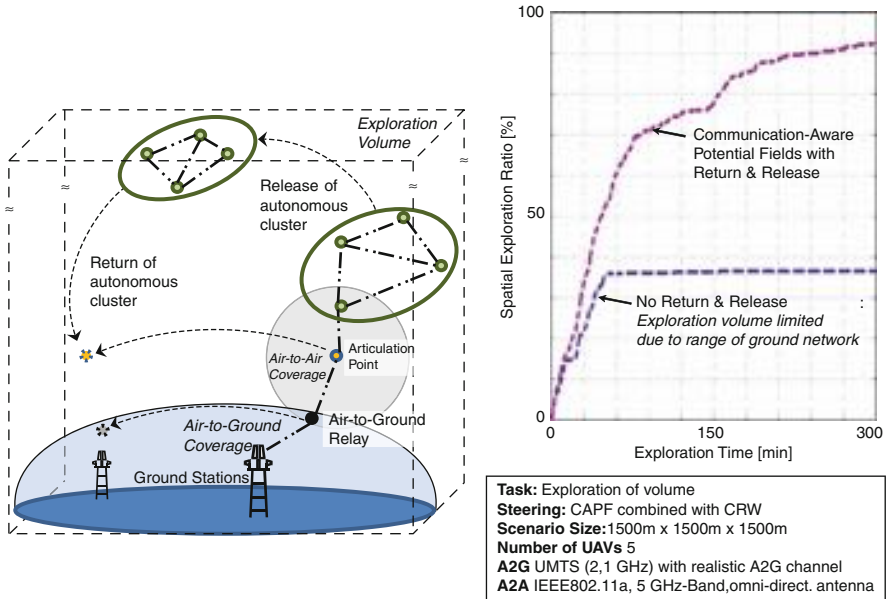

Fig. 33.15 Illustration of different roles within an aerial robot network with limited base station coverage and example results showing an improved spatial exploration ratio

33.6.4 Analyzing the Impact of Role-Based Connectivity Management

Various application scenarios, in which robot swarms can be very useful, require the operation of the swarm across larger distances and altitudes. In those cases, limitations in the range of the communication links need to be addressed by assigning different roles (Odell et al. 2004). In this last use case to be addressed in this chapter, a concept of Role Based Connectivity Management for UAV swarms is presented, taking into account the specific channel characteristics as outlined above. Figure 33.15 shows an example scenario in which publicly available cellular networks shall provide A2G coverage, while Wi-Fi technology is used for the A2A links. The swarm task requires operating in heights of up to 1.5 km, which is out of range of the cellular network coverage (as discussed above in the context of the A2G channel model). To extend the operating range of the swarm, multi-hop links are established: dedicated UAVs stay within the range of the A2G system, while others move beyond to explore the given volume. Thus, different roles are assigned to UAVs, such as an A2G relay node, an articulation point as relay node, and meshed sensor nodes, which are called scouts (cf. Fig. 33.15). While the swarm of scouts performs the exploration task, the relays ensure connectivity to the ground station: the A2G relay node maintains the direct link to the ground station. The articulation point identifies the intermediate node which is required to interconnect

the mesh network and the A2G relay. However, even the use of multi-hop links will not allow for the exploration of the complete scenario depending on the number of UAVs used. Hence, controlled temporary link interruptions are introduced: with a dedicated release and return strategy (RRS), a part of the swarm moves beyond the communication range of the articulation point and reintegrates according to an autonomous control algorithm. With such an approach, dynamically growing search volumes can be accommodated leveraging a given, eventually limited ground-based communication infrastructure. Figure 33.15 (right) shows an example comparison of the spatial exploration ratio over time, in which the RRS enables increasing the SER by exceeding the restricted communication range. In-depth investigations have proven the feasibility and benefits of this approach (Goddemeier et al. 2012).

33.7 Conclusions and Outlook

In this chapter key challenges and essential building blocks for the design of networked aerial robot swarms using self-organized, communication-aware mobility control are introduced. The contribution focuses on multipurpose UAV systems and therefore introduces a modular, service-oriented architecture, which allows supporting example services such as an Aerial Radio Access Network as well as a 3D Sensor Exploration Service. The work presented in this chapter shows that agent-based distributed intelligence is suited to perform the continuous trade-off between the competing requirements resulting from the swarm's application task and the communication-related requirements. Different channel-aware strategies for microscopic as well as macroscopic mobility algorithms have been introduced and discussed based on results, which have been produced by a dedicated multi-scale UAV network system simulation environment. Through the assignment of roles within the swarm, it is possible to cope with advanced scenarios, in which a continuous air-to-ground communication is not available. Implementation and validation experiments with UAV test systems have shown that the technology of task-driven cognitive networking for aerial robot swarms has advanced to be technically mature enough for future deployment. Nevertheless, there are many open research questions, for example, regarding the reliable networking of different UAV types and the communications-sensitive mobility control for networked heterogeneous teams of unmanned aerial and ground robots.

Abstract

Different networking hardware, protocols, and sensors can be combined to create a diverse and complex unmanned aircraft system through a layered design approach with modular supporting software. A layered design simplifies both testing and system reconfiguration, lending itself to incremental verification while only requiring the maintenance of standard interfaces. Critical software components, such as service discovery, simplify the inclusion of a diverse set of subsystems and sensors. Maintaining the modularity of these software components ensures that the system can be expanded while requiring minimal software changes. An example of these design approaches is provided through the description of a system that enabled flight operations of a multi-vehicle unmanned aircraft system for performing targeted, in situ sampling of supercell thunderstorms during the 2010 VORTEX2 field campaign. This network's flexible nature facilitated the complex interworking of many subsystems while accommodating the strict deployment time constraints and generally unknown starting configurations typical of nomadic field operations. Data required for situational awareness and mission-level decision making was retrieved from multiple remote and local sources, and mechanisms were provided for dissemination to any local participant. The architecture's modular design allowed for changes in the field and actively supported the addition and subtraction of nodes without requiring reconfiguration of the remainder of the system.

34.1 Introduction

Most unmanned aircraft (UA) operations are conducted using a single aircraft and rely on simple point-to-point static network configurations (Hipskind et al. 2002; Halverson et al. 2005; Lin and Lee 2008; Office of the Secretary of Defense 2009). This configuration is sufficient to meet the needs of the scientific, operational, and regulatory requirements for many applications. However, as unmanned aircraft systems (UAS) continue to advance and their applications are expanded, there is a need to provide communication beyond a single command and control link. This need is not solely restricted to operation of multiple aircraft (Tisdale et al. 2009; How et al. 2004; Beard et al. 2006) but also includes applications where ground vehicles or stationary nodes are involved in the system and must maintain their own communication requirements.

There are compelling reasons to have sensing systems composed of multiple vehicles with very different capabilities in communication range and bandwidth, sensor payloads, and onboard computational power. Bird-sized miniature UA have significant advantages in unit cost and safety of operation. However, they are burdened with limited payload size/mass, low flight speed/duration/range, limited computational resources, and small communication range and data bandwidth. These aircraft are well suited to multiple, dispersed, short-range sensing tasks, where attrition is expected, or the aircraft are considered disposable. However, such a flock or swarm cannot self-deploy to distant locations, self-organize to

perform complex tasks, or communicate data from distant regions. The addition of a few aircraft with greater capabilities, e.g., small UA, provides a system with the combined advantages of both platforms.

Communication is further complicated when applied to these heterogeneous unmanned aircraft systems. The vastly different payload capacity, avionics capability, communication range, and flight endurance limitations of unmanned aircraft classes lead to fundamentally different types of sensing and communication. For example, swarming miniature air vehicles will likely use local flooding schemes over short distances to disseminate data (Allred et al. 2007), while larger aircraft will use mobile ad hoc and delay-tolerant networking in conjunction with non-line-of-sight radio transmission. Combining these heterogeneous capabilities into a single system with robust functionality remains an open challenge.

Even with single vehicle operations, there has been an increasing need to interface vehicle subsystems with the communication link. In this manner, end users and remote systems can interact with particular subsystems to achieve mission goals. This is typically performed through a dedicated payload link, where sensing data is kept separate from vehicle command and control. This is not always an advantageous configuration, as it is difficult to expand beyond a point-to-point communication link. Furthermore, certain applications require the combination of command and control with payload information to optimize sensing. Examples include various applications of adaptive sampling (Leonard et al. 2010), the construction of communication-based relay chains (Dixon 2010), and the characterization and localization of WiFi sources (Stachura and Frew 2011).

Data-centric, targeted, in situ meteorological sampling is an example application for a complex UAS that requires the use of a heterogeneous, multi-node network that combines inter- and intra-vehicle communications. Conducting targeted sampling is particularly challenging for severe local storm phenomena given the large number of participating vehicles and widely distributed data sources for situational awareness (Elston et al. 2011). This configuration differs from previous uses of UAS for meteorological sampling (Hipskind et al. 2002; Halverson et al. 2005; Lin and Lee 2008) which typically occur over water with observations made over a period of days. Challenges created by the fast evolution of local storms are compounded with the differences in the regulatory environment for the rapid deployment of small UAS over land (Frew et al. 2012). These challenges led to the complex network and system design for the Tempest UAS fielded in 2010 during the second Verification of the Origins of Rotation in Tornadoes Experiment (VORTEX2) (Elston et al. 2011).

To address the difficulties associated with communications in complex UAS, the development of an inter- and intra-vehicle network has been decomposed using a bottom-up layered design approach (Fig. 34.1). This approach allows for the design of UA and supporting systems to reflect and enhance design decisions made at the lower layers. Given that the success of a UAS is based heavily on networked communications, this approach ensures the mission-level control algorithms can be implemented on the underlying network architecture. Subsequent decisions at higher levels of the design process are based in part on the decisions made below. The layers designed here include: *physical/transport*; *data routing*

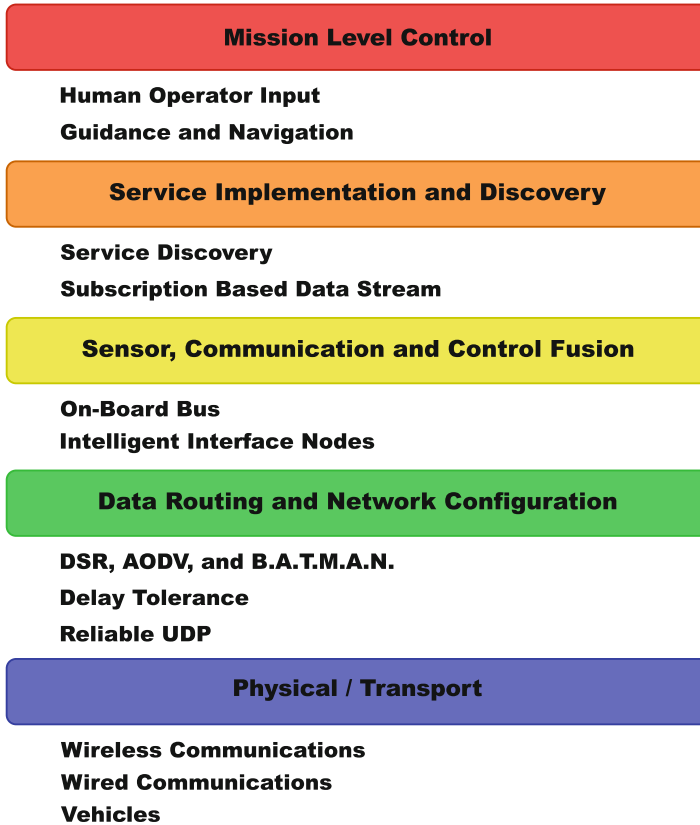

Fig. 34.1 Bottom-up design approach to hardware, communication, sensing, and control for networked UAS

and network configuration; integration of intra-vehicle communication for sensor, communication, and control fusion; application layer communication protocols for service implementation and discovery with data-stream publication; and mission-level control.

34.2 Physical/Transport

The *physical/transport* layer (Fig. 34.1) is the base layer that is directly responsible for moving data. This layer is comprised of three distinctly different transport media: mobile vehicles, wired communications, and wireless radios. Typically, design of the subsystems in the *physical/transport* layer is driven by the desire to use commercial off-the-shelf (COTS) hardware as much as possible to allow rapid development and easy deployment. Figure 34.2 contains examples of possible components and their associated protocols.

Fig. 34.2 The various transport methods supported by the network-centric architecture and resulting software

A complex UAS will use a large number of transport methods since many subsystems such as autopilots, sensors, ground stations, end users, etc., will need to share data or issue commands. Providing a system that seamlessly accommodates a large number of transport methods is critical to an adaptive and modular network-centric architecture and presents a significant challenge. It is also necessary to properly abstract this layer from the rest of the network design since these subsystems will typically change for different mission requirements and evolve over time.

Each transport method has its unique benefits and challenges. Mobile vehicle-based transport involves coupling onboard storage with mobility to transport large amounts of data from one geographical location to another, but requires the use of delay-tolerant networks (Brown and Henkel 2006). Wired communications systems are typically limited to intra-vehicle connections, but generally provide highly reliable transmissions. Wireless communications subsystems are required for UAS and can greatly influence system performance. Therefore, wireless communications are typically the focus of the design of the *physical/transport* layer for most UAS applications.

To aid in the wireless subsystem selection process, several of the more popular communications methods are presented here, all of which have been used with the NetUAS system. These include IEEE 802.11 (WiFi) and IEEE 802.15.4 (ZigBee) radios, 900-MHz modems with both RS-232 and IEEE 802.3 (Ethernet) interfaces, and Iridium satellite communications with an RS-232 interface. These systems are typically used in small UAS for their relatively small size and weight, low power

Table 34.1 Specifications for the EnGenius EMP-8602 PLUS-S

| | |
|-----------------------|------------------------------------|
| EMP-8602 PLUS-S | |
| Operating frequency | 2.4000–2.484 GHz (802.11b) |
| Output power | 100 mW (802.11b) |
| Range | up to 140 m (802.11b) |
| Configurations | Ad hoc, managed, master, secondary |
| Data rate | Up to 11 Mbps (802.11b) |
| Interface protocol | Mini PCI |
| Operating voltage | 3.3 VDC |
| Operating temperature | 40–85 °C |
| Dimensions | 59.6 × 44.45 mm |
| Weight | 15 g |

draw, and ability to operate at limited radiated power levels without a license. Each communications method utilizes different network topologies including multi-hop, point-to-point, and centralized, and the system design must be able to accommodate communications through these different schemes. Furthermore, selection of communications hardware will be restricted by the resources, dynamics, and sizes of the nodes in the network.

34.2.1 IEEE 802.11 Radio

IEEE 802.11 offers an ad hoc mode which allows for any single device to connect to others in proximity without requiring a centralized access point. This behavior is desirable in UAS where network nodes might frequently move in and out of range of other nodes. Furthermore, the 802.11 protocol allows high-bandwidth connections, for large amounts of data to be sent over the links. Unfortunately, without amplification, the radiated power of a COTS radio covers only a relatively short distance. Generally, 802.11 cards containing an Atheros chipset are a good choice because of the level of driver support in Linux, a commonly used embedded operating system for UAS avionics and ad hoc networks. One frequently used card is the EMP-8602 PLUS-S from EnGenius (EnGenius Tech Inc 2011) (Table 34.1). Characterization of the performance of a similar card in a UAS network was performed during the Ad hoc UAV Ground Network (AUGNet) experiment (Brown et al. 2007).

34.2.2 IEEE 802.15.4 Radio

In smaller UAS, where weight and power savings are paramount, a protocol like IEEE 802.15.4 is commonly used (see specifications in Table 34.2). This protocol is limited in bandwidth compared to 802.11, but its lower rate allows for lower power, and for implementation on much simpler devices (Zheng and Lee 2006). Furthermore, the radios implement the ad hoc on-demand distance

Table 34.2 Specifications for the Digi XBee-Pro radio

| | |
|-----------------------|----------------------------------|
| XBee-PRO | |
| Operating frequency | 2.4000–2.4835 GHz |
| Output power | 63 mW |
| Range | 90 m |
| Configurations | Master, slave, or slave/repeater |
| Data rate | 250 Kbps |
| Interface protocol | 3 VDC CMOS UART |
| Operating voltage | 2.8–3.4 VDC |
| Operating temperature | 40–85 °C |
| Dimensions | 24.38 × 3.294 mm |
| Weight | 3 g |

vector (AODV) routing protocol in hardware, allowing for mesh networks to be formed without special software. This protocol has been used with micro UA projects (Allred et al. 2007) and has been installed in larger UAS providing gateways to other wireless networks to enable participation of micro UA in larger scenarios (Elston et al. 2009b).

34.2.3 900-MHz Spread-Spectrum Point-to-Point Radios

For several different scenarios involving small UAS, a longer-range solution is necessary. Even with amplification and steerable antennas, the range of COTS 802.11 components remains limited by the relatively high frequency of its carrier. Although 900-MHz radio modems generally only offer point-to-point or centralized communications schemes, and are limited in bandwidth, they greatly increase the communication range over 2.4-GHz options in the unlicensed industrial, scientific, and medical (ISM) radio bands. The setbacks in the routing can be overcome with application layer networking software running on a computer paired with each modem. To save weight on the UA, smaller OEM models of the radios can be used such as the FreeWave MM2. At the ground station or in ground vehicles where power and weight requirements are significantly relaxed, a model such as the HTPlus could be used, which contains significantly more functionality. Detailed specification of these units can be found in Table 34.3.

34.2.4 Satellite Communications

For significantly long-range missions, satellite communications are required. These are typically expensive, unreliable, and very low bandwidth. However, given a sufficiently autonomous aircraft with a relatively static flight pattern, this small amount of communication can be sufficient to perform a mission. Before the exact range of operations required for supercell sampling missions was known, the Tempest UA was equipped with the A3LA-X Iridium modem from Nal Research

Table 34.3 Specifications for the FreeWave MM2 and HTPlus radios

| | |
|-----------------------|---|
| HTPlus | |
| Operating frequency | 902–928 MHz |
| Output power | 5 mW up to 1 W |
| Range | Point-to-point Up to 48 km Point-to-multipoint 24 km |
| Configurations | Master, slave, or slave/repeater |
| Data rate | Up to 867 Kbps |
| Interface protocol | IEEE 802.3 or RS232 |
| Operating temperature | –40 to 60 °C |
| Dimensions | 165 × 74 × 59 mm |
| Weight | 427 g |
| MM2 | |
| Operating frequency | 902–928 MHz |
| Output power | 5 mW up to 1 W |
| Range | Up to 96 km |
| Configurations | Master, slave, or slave/repeater |
| Data rate | Up to 153.6 Kbps |
| Interface protocol | IEEE 802.3 or RS232 |
| Operating voltage | 3.3–5.5 VDC |
| Operating temperature | –40 to 85 °C |
| Dimensions | 36 × 50.8 mm |
| Weight | 14 g (TTL version) |

Table 34.4 Specifications for the Nal research A3LA-X satellite modem

| | |
|-----------------------|--------------------|
| A3LA-X | |
| Operating frequency | 1,616–1,626.5 MHz |
| Output power | 0.6–7 W |
| Range | Works globally |
| Configurations | Slave |
| Data rate | 2.4 Kbps |
| Interface protocol | RS232 |
| Operating voltage | 4.0–32.0 VDC |
| Operating temperature | 30–70 °C |
| Dimensions | 162 × 67 × 27 mm |
| Weight | 340 g (0.75 pound) |

(see specifications in Table 34.4). Due to the regulations required for operating UA in the U.S. National Airspace System (Davis 2008), reliability became an issue for ensuring safe operations and a different solution was developed combining IEEE 802.11 and 900-MHz radios. Figure 34.3 shows the timeouts experienced during one mission, and Fig. 34.4 compares the amount of telemetry received through the modem’s limited bandwidth to a point-to-point 900-MHz link.

Fig. 34.3 Index of each data packet vs. the time of day it was received at the ground station using the Iridium modem. Note the four timeouts, around 20, 35, 38, and 50 min. At these points, the modem lost communications and the ground station was forced to reestablish the connection with the UA, a process that can take several minutes

34.3 Data Routing and Network Configuration

The *data routing and network configuration* layer (Fig. 34.1) is built on top of the COTS components used in the transport layer and is used to determine how to deliver data between nodes. For several of the network connections, it can be sufficient to use manufacturer-provided routing and configuration methods. However, for wireless connections to the aircraft and between the ground vehicles, most scenarios dictate the use of unique or modified protocols that can handle multi-hop connections and network topology reconfiguration Christmann and Johnson (2007). The managed mode of 802.11 fails quickly in these scenarios, and the ad hoc mode fails to provide for routing beyond single-hop communications (Brown et al. 2007). There is significant value in fielding a true multi-hop, ad hoc solution when deploying systems consisting of multiple cooperating vehicles, and several projects have employed these architectures (Brown et al. 2007; Elston et al. 2009b; Allred et al. 2007). Providing this unique environment generally requires the use of third-party routing protocols. Presented below are protocols that have been used with the NetUAS system along with the particular experiment each was employed in.

During the flights performed for the AUGNet experiment, an 802.11b card was combined with a Linux single-board computer and GPS to construct a mesh network radio (MNR) (Brown et al. 2007). To simplify development, the core of each MNR node for this experiment was identical, with only the packaging differing depending on whether the MNR is mounted at a fixed ground site, on a ground vehicle, or in an aircraft. Each MNR ran the *dynamic source routing* (DSR) protocol (Johnson et al. 2001): an on-demand protocol that only seeks a route from source to destination when data must be sent. Thus, radio nodes do not waste bandwidth trying to establish routes they do not need at the moment. When a node needs to send a packet, it initiates a route request process among nodes in the network to establish a route. DSR uses source routing whereby a packet source

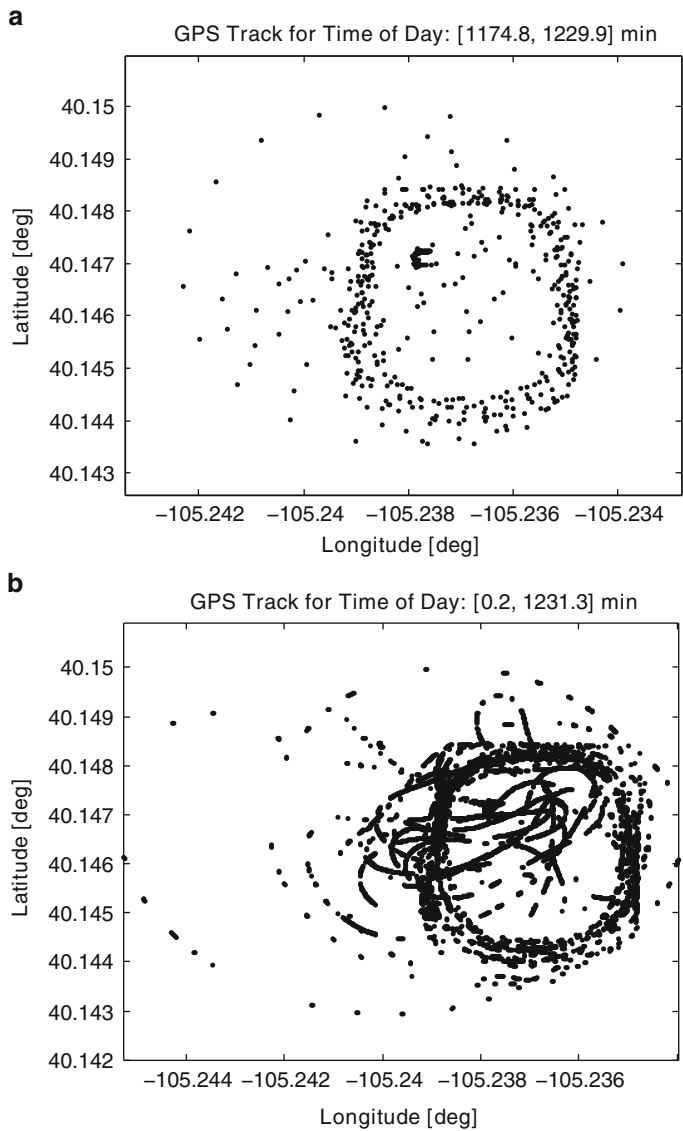

Fig. 34.4 The difference in spatial sampling with the (a) lower data rate from the Iridium and (b) higher data rate from the 900-MHz modem. Notice the reduced data points and missing sections in the stream transmitted via the Iridium modem

precisely specifies in the header packet which route the packet will follow. DSR was implemented using the Click modular router (Kohler et al. 2000), a software-defined protocol that enables the modification of the routing scheme as needed. During the experiment, it was determined that timeouts and hop lengths had to

be changed from the protocol's default values to accommodate the combination of node motion with the communications ranges from COTS 802.11 cards. However, even with these modifications, DSR was found to fail more often in highly mobile networks, especially when transmitting large amounts of data (Brown et al. 2007).

The *ad hoc on-demand distance vector (AODV)* (Chakeres and Belding-Royer 2004) protocol was used in the Collaborative Colorado-Nebraska Unmanned Aircraft System Experiment (CoCoNUE) to combat the issues encountered during the AUGNet experiment (Elston et al. 2009a). Unfortunately, although the AODV implementation created by CoReSoftware (AODV-UU 2010) provided the desired functionality in the lab and during some flight experiments, its use in the field uncovered several problems. Most of the issues came from the lack of updates since 2007, which mandated the use of older kernels and drivers. At that time, no other implementations were available, so the group was forced to use another protocol. AODV could still be a suitable protocol for use in UA networks, especially given that a hardware implementation of AODV is employed by some modes of operation in 802.15.4 radios. For IP-based networks, the use of Click could provide for an acceptable alternative to the CoReSoftware package, as at least one example of an implementation of AODV in Click already exists (Performance Analysis of Telecommunication Systems 2012).

An implementation of the *better approach to mobile ad hoc networking (B.A.T.M.A.N.)* protocol (B.A.T.M.A.N. 2010) was used to replace the AODV implementation in the CoCoNUE project (Elston et al. 2009a; Houston et al. 2011). This protocol was chosen based on the results of characterization of multiple different routing protocols (Abolhasan et al. 2009). In several experiments conducted in both the laboratory and in the field using mobile and stationary nodes, the functionality of B.A.T.M.A.N. was verified for identifying and properly selecting routes. It was later employed in the complex network system fielded in VORTEX2 (Elston et al. 2011), and provided effective routing despite the large number of participating nodes.

For certain UAS applications, suitable third-party implementations do not exist. In these cases, routing protocols must be designed to address the unique networking issues. As mentioned in Sect. 34.2, work has been performed to investigate the use of the vehicles themselves as data ferries. It considers optimal mobility and delay-tolerant networking to provide maximum bandwidth in a disconnected network (Brown and Henkel 2006). For UA networks with limited uptime given power or other considerations, work has been performed on modifying the UDP protocol to provide data delivery guarantees without the overhead required by TCP (Henkel et al. 2006).

34.4 Sensor, Communication, and Control Fusion

The *sensor, communication, and control fusion* layer (Fig. 34.1) integrates intra-vehicle communication between subsystems with the external meshed networking environment. In the NetUAS system, a modular architecture has been implemented

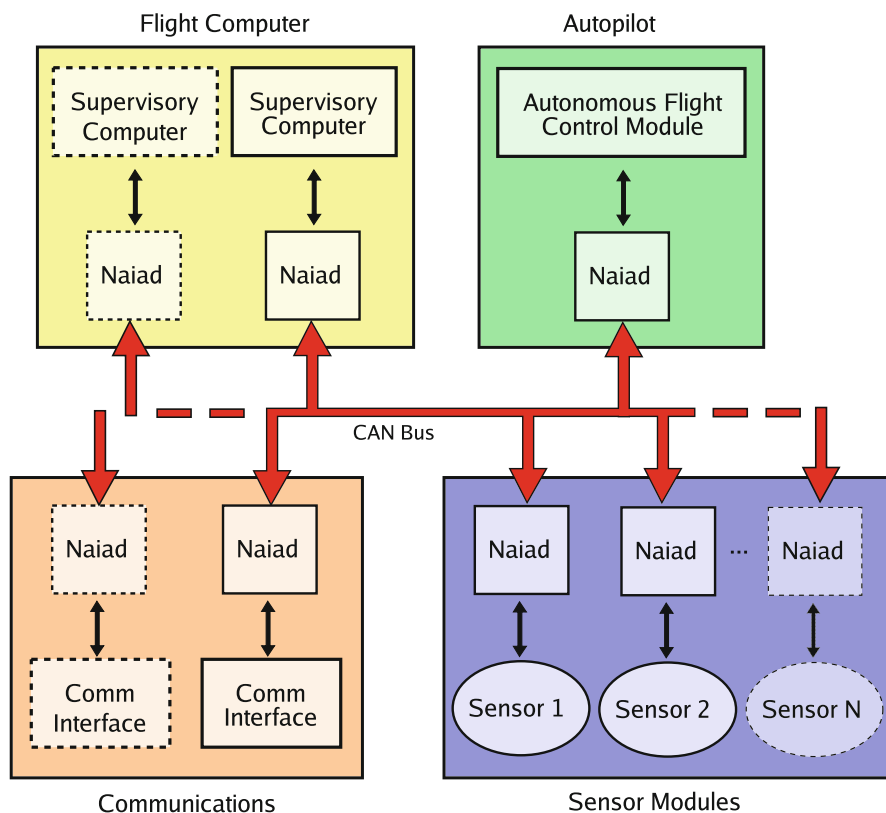

Fig. 34.5 Distributed onboard network architecture. *Dashed lines* indicate areas of system expansion, and *shaded blocks* represent subsystems

for the synthesis of onboard systems needed in mission-level decision making. The architecture employs a lightweight interface node to connect to each component, and provide an interface through a shared bus. Each node contains some intelligence and is responsible for initialization, data fetching, and data manipulation needed for a particular device. By enforcing this paradigm, the bus traffic remains high level and enables significant system scaling with no reprogramming of the existing nodes. Particular subsystem upgrades may also be performed with ease, assuming the high-level data being pushed to the bus by its interface node remains unchanged. A typical configuration consists of a supervisory flight management computer, the autonomous flight system, extra-vehicle communication hardware, and sensors (Fig. 34.5).

Using this distributed architecture, better fault tolerance and flexibility is achieved than by using a centralized approach. Without the hardware limitations of a single-board solution, only the inter-node bus protocol limits the number of times subsystems and interfaces can be replicated. The use of addressing-by-type allows for multiple nodes to both send and receive the same message type, and enables

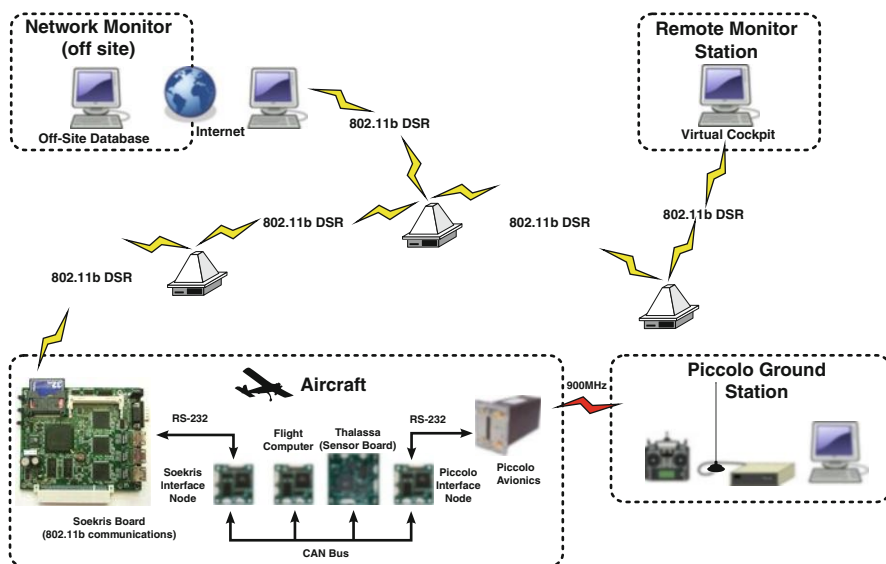

Fig. 34.6 Typical deployment scenario for the ares UA networked communication, command, and control system. The aircraft electronics consist of a distributed avionics system connected through a controller area network (CAN) bus using the Naiad interface nodes (Elston et al. 2009b)

transmission without knowing the hardware address of a destination node. Combining this functionality with the use of a health-and-status subsystem to identify and disable malfunctioning nodes makes changing between redundant subsystems transparent to the rest of the system. It provides a level of fault tolerance equivalent to the nearly independent subsystems of a federated architecture while maintaining the advantages of modular systems.

The integration of intra- and inter-vehicle communication plays a significant, albeit subtle, role in the performance of the unmanned aircraft system. By connecting subsystem information, e.g., telemetry from an autopilot or images from an onboard sensor to the external meshed network, the aircraft can exchange data directly to the subsystems that need it (Fig. 34.6). An example includes the interface of an ad hoc communications system to the autopilot to provide greater ground-station-to-UA communication range through a multi-hop connection, or to allow for control hand off between multiple remote operators via a mesh network. Including payloads in the intra-vehicle bus allows network participants to view mission-specific data generated from anywhere within communication range. This becomes very important when considering cooperative tasks shared between multiple vehicles.

Within NetUAS, the Naiad is the first incarnation of the interface nodes used to implement this architecture (Elston et al. 2005). A Naiad node is approximately 1.5 in. on each side, weighs about 0.5 oz, and nominally uses 50 mA at 5 V. The node contains a watch-dog timer with brown-out detection. The microcontroller is capable of about 14-MIPS throughput, but requires very little power to operate and

is relatively inexpensive. Each node has mounting holes to enable easy placement about the aircraft, or to be stacked in a convenient location using small standoffs. Inter-node communications are made through the message type-based controller area network (CAN) protocol. Each node contains a fault-tolerant CAN transceiver to guarantee data transmission and allows the system to run on a single wire in the case of a separated bus line. Furthermore, the use of high differential voltage levels by the transceiver protects the bus from interference.

34.5 Service Implementation and Discovery

Components at the *service implementation and discovery* layer (Fig. 34.1) define how elements of the UAS can interact with one another, enabling seamless command and control across a heterogeneous network. This layer accommodates functionality such as the use of more than one ground station, interaction with the UA from outside of the ad hoc network, in flight reconfiguration of the entire UAS, and communication between different UA types and heterogeneous subnetworks. Components at this layer ensure that network configuration (e.g., the existence of nodes and their addresses) no longer has to be specified before the system is deployed. New UA can be injected into the system or new ground stations may be brought up, and the network configures itself appropriately in response. All of this functionality is enabled by mechanisms for service discovery, data-stream subscription, and command issuance.

In the NetUAS system, the *service implementation and discovery* functionality is implemented by several user-level threads running on a Linux computer. These threads not only provide interfaces to the network and system components but also provide support functionality such as message logging and a graphical interface for users to either visualize available data streams or inject control messages into the UAS. Components are programmed in a way to provide a simple application programming interface (API) for the development of cooperative algorithms based upon the information handled by the underlying mechanisms. The software maintains a level of modularity that allows for reliability, ease of upgrading, and the ability for programmers to contribute functionality without needing to understand all of the components in the system.

34.5.1 Application Layer Networking Components

The application layer networking software uses an object-oriented approach to define component modules. These modules are based upon the idea that any task implemented on a particular node can be represented by a combination of up to three different types of blocks. These blocks are as follows:

- *Communication Block.* The communication block provides an interface to some physical device. It might be a device on a serial port, a socket, or a video camera. It is responsible for initialization, reading from, and writing to the device.

Fig. 34.7 The *threaded pipe* object. The block in the *center* can be instantiated as a communication, translation, or computation thread

- *Translation Block*. Considering the non-standard internal message format, most device interfaces require translation from the device's protocol to the internal messaging scheme. Two examples are XML parsing/serialization from a socket interface or conversion of proprietary binary GPS data from a serial interface.
- *Computation Block*. Occasionally the interface will also require that some computation is performed using the data made available by the interface/translation block combination. An example of this could be a filter implemented to condition the data coming in from a sensor. There are also cases where internal data needs to be processed and then pushed back to the system (i.e., no interface or translation blocks).

All three of these blocks are specialized instantiations of a single class. This class is implemented as a thread, allowing each block to perform its function asynchronously with the remainder of the system. Because of their asynchronous nature, data transfer between a series of blocks is performed through first-in-first-out buffers (FIFOs). A *threaded pipe* comprises a combination of FIFOs and a block. The *threaded pipe* is the basis for application-based networking and is shown in Fig. 34.7.

The combination of up to three of these *threaded pipes* (communication, translation, and computation), connected through their FIFOs, creates an *Interface*, shown in Fig. 34.8. Each one of these interfaces completely defines the mechanisms necessary to implement a particular capability. Examples include providing an interface to a network, reading from a sensor, actuating a controller, or providing decision making about a specific task based upon system parameters.

A critical component of the *interface* is the *client list manager*. This block is used by interfaces that provide communications to maintain a list of clients whose traffic has been seen on the network. It provides the ability to store information about each client that is frequently used on a system-wide basis, including service discovery information, last known GPS location, time since last received transmission, etc. It can store multiple addresses for a particular node, which is required to implement a gateway between two different types of networks.

By linking two or more of these interfaces together, and sharing the client list between each, data can be transferred from one interface, such as a sensor, to

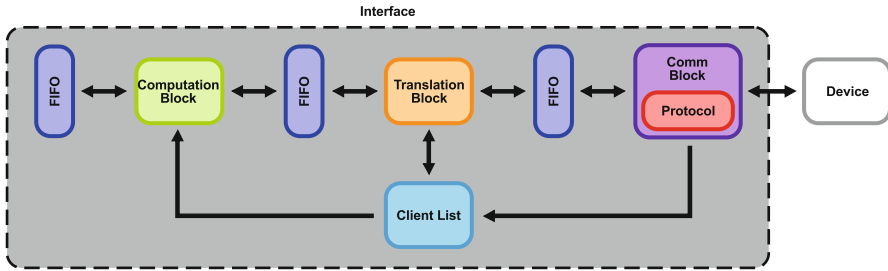

Fig. 34.8 An *interface* object, which enables a device to communicate with the remainder of the UAS. The interface is composed of up to three different *threaded pipes* (computation, translation, and communication) and a client list stored in shared memory

another interface, such as a socket to an ad hoc network (Fig. 34.9a). The intelligent routing of messages between interfaces is performed by a *data distribution* object. This object uses a destination address associated with each message and looks it up in the client list to determine the proper interface to send the message. All internal messages have to go through the *data distribution* object, and it is therefore used to provide logging functionality when desired.

Service discovery implementation is performed through the *capabilities manager* object. As each *interface* is invoked, it registers the capabilities it enables (autonomous flight, gateway to external networks, etc.) with the *capabilities manager* object (Fig. 34.9a). This process of collecting the various capabilities allows for the complete specification of all data streams available for subscription and all accepted commands. This information is broadcast over the entire network at a fixed interval providing the basis for the service discovery mechanism.

Combining the *capabilities manager*, *data distribution* object, and some multiple of *interface* objects composes a *network appliance* as shown in Fig. 34.9. A large number of interfaces may be added to the *network appliance* enabling more functionality for the particular node. Complicated nodes can be managed in this way, with the *network appliance* providing interfaces to multiple types of networks and translating between different addressing schemes or data transport methods. A specific example of this would involve a node that takes in XML command packets from an 802.11 network, parses the XML and translates the source address, then forwards it to an 802.15.4 network with the proper packet-based format and addressing scheme. Another example is managing the complex interfaces to provide a human operator system-wide status through a GUI.

34.5.2 Service Discovery

In order to facilitate self-coordination in a complex UAS, a significant amount of infrastructure must be in place. A vital component of this infrastructure is the ability of other UA to obtain information about the status and capabilities of

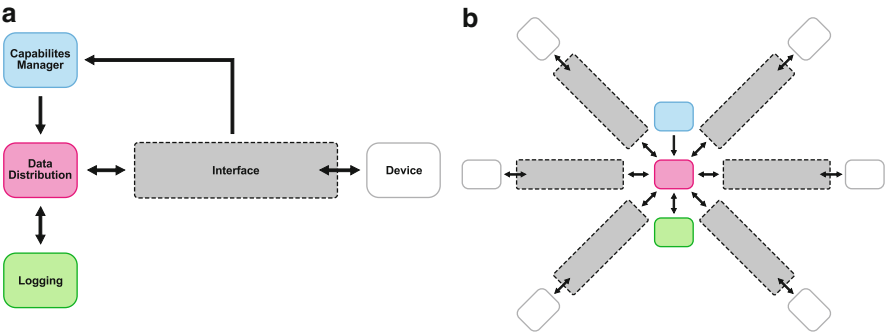

Fig. 34.9 The *network appliance* object. (a) Depicts a simple, one-device *network appliance*, where (b) shows how this can easily be expanded to accommodate a large number of devices

Table 34.5 Comparison of service discovery protocols

| | Distributed directory | Central directory | Flat | Hierarchical | Local cache | Unicast | Multicast | Broadcast | Push | Pull |

surrounding aircraft. It is only when this information is known that aircraft may then employ neighboring assets to collaboratively complete mission objectives. The concept of service discovery is well established; however, few service discovery protocols exist for ad hoc networks. Many of the protocols still have no method for dealing with high levels of node mobility which typically leads to sporadic disconnections and the need for continual updates of routing information. Furthermore, many protocols might be able to adapt to a highly dynamic environment, but were designed with another architecture in mind and not tested in such a manner. A summary of some existing protocols is given in Table 34.5, and further detailed in Elston (2011). Each contains some component that makes it unsuitable for highly dynamic ad hoc networks, and more significantly, no protocol allows for the easy definition

of services typically used in a UAS. Most were designed to establish the presence of services such as file sharing or a networked printer on a local area network.

A service discovery protocol was implemented from scratch, as no satisfactory third-party solution was available. To define each vehicle's services, a description language was implemented which combines the vehicle's subsystem definitions with system-level information. The functionality of the vehicle's subsystems are broken into two components: data that it can transmit to clients on a periodic basis (data streams) and commanded actions or configuration settings that each subsystem accepts (accepted commands). System-level information includes the network address of any onboard communication nodes, a unique vehicle ID to enable translation between different addressing schemes at gateway nodes, and a subset of the vehicle's telemetry for higher-level queries, such as when looking for "Neighboring nodes containing a GPS."

The *capabilities manager* is in charge of implementing the service discovery protocol. Each interface registers its capabilities with this block by indicating the particular subsystem type it represents and which streams and commands are associated with it. After 10 s has elapsed, the computation block assembles all known subsystem capabilities with the system-level information into a small packet that is broadcast to all connected networks. This heartbeat message enables other nodes to track the connectivity status of their neighbors and identify their various associated capabilities. Since this packet is reconstructed each time it is sent out, capabilities can be changed in real time, effectively accommodating system failure or reconfiguration.

34.5.3 Service Subscription and Command Interface

After the reception of a capabilities packet, a node has all the information it needs to either issue a command to a particular subsystem, or subscribe to the data provided by it. Command issuance is performed through the transmission of a request addressed using the system-level data stored in the client list. The request includes the unique subsystem ID to be commanded, the accepted command ID, and the desired actions. The method of confirmation for successful reception and execution of the command varies by subsystem. This is typically performed through the transmission of a simple ACK or NACK packet; however, some systems might require more complex responses. An example would be acknowledgement of the reception of a flight plan by echoing the entire plan back to the sender. Each subsystem is responsible for maintaining its own acknowledgement protocol, along with rules for retransmission assuming no acknowledgement is received.

Stream subscription is conducted through the transmission of a request containing the subsystem ID defined in the capabilities packet and a "Subscribe" message. Upon reception of this request, the remote node's *data distribution* object directly handles each subscription. Subscription status is indicated by adding the unique ID of the subsystem and its associated stream the client wishes to receive to the info in the client list. An ACK or NACK packet is then sent back to the subscriber

indicating its subscribed status. Data transmission to the subscriber occurs whenever the *threaded pipe* representing the subsystem of interest decides to publish data. To determine recipients, the *threaded pipe* requests the list of subscribers from the *data distribution* object. When no clients have subscribed to the data, no data is transmitted, preserving network bandwidth for other uses. At any time, a subscriber can send an “Unsubscribe” packet to remove it from a data service.

34.6 Mission-Level Control

The *mission-level control* layer (Fig. 34.1) defines algorithms and rules that allow for the UAS to achieve an overarching goal. Elements on this layer are generally the focus of research work and tend to drive system design Love et al. (2009), which can cause significant issues when fielding a system that has not considered the underlying infrastructure. A myriad of control architectures have been developed based on simple communication models (Behnke et al. 2011; Alighanbari and How 2006; Beard et al. 2006). In many cases, these models assume perfect communication or a graph-theoretic disk approximation such that nodes can communicate perfectly when within some maximum range of one another. In any case, realistic communication issues such as data routing and quality of service are mainly ignored. Construction of this layer as the last component of a bottom-up methodology ensures the underlying layers can support the needs of the mission-level control algorithms, and that the algorithms themselves maintain realistic expectations for network performance.

34.6.1 Human Operator Input

Human operators usually provide mission-level control through a graphical user interface. The challenge of a GUI for a complex system is to allow the user the interaction and information they need to perform specific tasks without overwhelming them. This can be achieved by abstracting out the complexities of the system to give a broad overview of the system while allowing the user to access more specific information when necessary.

For the NetUAS system, the GUI is implemented as a computation block in the application layer networking and therefore can be invoked from any machine running the software, including multiple computers on the same network. This allows the flexibility of supporting redundant human operators, or independent human operators in charge of their own subsystem. The GUI can act as a gateway to allow users outside of the internal network to invoke a fully functional instance. It can also be limited to a read-only state where an operator is not allowed to issue commands over the network.

The NetUAS GUI is divided into five spaces as seen in Fig. 34.10 and is designed to be as simple as possible while still relaying pertinent information to the operator. The toolbar across the top enables user interaction with the map space using

Fig. 34.10 Annotated NetUAS GUI screenshot depicting the components (Elston 2011)

quick-reference icons. The upper left pane displays all service discovery, stream subscription, and command status. The lower left pane displays all map layers and allows each one to be toggled by the user. The map space provides the user with spatial situational awareness and can show all of the layers controlled by the lower left-hand pane. The bottom bar gives quick status, such as the time, location of the cursor on the map page, and that cursor location's distance from the current position of the node running the GUI.

Status of the service discovery mechanisms is provided as a list to the user and separated by node. As each node announces itself to the system, its human-readable ID is displayed. Should the node fail to communicate its status for longer than a timeout interval, which is set depending on the mission and underlying network, its background will turn red to indicate this status to the user. By selecting the arrow next to each client, the services/commands that each particular node provides/accepts are displayed to the user (Fig. 34.10). Requests for subscriptions to a particular data stream are performed by clicking on the check mark next to each stream. Once the first packet is received, the background of the stream will turn green to indicate that the subscription went through, and certain streams will show up as information in the rest of the GUI (i.e., the map space).

If the user desires further interaction with any particular node, clicking the check box next to the human-readable name will bring up a separate window (Fig. 34.11). This window is populated with tabs depending on the services provided by the node. Figure 34.11 shows two windows from two separate nodes. One node is an aircraft carrying a pressure, temperature, and humidity (PTH) sonde, and the other

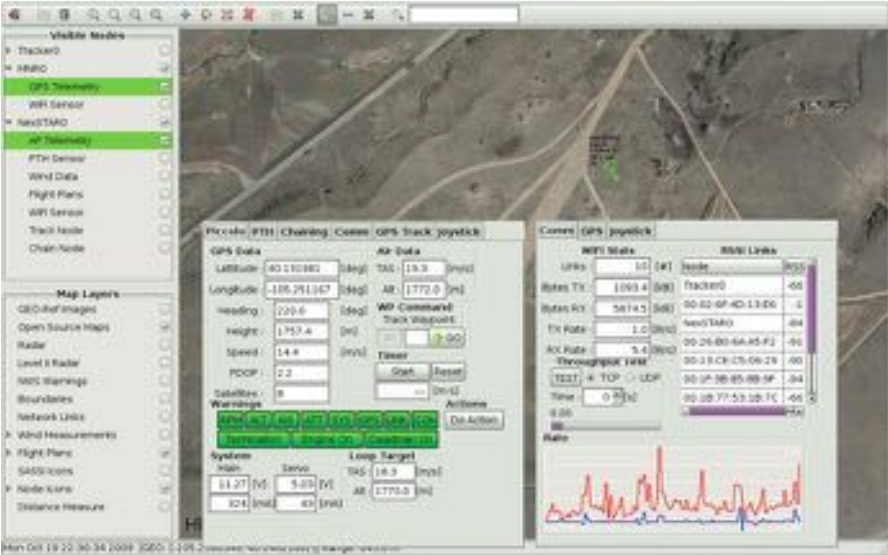

Fig. 34.11 NetUAS GUI with node windows displayed. Each window provides tabs that correspond to capabilities of the particular node and allows the user to see detailed status or issue commands

is a simple meshed network radio. This diversity demonstrates how very different sets of capabilities can be displayed in the GUI. The tabs and their content are all determined dynamically using the service discovery protocol, and their content is defined using XML, making it easy to add a GUI for new services/accepted commands.

Issuing a command to a particular node is simple, requiring the user to open the associated node window and click the appropriate buttons. As an example, the user can command the UA to track an MNR by selecting the appropriate tab of the UA node window and clicking the “Track” button to issue the command. Furthermore, the orbit parameters can be adjusted, such as the altitude or relative distance of the center point from the tracked node. This is particularly nice when attempting to track an aircraft from a moving vehicle. By allowing a user in the car to position the UA to any side of the car, the user can better keep it in view and away from visual obstructions.

Some functionality for commanding nodes is performed outside of the node windows. For example, each node accepting flight plans can be sent a flight plan from the map plane. Clicking on the appropriate menu bar item allows for a plan to be drawn. Upon completion, the user may left click the plan they have drawn (or opened from a file) and using the correct modifier key, translate it, rotate it, or change the position of one waypoint. Once the plan is ready, the user simply has to right click on it, choose “send waypoint,” and then pick the particular client to receive it.

The map plane of the GUI (Fig. 34.10) displays several geo-referenced layers of data including the following: maps, weather information, flight boundaries, network status, wind measurements, flight plans, and node telemetry. The first of these layers, “Open Source Maps,” contains one of several selectable forms of maps: satellite imagery, road network, topographical, and aviation charts. These maps provide background imagery for spatial reference and supply pertinent local information such as road names and elevation. This data is presented in a tiled, scrollable interface similar to what Google Maps offers, allowing the user to easily navigate an area by dragging and zooming with the mouse. Right clicking on the imagery allows the user to switch between the different types of maps.

Each component of the NetUAS GUI was designed to provide for management of a multi-UA system, while presenting the necessary data in such a way to avoid overwhelming the operator. Every component allows for the user to select which data he desires to display, as is evident with the ability to toggle the visibility of map plane layers, the expandable nodes and services lists, and the ability to open windows for more in-depth interaction with a specific node. Intuitive mouse and keyboard control also simplifies the user interaction process, allowing for essential tasks to be completed quickly and easily.

34.6.2 High-Level Control Algorithms

Automated mission-level control is provided through cooperative algorithms. A well-designed network-centric UAS architecture facilitates vehicle coordination which greatly simplifies the creation of high-level control algorithms. Networking components such as service discovery provide for easy identification of nodes with a particular capability, so that partners can be identified. Once these partners are identified, command and data exchange interfaces provide the algorithm with the necessary means for accomplishing coordinated tasks.

The Research and Engineering Center for Unmanned Vehicle (RECUV) Heterogeneous Unmanned Aircraft System (R-HUAS) is an example of a system that has implemented cooperative algorithms using the NetUAS architecture. The layered nature of the NetUAS enabled the R-HUAS to combine both small and miniature UA through a multi-tier heterogeneous airborne network to perform cooperative tasks. The R-HUAS has supported research efforts on a large variety of topics that include cooperative search, acquisition, and tracking (Frew et al. 2008); flocking of miniature air vehicles (Allred et al. 2007); volumetric atmospheric sampling (Argrow et al. 2005); ad hoc networking on small UA (Brown et al. 2007); controlled mobility in ad hoc networks (Brown and Henkel 2006); mother-ship/daughtership control architectures; the construction of communication-based relay chains (Dixon 2010); and the characterization and localization of WiFi sources (Stachura and Frew 2011). Successful demonstration of each of these algorithms have been performed through either flight tests or hardware-in-the-loop simulations.

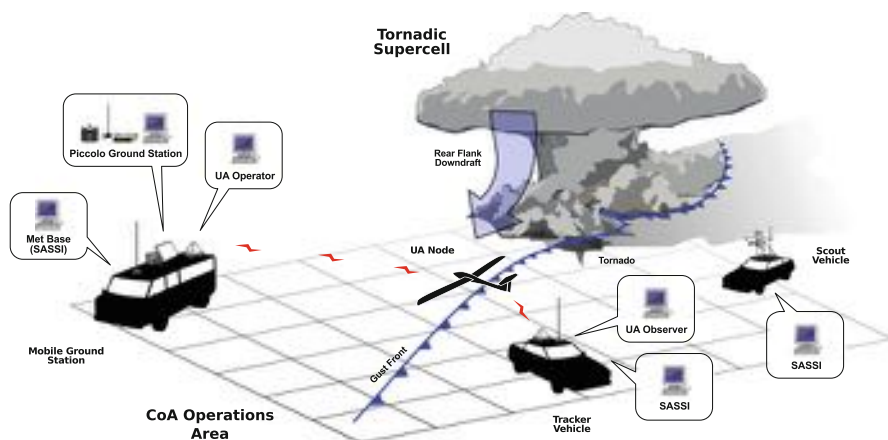

Fig. 34.12 Schematic of the Tempest UAS and ground vehicles for in situ sampling of severe storms (Elston et al. 2011)

34.7 VORTEX2 Implementation

The value of the layered design of the communication, command, and control network described here was demonstrated through successful sampling of severe supercell thunderstorms as part of the VORTEX2 field campaign (Elston et al. 2011). The concept of operations (CONOPS) for sampling supercell storms required the most complex incarnation of the NetUAS architecture to date (Fig. 34.14). This was mainly due to the large number of networked vehicles, and the large number of subsystems and interfaces per vehicle. The unmanned aircraft system (Fig. 34.12) consisted of a total of four vehicles: (1) the Tempest unmanned aircraft, (2) a mobile ground control station used to command the UA, (3) a ground “tracker” vehicle tasked to observe the aircraft, (4) and a “scout” vehicle outfitted with a mobile mesonet (Straka et al. 1996) sensor suite used to provide situational awareness for the ground station.

The Tempest UAS (Tempest 2010) was designed as a low-cost UAS for collecting in situ data in supercell thunderstorms. Two key mission requirements were the ability to launch within 10 min of arrival at the launch site and to maximize sampling time while operating in severe atmospheric conditions. The UA is flown semiautonomously with a Piccolo SL autopilot (Cloudcap 2011), and in situ meteorological data is collected with a Vaisala RS-92 sonde (Hock and Franklin 1999). Networking is provided through a custom version of Linux running on an Overo SBCs from Gumstix (2012). The Overo platform has an onboard 802.11 solution and worked well with an implementation of B.A.T.M.A.N. protocol. The ARM processors required cross compiling the NetUAS software, but the persistent storage is provided through an SD card, making data logging and reconfiguration of the operating system relatively simple.

A mobile ground control station (GCS) is used to support the deployment of the UAS by providing the necessary tools for operation and maintenance of the system. Its crew consists of a driver, meteorologist, UAS manual pilot (who can control the UA through joystick commands issued to the autopilot from a conventional radio-control handset), UAS operator, UAS technician, and pilot in command (PIC). Four different networked computer systems provide interfaces for the meteorologist, UAS operator, and PIC to visualize data from a variety of sources and make mission-level decisions. UAS command, control, and communication are maintained with the UA up to the 20-mile (32 km) operational range through two tracking antennas positioned on the roof of the GCS. These consist of a mechanical system with a high-gain 900-MHz patch antenna and a phased array antenna for directed 802.11 communications. A small Linux single-board computer automatically points the antennas using GPS feeds from the GCS and the UA in conjunction with local magnetometer readings. This helps ensure continuous communication over the range of operations, and although the GCS typically remains stationary during a flight, this enables the GCS to move in the case of an emergency while maintaining communications with the UA.

A wide area network (WAN) interface is available in the mobile GCS through the use of two types of cellular connections. This provides access to the Internet, which allows the head meteorologist to make navigation and targeting decisions based on real-time radar data using the Gibson Ridge Level 3 (GR3) (GRLevel3 2010) software package. It also allows for visualization of the positions and real-time data of other assets in the VORTEX2 armada using the SASSI tool (Rasmussen 2010) for severe weather situational awareness. The Internet is also used by the UAS operator for dynamic map requests and for the real-time publication of the UA location and meteorological measurements.

During flight operations, the UA is commanded to orbit within 1,000 ft vertically and 1/2 mile horizontally of the tracker ground vehicle that carries the UA observer. This is done to satisfy Federal Aviation Administration (FAA) see-and-avoid requirements (Elston et al. 2011). The tracker vehicle contains two systems that allow the UA to follow with a high level of autonomy and that free the observers to focus on airspace monitoring and UA observation. The first system is a modified version of the MNR, based on the Alix 3d2 single-board computer. The MNR contains a GPS receiver and provides the location of the tracker vehicle to subscribers. By allowing the UA flight computer to subscribe to this GPS location, a controller on the UA can track and orbit the tracker. This provides two advantages: the UA remains within the required distance of the tracker, and the sampling of the storm is simplified to directing the driver of the tracker using voice commands over a VHF radio, which indirectly moves the UA. The second system is a laptop computer running the networking software and a limited-functionality graphical user interface. This interface provides status of the system and position of the UA at all times, allowing the personnel in the tracker to provide an offset to the UA orbit. This tracker-relative orbit is chosen to allow easy, full-time observation by one of the designated UA observers through a side window or sunroof.

Fig. 34.13 Aggregate histogram of communication timeouts using finalized system over 4 VORTEX2 deployments from June 6, 7, 9, and 10, 2010 (Elston et al. 2011)

34.7.1 VORTEX2 Experiment and Results

System development and flight testing for the VORTEX2 project was conducted over 2 years and 69 flights of the Tempest UAS. During each of the flights, in addition to recording pressure, temperature, humidity, and wind information, logs were kept of all traffic through the NetUAS system, routing and network statistics (Fig. 34.13), the locations of the vehicles, telemetry from the autopilot, and data from the electronic speed controller (ESC). The field component of the VORTEX2 project was composed of the final 21 of the 69 Tempest UA flights and used two different aircraft from 2 May to 10 June, 2010.

All flights during the VORTEX2 campaign occurred without incident despite being flown near and beneath supercells and other severe convective storms, and through light precipitation. A total of six flights in the proximity of supercell thunderstorms were performed, including one flight (10 June, 2012) conducted shortly after the supercell produced two tornadoes. Basic information for each flight is provided in Table 34.6, which includes date, aircraft flown, time of flight, COA area for flight, and whether or not the UAS team was performing the mission in coordination with the rest of the VORTEX2 armada. This coordination is significant as it provides the opportunity for UAS data to be combined with measurements of the storm taken from the other sensor platforms in the armada. The UAS team was not always able to coordinate with the armada given the limited area for UAS operations compared to the entire range of the VORTEX2 project (Elston et al. 2011).

Table 34.6 Summary of significant VORTEX2 deployments

| Date | With armada | Flight (mm:ss) | COA area |
|--------------|-------------|----------------|-------------|
| 6 May 2010 | Yes | 44:15 | 2009-CSA-37 |
| 26 May 2010 | Yes | 45:01 | 2009-WSA-23 |
| 6 June 2010 | No | 19:35 | 2009-WSA-13 |
| 7 June 2010 | No | 27:30 | 2009-CSA-9 |
| 9 June 2010 | Yes | 33:30 | 2009-CSA-6 |
| 10 June 2010 | Yes | 34:00 | 2009-WSA-33 |

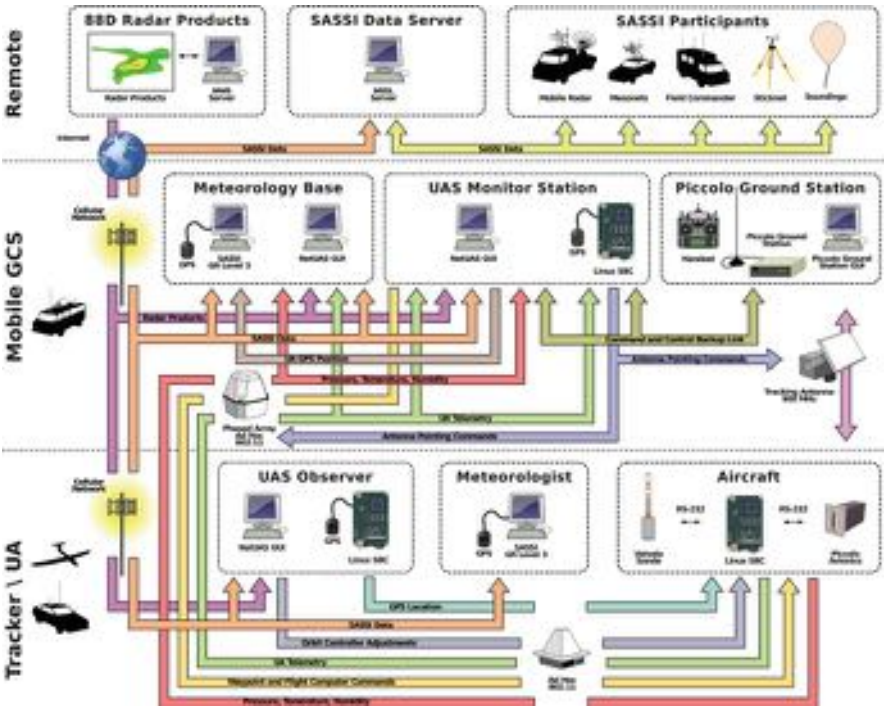

Fig. 34.14 System diagram for entire UAS including remote data sources (Elston et al. 2011)

Figure 34.14 represents the complete, ideal system configuration for the VORTEX2 experiment, with each arrow representing a directed data stream that is provided and managed through the NetUAS service discovery functionality. In practice, portions of the data streams would go down, e.g., from loss of connectivity due to separation, and the architecture provided seamless transitions between configurations. The ad hoc networking capabilities of the NetUAS accommodated a large number of networked subsystems and vehicles, while also allowing for switching out aircraft, vehicles, computers, and nodes in the field without requiring reprogramming of the system.

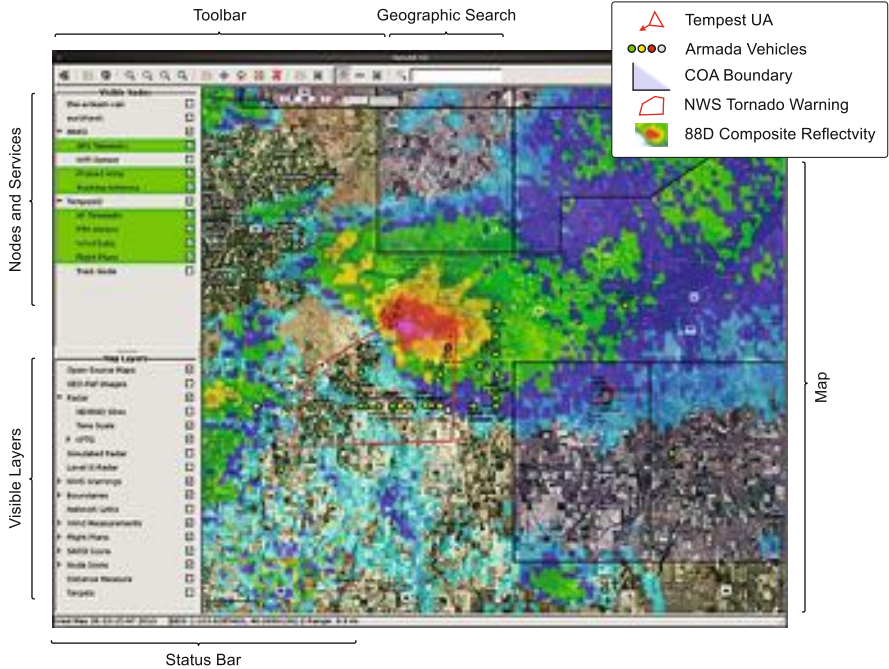

Fig. 34.15 Annotated NetUAS GUI screenshot taken during 26 May 2010 operations. The *left panel* contains a list of connected nodes and their respective services, along with a list of displayable layers. The *right panel* shows the overlay of WSR-88D image of the supercell, COA boundaries, and locations of other deployed VORTEX2 vehicles (Elston et al. 2011)

The modular nature of the NetUAS architecture easily accommodated new enhancements to the system. As an example, interfaces to external data sources were added at several points in the system, and functionality was added to the GUI to display this data (Fig. 34.15 shows a screenshot of the GUI taken during 26 May 2010 operations). Several new GUI layers were added including real-time WSR-88D weather radar data, National Weather Service warnings, flight region boundaries, VORTEX2 vehicle locations (available through SASSI (Rasmussen 2010)), and real-time UA wind measurements. In addition to being able to display new data sources, the GUI was also enhanced to satisfy the needs of the atmospheric sampling mission. Support was added for centering the map using city or road name searches, quick flight plan generation, and the ability to send waypoint plans to all vehicles (including ground vehicles).

The NetUAS also accommodated software changes to increase system functionality while in the field. These changes were generally implemented between flight experiments, a capability that was only achievable due to the ability to quickly change modules without affecting the rest of the system. During the deployment, a module was added to the operator interface to include battery usage estimates for determining a safe time to terminate operations with enough power to return to the

GCS and land the aircraft. A module was also added to the operator station in the GCS that subscribed to UA telemetry and converted it to an NMEA string. This string was transmitted over a USB interface. In this manner, a computer connected to the other end of the USB saw it as a GPS device. This allowed for easy integration of UA telemetry into the GR3 software, which already had support for reading GPS devices.

The layered design of the network also allowed for easy system reconfigurations to address issues encountered during the experiments. The design accommodated one deployment which required the UA operator station in the GCS to be field swapped when the graphics card failed with a laptop used as a backup in the tracker vehicle. It also allowed for the tracker's entire system to be reconfigured several times following the discovery that the ad hoc link from the UA to the tracker was problematic in both packet loss and, more importantly, occasional lengthy communication timeouts. During these timeouts, the GCS could still command the UA; however, if the UA was not tethered to the tracker, it was much more difficult for the observer in the tracker to maintain a visual fix on the UA (Elston et al. 2009a; Houston et al. 2011).

Due to the time constraints of the project, a more thorough investigation of this problematic link was not possible, so a solution had to be found using the available hardware. Changes were made on multiple levels of the design, but due to the modular and abstracted nature of the NetUAS architecture, no software changes were required, and little reconfiguration was necessary for the rest of the system. One of the configurations consisted of removing the MNR and connecting the observer's laptop to a USB GPS unit to provide the location to the UA. By using the publish/subscribe architecture and service discovery, this was seamlessly accomplished, requiring only that the operator at the mobile GCS identify the laptop as the target to be tracked instead of the MNR. Another configuration was attempted using a wired interface through an Ethernet cable from the observer laptop to limit WiFi interference with the UA-to-tracker link. In this configuration, NetUAS provided the functionality necessary to establish a gateway between the wired and wireless networks. Because of this ease of reconfiguration, in relatively little time several configurations were tested, and one was eventually found that proved a solution that worked well enough to successfully complete the scientific experiments (Elston et al. 2011).

Conclusion

The bottom-up design approach described here enables the creation of a net-centric command and control architecture for a complex unmanned aircraft system. The design philosophy was centered on using modular and off-the-shelf technology as much as possible. This philosophy is evident across the layers. At the lowest hardware layer, several types of COTS networking components and radios were used to provide communication between aircraft, ground vehicles, and static nodes. The establishment of links between the radios was performed using commercial routing protocols wherever possible, with the

exception of a few custom solutions to accommodate unique applications. Intra-vehicle communication was enabled between a commercially available autopilot, communication solution, and sensing payload using modular interface nodes with a reliable bus protocol. Finally, these were tied together through a unique application layer networking solution which provided mechanisms for service discovery, a publish/subscribe data architecture and the issuing of commands.

Given this layered architecture, the development and implementation of cooperative algorithms was greatly simplified. Algorithms were constructed without worrying about details of data and information flow. In some cases, like tracking a ground vehicle, the aircraft communicated directly with the target, while in others, such as when working with heterogeneous vehicles and networks, the data was routed through several nodes before reaching its destination. Service discovery mechanisms allowed for cooperative algorithms to easily identify nodes capable for performing the tasks necessary, request their participation, and exchange the data necessary for each vehicle to complete its task.

The benefits of this architecture and layered design approach were demonstrated through the successful deployment of a complex UAS for use in the VORTEX2 project. The Tempest unmanned aircraft system accomplished several milestone goals including the first ever use of a UAS to collect data in close proximity to a supercell on 6 May 2010, and the first ever sampling of a supercell rear-flank downdraft airmass by a UAS on 9 June 2010. The network-centric nature of the operation enabled data to be gathered about the storm environment and UAS (such as observed winds, control surface deflections, and control-loop tracking) that will be used as the basis for the design of future networked unmanned aircraft systems.

Abstract

This chapter examines the enabling role of cognitive radio technologies for unmanned aircraft systems to access more spectrum needed for flight operations. Analysis of stakeholders sets the requirements for cognitive radios. With these requirements, the paper describes the different architecture choices available to the UAS cognitive radio designer. These include the communication architecture, the spectrum awareness techniques for assessing what spectrum is available, and the spectrum access techniques for deciding which available spectrum to use. Cognitive radios provide a number of benefits over traditional radios: they increase spectrum management flexibility and automatically resolve conflicting allocations. This promotes more widespread spectrum sharing, increasing the spectrum available. It provides mechanisms to automatically make fine-grained allocations, such as spectrum reserved for specific phases of flight, which increases unmanned aircraft flight safety. It enables new business models of spectrum management that can encourage better allocation of spectrum resources. Information from this chapter is relevant for the development of future unmanned aircraft systems rules and standards.

35.1 Introduction

Unmanned aircraft systems (UASs) have the potential to play an important social, economic, and security role for countries around the globe. Unlike manned aircraft where aircraft flight control systems are an integral part of the aircraft, pilot controls of UAS are physically separated from the aircraft. Further, communication to air traffic control (ATC) and sensors for detect sense and avoid (DSA) will be required to safely integrate UAS into national airspace systems (FAA 2001). This poses a great technical challenge to remotely operate the UAS. Thus, one of the primary concerns regarding the ability of UAS to meet safety regulations without conflicting with existing systems is the availability and allocation of bandwidth and spectrum for control, command, and communication (C3) (FAA 2006; Neale 2007). In addition to C3 for remote piloting and platform safety, UAS communication with payloads, including backhaul of imagery and sensor data, and payload management is required and may in some cases demand more bandwidth than the C3. These communication needs are shown in Fig. 35.1. As noted in the figure, the communication is both with the aircraft and among parties.

It is useful to distinguish internal and external communication (Heppel 2008). Internal communication is within the UAS and includes the C3 connection between the unmanned aircraft and the pilot as well as the payload management. External ATC and DSA communication will use standardized frequencies (e.g., standard ATC voice, ADS-B, weather radar, transponder, and GPS channels). As such they are outside of the scope of this study. It should be noted that these external communications will require additional internal communication back to the pilot

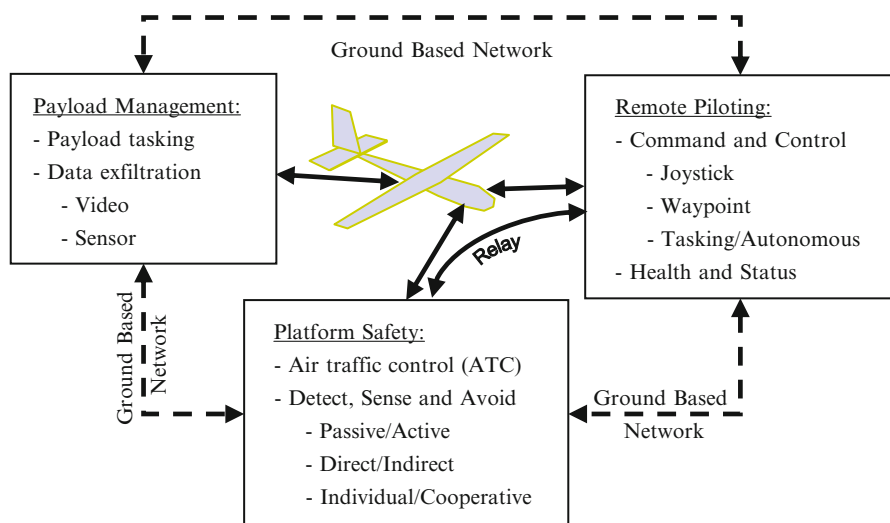

Fig. 35.1 Types of communication in UAS

for pilot situational awareness and proper integration into airspace management systems. So, the focus of this chapter is to support internal communications.

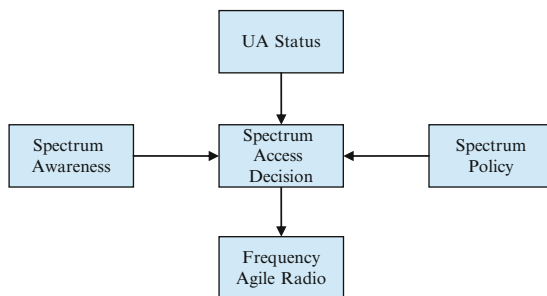

Existing UASs, use technologies ranging from military aviation links, to satellite links, to short-range links adapted from other standards. Regardless of the link technology, addressing this communication need requires radio spectrum. Today UASs face two spectrum problems:

- Spectrum scarcity
- Static spectrum management

The RTCA has estimated that the spectrum requirement for UAS C3 is at least 13MHz and as much as 300MHz (Box et al. 2009). However, there is currently limited spectrum allocated for civilian and military UAS C3, and demand for spectrum from all applications is growing. All useful bands for radio communications have been allocated. Allocation of spectrum on a global basis is controlled by international agreements, which are handled by the World Radio Conference (Griswold 2008). In Agenda 1.5 of the World Radio Conference (WRC) 2015, there will be discussion of use of spectrum allocated to satellites for UAS (ITU 2012). However, in general, spectrum allocation agreements are difficult and slow to be changed. Even if there are additional spectrum allocated for UAS use, there could be years of delay waiting for the existing spectrum users to vacate the bands. Further, any allocation is likely to fall short of long-term UAS spectrum needs.

While spectrum is fully allocated, paradoxically, studies show that spectrum is underutilized for most of the time. According to the Federal Communications Commission in the U.S. (FCC 2003), there is a large variation in the use of spectrum bands in space and time. The utilization varies from 15 to 85 % indicating large

Fig. 35.2 Functional blocks of a cognitive radio

portions of usable spectrum are underutilized or “vacant.” Such unused spectrum is referred to as spectrum *white spaces*. Although artificial, a spectrum scarcity exists and is a side effect of the inefficiencies of fixed assignment. This results from the currently static approach to spectrum management, where a large amount of spectrum is assigned for long periods of time over large regions (Akyildiz et al. 2006; Mitola 2006). Additionally, with “manual” spectrum management, deployment of systems is troublesome. If there are conflicts in frequencies assigned, the time needed to resolve such conflicts can be substantial. For example, Griswold (2008) has illustrated that “In Iraqi Freedom, the Army’s Hunter [UAS] did not operate for the first 30 days in-theater because it was awaiting frequency deconfliction in order to obtain operational frequencies to use.” Worse, such conflicts can go undetected until interference is observed in flight operations.

A significant communication role can be filled by new radio technologies. One such technology is *cognitive radio* (Akyildiz et al. 2006). A cognitive radio determines unused portions of the existing wireless spectrum and adapts the radio’s operating characteristics to operate in these unused portions in a manner that limits interference with other devices. The functional components of a cognitive radio are shown in Fig. 35.2. The cognitive radio is built on top of a frequency agile radio that can change the frequency bands or modulation with which it communicates under software control. The choice of bands is a so-called *spectrum access* decision that is based on several factors. Three factors are considered in this chapter. *Spectrum awareness* is how the cognitive radio discovers what frequency bands are not being used by an incumbent user and thus potentially available. *UA status* is information such as the location of the unmanned aircraft and its current phase of flight. *Spectrum policies* are machine-readable rules that specify in which bands a radio is permitted to (or prohibited from) transmitting and under what conditions. Thus, to transmit in a band requires that the band is within the capabilities of the radio, not occupied by an incumbent user, and there is a policy permitting its use and appropriate for the current location and status of the UA.

Cognitive radios address the problems of spectrum scarcity in three ways. First, through the use of spectrum awareness, a cognitive radio can find unused spectrum to utilize. Second, since the radios are frequency agile, they can use bands that would

otherwise be neglected. The radio can use bands based on location, phase of flight, and other conditions. For instance, several planes can share low-quality unlicensed bands during preflight where packet losses and delays are tolerable leaving more spectrum for higher-quality dedicated bands during more critical phases of flight such as takeoff. Third, policies enable a mechanism to acquire spectrum through spectrum leasing. Spectrum leasing (FCC 2004) is an agreement where a spectrum holder leases its spectrum to another spectrum user. Machine-readable policies can be used to define lease terms in a spectrum-leasing agreement. Machine-readable policies allow lease terms to be defined precisely and be followed strictly. So, the policy-based approach could encourage spectrum holders to lease their spectrum. Generally, the policies are used to define time-limited leases that limit the period for which the spectrum is valid to a specific period (Chapin and Lehr 2007). This time limit limits the risk even if the terms are found later to be unfavorable to either the lessor or lessee.

More generally, policies address the problem of static spectrum management. Cognitive radios enable fine-grained time, frequency, and location allocations of radio spectrum for communication. Current approaches allocate large swaths of spectrum over large regions for decades at a time. Finer-grained allocations foster more efficient use of the spectrum with greater communication capacity to support future UAS growth and innovation. More importantly, cognitive radio can make such allocations automatically while still adhering to stakeholder requirements. This automation provides government regulatory flexibility that is not currently present and promotes better use of the spectrum. Spectrum regulators, such as the FCC in the U.S., recognize that cognitive radios can be applied to dynamically reuse white spaces in licensed spectrum bands, thereby efficiently utilizing underutilized spectrum (FCC 2002). More importantly, as will be shown, cognitive radios enhance UAS flight safety. They provide more spectrum for better aircraft control. They are naturally frequency agile so that they can avoid interference. They allow spectrum to be preplanned so that UAS pilots can have some assurances that they will have the requisite spectrum before the flight starts. And, they can automatically navigate and manage complex spectrum assignments and avoid hazardous conflicts on UAS C3 channels. However, there remain many open questions about how such a cognitive radio system should be organized and operated. Therefore, this chapter seeks to answer the following questions:

- What are basic architectures for UAS communication?
- Who are the UAS spectrum stakeholders?
- What are the mechanisms for UAS spectrum awareness?
- What are the mechanisms for UAS spectrum access?

Certain questions such as cognitive radio security are not addressed here (Brown and Sethi 2008). The remainder of this chapter addresses the above four questions and then provides an example scenario to suggest how the different elements fit together. The goal is not to find the right answer to each of these questions. But, rather, to lay out the possible range of solutions that are available to guide system designers as they try to adopt cognitive radio technology for specific UAS.

35.2 Basic UAS Communication Architectures

UASs consist of a wide range of aircraft sizes, ranges, altitudes, and endurances (van Blyenburgh 2009). Unmanned aircraft sizes can be as small as a handheld aircraft or as large as a 12,000-kg Global Hawk. Ranges can be less than a kilometer to thousands of kilometers. Altitudes range up to 20,000 m. Endurances go from a few minutes to several days.

UASs operate through different phases of flight (RTCA 2011):

1. Flight Planning: flight tasking and uploading of the flight plan
2. Start and Taxi: performing checklists, rolling down taxiways, rolling down runway
3. Takeoff and Departure: leaving ground to being assigned to en route ATC authority
4. En route: traveling directly from one place to another after takeoff and departure
5. Aerial Work: loitering, searching patterns, etc. as part of operations
6. Decent and Approach: decreasing altitude to final approach point
7. Terminal and Landing: arriving at airfield, landing, and exiting the runway
8. Postlanding: taxiing and parking
9. Emergency: UAS failure that prevents normal operation

The different phases of flight are related to the bandwidth, delay, and reliability requirements (Box et al. 2009). To accommodate these requirements, various communication architecture and spectrum bands can be used to connect the unmanned aircraft and the unmanned aircraft control stations (UACS). The next section describes UAS communication architectures and then the role of cognitive radios.

35.2.1 UAS Communication

These wide-ranging specifications foster a variety of architectures to meet UAS communication needs between the UA and control station. UASs currently use several models of communication including satellite and direct ground-based line of sight. Short-range UASs as well as other UASs during takeoff and landing use direct line-of-sight communication links. These can have communication ranges beyond a 100 km for larger aircraft and more capable radio systems or less than a kilometer for simpler systems. Longer-range UASs use satellite communication links en route when beyond line of sight of the control station. Generally, these are on larger aircraft but simple satellite-phone-based links have been used on smaller aircraft.

The RTCA SC-203 has been examining the architectures and spectrum requirements for UAS operations (Heppe 2008). In addition to current approaches, outlined above, they also recognize a third approach, in which there is a network of ground-based radios similar to a cellular telephone system. Cellular telephone systems are noted for their very efficient use of the spectrum, ability to implement strong security, and the ability (when well planned) to provide seamless coverage.

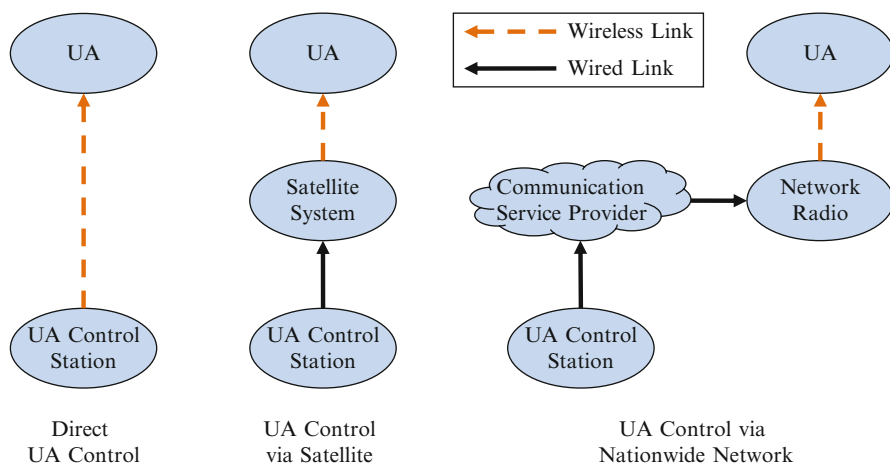

Fig. 35.3 UAS C3 architectures

Fig. 35.4 UAS mesh

The use of a cellular-like ground-based system to provide nationwide high-bandwidth communication service has been demonstrated by a commercial vendor. AirCell of Louisville, CO (www.aircell.com), provides a nationwide multimegabit per second air to ground communication service in the U.S. Although based on commercial cellular technology and not approved for flight-safety communications, the AirCell system does demonstrate the feasibility of this technology and also is collecting valuable operational experience. The three types of command and control architectures are illustrated in Fig. 35.3. A given UAS may use one, two, or all three of these architectures depending on location and phase of flight.

In addition to these architectures, a fourth architecture builds on the previous architectures in a so-called mesh as shown in Fig. 35.4. In this architecture, one or more UA have a connection to the control station using one of the above architectures. Other UA have C3 access via relay communications back to the control station. This architecture is more useful for controlling multiple UA from the same control station. Here the focus is on controlling a single UA.

Fig. 35.5 Cognitive radio (CR) architecture for UAS

35.2.2 Cognitive Radio Architecture

The cognitive radio architecture should support the different UAS communication architectures. For each of these architectures, a cognitive radio is added on the final link as shown in Fig. 35.5. In the direct architecture, a cognitive radio is connected to the UA control station (either directly or through some intermediate network). In the satellite architecture, the cognitive radio is on the satellite. The cognitive radio would likely be distributed with the transmitter and receiver on the satellite and the other cognitive radio components located on the ground portion of the satellite system. In the nationwide network, the cognitive radio is located at the network radios.

In each of these architectures, the cognitive radios need to have access to policies. Conceptually these can be thought of as residing in policy databases (PDB) that are connected to the cognitive radios in the UAS.

Cognitive radio technology can address the UAS spectrum problem. However, what are the unique challenges for UAS and the components that make up a UAS cognitive radio architecture? The next section starts with the UAS spectrum stakeholders.

35.3 UAS Spectrum Stakeholders and Requirements

Cognitive radios can allow a UAS to share spectrum with an existing spectrum user. In this model the existing spectrum user is denoted the *incumbent*, and the UAS that is attempting to use the spectrum is denoted the *entrant*. This section describes the incumbent’s and the UAS entrant’s requirements that a spectrum-sharing approach must meet as well as the requirements of the spectrum regulator. The incumbent could be another UAS or a different type of wireless service. It is critical to understand and to address these requirements in any spectrum-sharing scheme.

35.3.1 Incumbent Requirements

Some of the requirements that incumbents would expect to be implemented through technology, spectrum-sharing criteria (i.e., regulations or standards), or negotiated sharing arrangements are shown in Table 35.1. The most obvious mandatory requirement involves assured coexistence and compatibility, addressing the core concern that any new entrant must not cause “harmful interference” to the incumbent systems. Another critical, but potentially optional, requirement is that incumbent must not only have the rights to change and upgrade its operations (e.g., waveform, locations, bandwidth), they need strong, reliable means to enforce those rights.

Table 35.1 Requirements of incumbents

| Requirement | Purpose/description |
|--|--|
| Coexistence | Entrants must not cause harmful interference to incumbents; their respective operations must be compatible with each other |
| Accommodate reasonable changes in incumbent operations or technical parameters | Incumbents should be able to change waveform types, occupied bandwidth, locations, frequencies, duty cycle, etc. without objections from entrants |
| Right to use spectrum | Entrants should accept outages or have alternative means to communicate so that incumbents can reclaim shared frequencies at times of need |
| Enforcement | There must be a method to track down and remedy interference events economically and quickly |
| Safeguards/security | Systems must be protected against unauthorized and accidental use and prevent hackers |
| Spectrum-sharing system diversity/complexity | The number and types of entrants should be manageable |
| Trust/confidence among parties | Incumbents must have assurance that sharing criteria and negotiated arrangements will not be challenged or changed except after reasonable amount of time (as mutually agreed) |
| Information security | Incumbents’ confidential information should not be revealed |

35.3.2 Entrant Requirements

Some of the initial requirements that new entrants in shared bands would expect to be implemented through technology, spectrum-sharing criteria, or negotiated arrangements are shown in Table 35.2. Again, the most obvious, mutual coexistence requirement involves some level of assured access to the shared bands and geographic areas without an unreasonable risk of “harmful interference” from the incumbent systems. A related requirement is that entrants need access to a significant amount of spectrum, especially at times of peak capacity. Another key issue for entrants is the need for standardized equipment. This may be a short-term

Table 35.2 Requirements of entrants

| Requirement | Purpose/description |
|--|--|
| Coexistence | Entrants should be able to have access to shared band without being subject to unreasonable interference protection criteria or surprises as a result of, for example, unexpected incumbent system/receiver characteristics |
| Safeguards/security | Systems must be protected against unauthorized and accidental use and prevent hackers |
| Support current architecture | Entrants should be able to use the same type of system architecture in shared bands compared to exclusive bands |
| Minimal changes and standards | Entrants need to purchase standardized, non-proprietary equipment from multiple vendors |
| Low prime power | Spectrum sharing should not significantly increase the power consumption of end user devices |
| Technical flexibility and minimal software integration and equipment upgrade costs | Entrants should be able to deploy alternative and cost-effective spectrum-sharing solutions that provide comparable interference protection to incumbents |
| Capacity and coverage assurance | Entrants’ capacity and coverage expectations in shared bands should be well understood and, subject to negotiation, binding on incumbents; a specified amount of spectrum capacity needs to be available at specified times and places |
| Spectrum and network management workload | Entrant’s spectrum and network management costs must be reasonable |
| Trust and confidence among parties | Entrants must have assurance that sharing criteria and negotiated arrangements will not be challenged or changed except after reasonable amount of time (as mutually agreed) |
| Fair use policy | In the unlicensed entrant scenario, spectrum sharing should have a policy to enable all entrants to have fair use of the shared spectrum |

matter because LTE, CDL, and other popular standards do not currently include advanced spectrum coexistence modalities, but such development is underway or expected over the next several years.

35.3.3 Spectrum Regulator Requirements

The role for regulatory officials (e.g., the FCC and National Telecommunications and Information Administration (NTIA) in the U.S.) is to maximize use of spectrum in a fair and equitable manner. Attempts to reduce spectrum sharing to a uniform, simple set of interference avoidance rules have proven to be very difficult. For example, the FCC TV white space proceeding started in 2004 and is still ongoing. Detailed technical interference avoidance rules for dynamic frequency selection to enable sharing with radar in the 5,470–5,725 MHz band had unintended consequences that made them unusable in practice. Thus, a key issue in both sets of requirements is that firm numerical values or detailed criteria should not be contained in regulations or industry standards, but could be subject to negotiation between or among the parties. There are too many potential sharing scenarios and not enough experience with more complex spectrum-sharing approaches to quantify many parameters. This can be addressed technically by developing specific system design options for policy-based spectrum-sharing systems that can be demonstrated for stakeholders for detailed feedback, which then leads to some quantification or standardization of specific requirements.

On the policy and economic side, the UAS industry needs to develop concrete recommendations to ensure that adequate spectrum-sharing rights and responsibilities can be embodied in the most appropriate and cost-effective manner. Only a few sharing criteria need to be embodied in government rules and regulations. Some may be documented in etiquettes, standards, and best practices, and they can be easily implemented in policy-based systems through machine-readable policies. The bulk of these requirements, rights, and responsibilities would be part of negotiated sharing agreements or through brokered arrangements.

If continuous regulatory involvement is necessary to manage spectrum sharing, then the regulators will impose a requirement that the management approach is required to minimize government investment. For example, a cost-effective enforcement approach will be required to track down and to mitigate any interference events.

35.4 Mechanisms for UAS Spectrum Awareness

There are multiple UAS spectrum-sharing approaches possible that have different features, capabilities, and costs. Viable approaches must be comprehensive and consider all stakeholder requirements. For example, some sharing approaches rely on geolocation (typically via GPS) and frequency assignment databases to determine

what channels an entrant can use without causing interference to incumbents. Other approaches use RF sensing to achieve that same goals. In addition to avoid causing unintended interference, the systems must have a method to enable the incumbent to enforce his spectrum rights in case the entrant system has a fault.

35.4.1 Geolocation and Database Approaches

A geolocation and database spectrum-sharing approach can consist of two types: geolocation and database and geolocation and database pooling.

35.4.1.1 Geolocation and Database Approach

The geolocation and database UAS spectrum-sharing approach uses incumbent and entrant position information, and propagation models to determine entrant operating frequencies as shown in Fig. 35.6. There could be multiple types of incumbents in several spectrum bands and multiple types of entrants sharing the spectrum. There could be multiple types of entrants system, each with different network operators. In this approach a so-called band or spectrum manager (see Sect. 35.5.2.3) collects the position and operating frequency information and estimates the propagation loss and antenna gains between the incumbents and entrants. The spectrum manager then determines the allowable entrant operating frequencies using specified interference to noise ratios (INRs) for co-channel operation and adjacent channel operation. This frequency list is then transmitted to the network operator who then decides what frequency each entrant should use. The network operator then periodically sends the frequency to entrants.

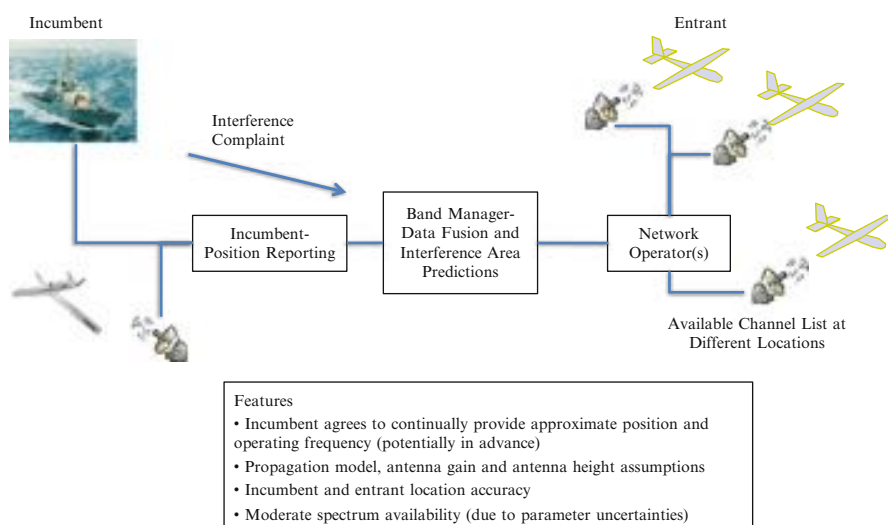

Fig. 35.6 Geolocation and database spectrum-sharing approach

This approach meets the enforcement goal because the entrants are supplying their position to the spectrum manager and they are receiving frequency lists from the spectrum manager. If an incumbent reported interference, it would be relatively straight forward to determine what entrant was causing the problem and to make adjustments.

This type of approach is being proposed for some federal bands for geographic spectrum sharing using exclusion zones or coordination zones (NTIA 2010). The FCC has issued rules for using competitive geolocation and databases to enable access to the television broadcast bands by entrant, low-power devices (FCC 2010).

The geolocation and database UAS spectrum-sharing approach has disadvantages. Agencies operating in federal frequency bands are very unlikely to provide sufficient information (e.g., location and operating frequency) on their operations, especially military uses, that is necessary to populate such databases. Obfuscation techniques such as diluted precision or added false entries may alleviate this concern. Such operations are also likely to involve shipboard, airborne, and other mobile operations that cannot be accurately captured in a database. Accordingly, a stand-alone geolocation and database approach would not likely yield significant spectrum capacity or coverage for new entrants especially if large geographic exclusion zones are the result of information gaps. This information gaps include the actual propagation losses, the current entrant and incumbent positions, the true antenna patterns as a function of angle, and other parameters. The geolocation and database must make assumptions of all of these parameters to determine the available frequencies.

The advantage of the geolocation and database UAS spectrum-sharing approach is that it may be attractive to new broadband entrants because minimal system modifications are required. For the entrant, the process is similar to the already required need to access a policy database. For less dynamic incumbent users, the incumbent reporting requirements may be minimal. For instance, a band for fixed radar would only require database changes when new radars are built.

35.4.1.2 Geolocation and Database Pooling Approach

The geolocation and database pooling UAS spectrum-sharing approach shown in Fig. 35.7 is similar to the geolocation and database approach, except in the pooling approach the spectrum sharing is among peer UAS spectrum users (there is no incumbent users). There are a single spectrum manager. The advantage of this approach is that the allowable interference levels are known and controlled by the UAS community. There are reduced issues about sharing position information since the information stays within the UAS community.

35.4.2 Sensing Approaches

A sensing spectrum-sharing approach can consist of four types: sensor network, off-board sensing, onboard sensing, and onboard sensing pooling. The goal is to identify spectrum “holes” that are not being used by incumbents (Tandra et al. 2009).

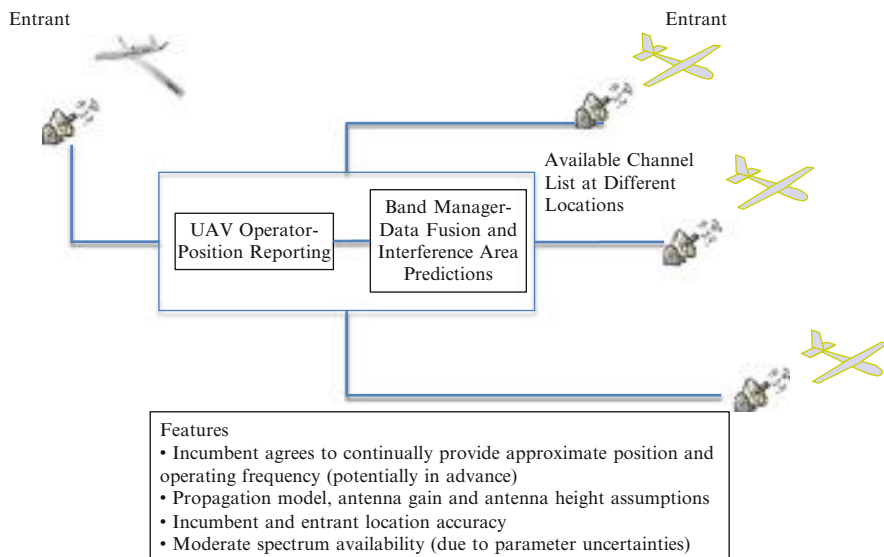

Fig. 35.7 Geolocation and database spectrum-sharing pooling approach

35.4.2.1 Sensor Network Approach

In this approach, a network of interoperable entrant UAS radios acquires context information about the regional spectrum environment by querying a stand-alone external sensor network as shown in Fig. 35.8. The sensors are located near the incumbent system locations.

This approach supports the enforcement requirement. Insufficient densities or uneven sensor distributions can result in a higher likelihood of false positive or false negative spectrum white space detection decisions. Some kind of control channel or “cognitive pilot channel” (Delaere and Ballon 2008) is therefore assumed.

One of the key advantages of this approach is to simplify the entrant radios, which would result in reductions in cost and energy consumption (Weiss et al. 2010). Another advantage is that this approach also improves the availability of spectrum white space based on superior local knowledge (the exact incumbent operating frequency and operating state is known) when compared to a stand-alone geolocation and database approach (where the incumbent operating frequency and operating state are inferred by reports and predictions).

The disadvantage of this system is the cost to install and to operate the dedicated sensor network. Another disadvantage is that the incumbent might operate in a nonstandard location (e.g., respond to hurricane in New Orleans) where there are no dedicated sensors.

35.4.2.2 Off-Board Sensing Approach

In this approach, off-board sensors are colocated with or integrated into the network base stations as shown in Fig. 35.9. Standardized or separate proprietary sensors are

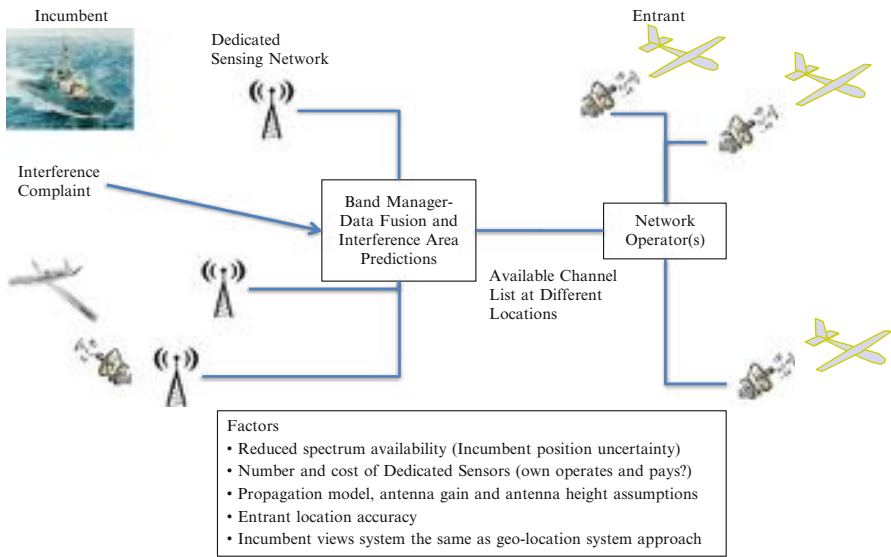

Fig. 35.8 External sensor network spectrum-sharing approach

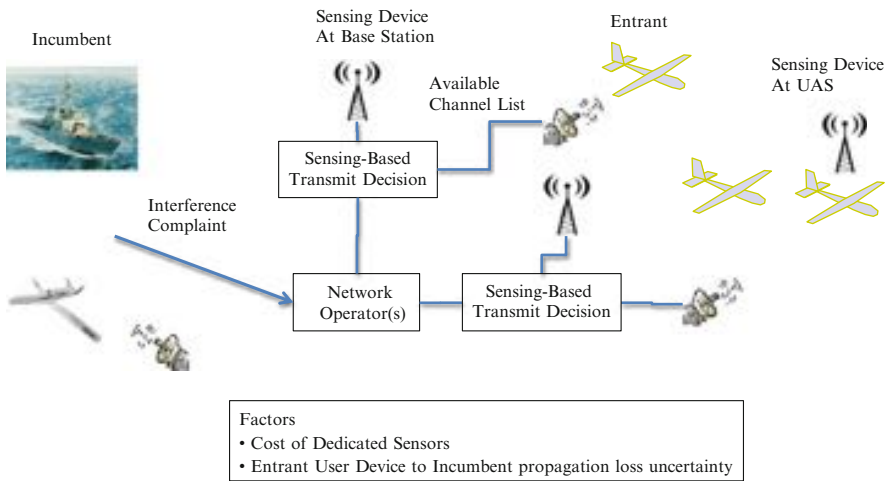

Fig. 35.9 Sensing on some entrant radio spectrum-sharing approach

used that incorporate complex technical methods to “look through” the entrant system co-channel interference to detect the weak incumbent signals. They sense the local spectrum environment with improved coverage density and distribution, thereby reducing incorrect spectrum availability decisions. Since these sensors are within close proximity to and interoperate with the end-user devices, they provide better local spectrum environment information when compared to the previous approach.

Therefore, the principal advantage of this approach is increased spectrum availability for the broadband system because of less uncertainty in determining the propagation losses between protected emitters and the broadband system base stations. However, the “look through” method might not provide enough detection sensitivity for interference free operation.

Another potential disadvantage of this approach if proprietary software solutions are used, is the nonrecurring development and testing costs required for full UAS entrant transceiver integration into the base station radio. A short-term solution involves a colocated, nonintegrated hardware/software sensor, which also adds to the incremental costs. This method could also be more difficult and costly to implement for ad hoc and low-power networks with no fixed infrastructure.

35.4.2.3 Onboard Sensing Approach

In this approach, all or a large number of interoperable UAS entrant transceivers sense the RF environment directly and make operational decisions based on those inputs as well as information gathered from neighboring, collaborative devices as shown in Fig. 35.10. The onboard sensors integrate coordinated sensing periods into the entrant waveform, measure the signal power of incumbent transmitters, and share these measurement results with other UAS entrant transceiver radios.

This approach supports the enforcement requirement because each UAS ground station is in contact with a network operator. If there is an interference event with an incumbent user, the network operator is contacted by the spectrum manager, and the offending UAS or ground station is identified and fixed. Each UAS has

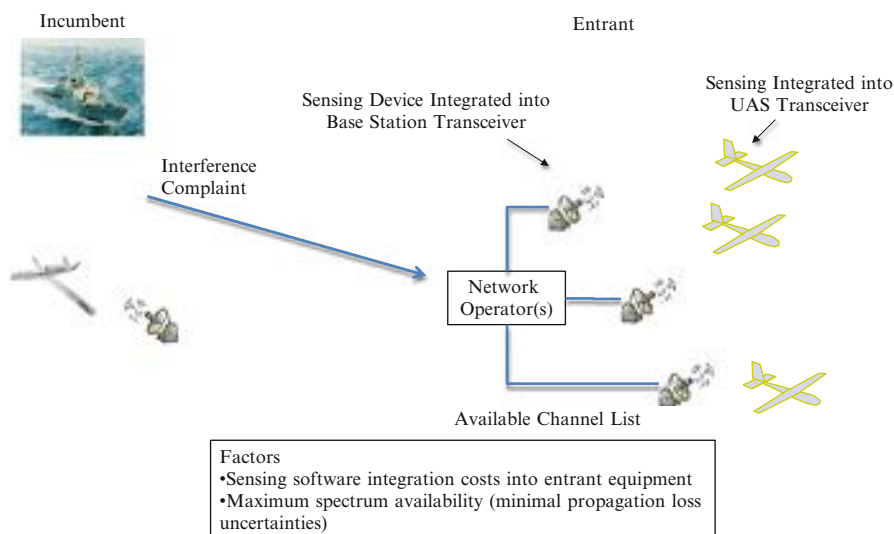

Fig. 35.10 Sensing on all entrant radio spectrum-sharing approach

a time-limited set of operating frequencies, so if it loses contact with the ground stations, it reverts to a “safe frequency” that is not likely to cause interference to an incumbent user.

The greatest advantage of this approach is that it provides the maximum spectrum availability in terms of capacity and coverage for broadband systems because of the minimal uncertainty in determining propagation losses between the incumbent systems and the device itself. Another advantage is that there are no extra hardware costs since the UAS radios will only sense in bands in which they already transmit.

A main disadvantage for short-term prospects under this approach is that non-recurring software and API development and testing are necessary to fully integrate the spectrum-sensing software in end-user devices. In addition, although some spectrum-sensing concepts (such as using the RSSI (received signal strength indicator) to select the operating frequency) are in the Long-Term Evolution (LTE) and other standards, further spectrum-sensing standards development must continue (IEEE DySPAN 2011). In light of the current lack of standards for embedding full spectrum-sensing functionalities together with the initial costs to upgrade end-user devices, this approach may be of less interest to service providers and manufacturers in the near term. Nevertheless, the preferred, long-term commercialization approach would lead to widespread development and deployment of spectrum-sensing-enabled end-user devices with onboard sensing capabilities.

Cooperative sensing information could be used to improve the incumbent radio detection probability and/or reduce the UAS sensing requirements. The problem with cooperative sensing is that if there are not enough UASs participating, then there is no sensing improvement. The requirement to operate with a single UAS sets the sensing requirements.

35.4.2.4 Onboard Sensing Pooling Approach

In this approach, all or a large number of interoperable UAS entrant transceivers sense the RF environment directly and make operational decisions based on those inputs as shown in Fig. 35.11. There is no collaboration with other UAS.

The advantage of this approach is the lowest deployment and operational costs. This approach does not require any backhaul between the ground stations, hence, is applicable to remote UAS operation. This approach is used by the military for its dynamic spectrum access tactical radios.

This approach does not directly support the enforcement requirement because the UAS positions are unknown to the incumbents and the incumbents do not have direct control of the UAS operation.

35.4.3 Beacon Approaches

A transmitter beacon spectrum-sharing approach can consist of three types: per radio, area, and entrant signaling.

Fig. 35.11 Sensing on all entrant radio spectrum-sharing pooling approach

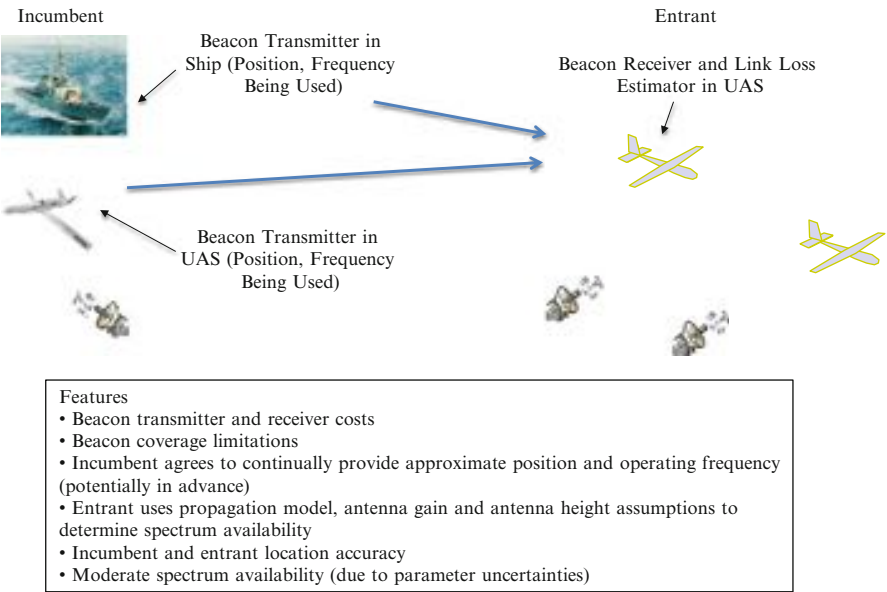

Fig. 35.12 Per radio beacon spectrum-sharing pooling approach

35.4.3.1 Per Radio Beacon Approach

A direct approach to alerting the presence of an incumbent service to entrant devices is for each incumbent transmitter or receiver to have a standardized, easy to detect, simple to receive beacon as shown in Fig. 35.12. To simplify the search for these beacons, they should be located at carrier frequencies that are standardized for

each incumbent band. The beacon could be as simple as a carrier tone. This has the potential to interfere with the incumbent signal or for spurious signals and harmonics from other bands to be detected. A more reliable approach would be to modulate the carrier with a random direct sequence spreading code. The spreading code would make it much less likely that unwanted signals could lead to false-positive detections. It could also spread the signal over a greater bandwidth so as to cause less interference to the desired incumbent signal. The beacon can encode information on the beacon signal such as the location of the transmitter, its transmit power, or a definition of its coverage area.

The advantage of this approach is more reliable channel detection while keeping full control of the beaconing with the incumbent service provider. Further, each transmitter can beacon the precise channels they are using rather than the set of channels they could be using.

The disadvantages of this approach are the beacon transceiver costs, the difficulty in integrating the beacons to existing incumbent devices, many incumbents may not want to transmit a beacon signal for security reasons, and the limited beacon link range compared to the entrant-to-incumbent interference range.

35.4.3.2 Area Beacon Approach

Instead of each transmitter having to integrate a beacon into its signal, a small amount of bandwidth could be set aside for dedicated beacons that would act as a service for all the incumbent transmitters in an area as shown in Fig. 35.13.

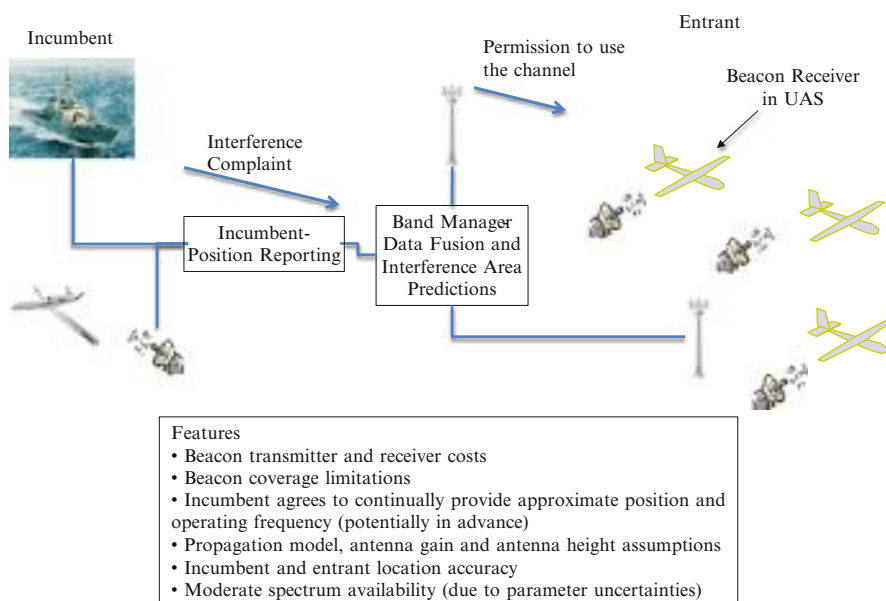

Fig. 35.13 Area beacon spectrum-sharing approach

Being in a dedicated channel, they can be higher power. Using spread spectrum techniques similar to CDMA cellular service, the same beacon channel can be used throughout the country, with different offsets of the same spreading code used for different beacons to prevent inter-beacon interference. Each beacon can provide a low-data rate service that announces the frequency band, location, and coverage area of each incumbent transmitter in the area. The required bandwidth can be small (e.g., 12.5 kHz). The power can be relatively high (relative to the bit rate) so that the coverage is large at modest power (e.g., 100 W). Approximately 1,000 area beacons could cover the continental USA.

In essence this would be a push model for the geolocation and database method with the exception that the information is limited to primary radios in the area of the beacon. The beacon information would be derived from an incumbent database. The beacons can independently choose the information they broadcast depending on their location and intended coverage area. The incumbent users can be shielded from when beacons are added, moved, or removed. This provides a level of separation between the incumbent users and the beacons. Incumbents edit the database. The beacons read the database.

This method has the advantage of providing a dedicated standardized access to the incumbent user database that avoids the need for Internet access. Since presumably there are relatively few beacons compared to the number of entrant device, the load on the central database would be minimal and therefore the database could be simpler and lower cost. Like the database method, it requires the entrant devices to have a location for themselves, although the beacons themselves provide a crude localization. For instance, the beacon might include a list of channels that can be used by any entrant device that can receive the beacon signal. In congested areas, this list may be empty, but in rural areas, this is sufficient precision to identify many unused channels. The disadvantage to this approach is the cost of the beacon network and the need for the entrants to be able to access these beacons which may be at frequencies quite different from the desired operating frequencies.

35.4.3.3 Incumbent Signaling

A more distributed option is to set aside a small frequency band for entrant devices to exchange information about incumbent transmitters. It would provide a known open channel that the entrant devices could use to signal each other about the presence of incumbent and entrant services in the area. Like the area beacons, the format could be standardized as an etiquette protocol that would enable disparate devices to communicate with each other. This would be used to augment any of the other methods in this chapter and enable new methods. For instance, entrant users might set up dedicated monitoring devices at prominent locations to identify and locate incumbent transmitters. These would in turn broadcast their findings for a user community. This could all be done on an existing entrant band, but, usable bands like the 902–928-MHz ISM band are far from the incumbent bands below 100 MHz and would add expense to the entrant radio antenna and front end if it was required to operate over this wide a range of frequencies. Alternatively, a small amount of spectrum could be set aside in or near each incumbent service frequency band.

35.4.4 Hybrid Approach

The choice of which approach to use depends on many factors. The geolocation and database approaches and the beacon approaches impose a burden on the incumbent to either maintain database information or to install beacons. The sensor approach imposes fewer burdens on the incumbent although for best detection, the sensors would need to know and track specifics of the incumbent waveform.

From the entrant perspective, each of the approaches imposes different burdens. The geolocation and sensing approaches require access to a database. The sensing imposes a burden of requiring the sensing capability as well as potentially using some spectrum resources for the sensing operation. The beacon may require the entrant to build a beacon network and require the incumbent to be able to populate the information in the beacons. In the case of the pooling approaches, the entrants need protocols and signaling channels in order to coordinate.

In terms of protection of the incumbent user, all of the approaches can be made sufficiently conservative so as to avoid harmful interference to the incumbent. Generally, as the approaches become more conservative, less bandwidth is available to the entrant. The entrant will miss opportunities to communicate if its access to the database is infrequent or its geolocation is imprecise. Sensing of weak radio signals is notoriously difficult and the number of false positives (where an entrant decides not to use a frequency band that, in fact, has no incumbent) high. Per radio beacons can be more precise but only to the extent that the beacon propagation matches the interfering signal propagation. Area beacons have the same limitations as the database approach.

Each of the approaches has advantages and disadvantages. Therefore, a combination of the above techniques may be used to address short-term cost and performance concerns. For example, onboard sensing could be supplemented with off-board or other sensing or database information.

35.5 Mechanisms to Manage UAS Spectrum Access

Spectrum access is the process by which the cognitive radios in the UAS choose which frequency bands to communicate. It consists of several dimensions related to the type of spectrum, which parties control its use, and how it interacts with UAS operations. Conceptually, spectrum access can be thought of as having a policy that permits usage of a specific band for a specified period.

As an example, consider ATC communications for a manned aircraft at a small airport. Aviation maps indicate the ATC channel for the airport. So based on location and phase of flight (i.e., in Start and Takeoff), the pilot has an existing “policy” for this situation to use the ATC band on a shared basis without asking permission. After the plane takes off and enters the en route phase of flight the access changes. Now the pilot does not have an existing “policy” for using an ATC channel. The pilot is assigned a channel by the en route controller who periodically assigns the

pilot to new channels based on plane location. In this case, the channel used is not in a set of stored policies selectable by the pilot. Instead, the policy is dynamically assigned by the ATC center. Like the airport channel, the en route channel is shared; however, access to the channel is controlled and limited. The goal of the cognitive radio is to automate these processes while retaining the level of control required by the different stakeholders.

35.5.1 Types of Spectrum Access

Spectrum access can be classified along two dimensions. In one dimension, spectrum access can be *licensed* or *unlicensed*. Licensed refers to an access where UASs have to ask for a permission before they can use spectrum. Unlicensed refers to an access where UASs can use spectrum without having to ask for any permission. But, they may still have to follow certain rules.

In another dimension, spectrum access can be *interruptible* or *uninterruptible*. Interruptible refers to when a UAS entrant accesses the idle incumbent spectrum on the condition that UAS does not interfere with the incumbent. UASs have to vacate the spectrum if the incumbent starts to transmit. In other words, incumbents have priority over UAS entrants.

Uninterruptible, in contrast with interruptible, refers to an access where UASs do not have to avoid any other incumbents but may have to avoid interfering with other UASs via the use of some etiquette protocol. There are no other spectrum users having priority over UASs.

The two dimensions combine as shown in Table 35.3 and described below.

Licensed, Uninterruptible: One version of this model resembles the traditional approach for licensed spectrum use. UASs are the incumbents and have exclusive rights to use spectrum granted by the spectrum regulator. But the spectrum assignment in this model could be more dynamic – the spectrum rights could be changed frequently and assigned quickly. In a further variation, UASs lease spectrum from other spectrum holders and temporarily have the rights to use the leased spectrum for a specified period. During the lease period, the spectrum holders cannot interrupt the UASs.

Unlicensed, Uninterruptible: UASs use designated unlicensed bands like the 2.4-GHz ISM band.

Unlicensed, Interruptible: UASs are unlicensed entrants accessing white spaces in incumbent’s spectrum. Certain bands that are normally used by incumbents are available to UASs for unlicensed operation when and where the incumbents are not using channels. UAS radios have to be capable to avoid interfering with primary

Table 35.3 Types of spectrum access and an example of each

| | Uninterruptible | Interruptible |
|------------|-----------------|----------------------------|
| Licensed | Cellular | Secondary spectrum leasing |
| Unlicensed | WiFi | TV white space |

users and vacate channels if primary users appear. This model is similar to the approach in which the FCC has allowed TV band devices accessing TV white spaces (FCC 2010).

Licensed, Interruptible: This is a secondary spectrum-leasing model, where UASs lease spectrum from other incumbents but must avoid interfering with these incumbents. This model is similar to the licensed, uninterruptible spectrum leasing, but the difference is that the spectrum holders can interrupt the UASs anytime as they wish. If the incumbents interrupt, UASs have to vacate the spectrum. This model is also similar to unlicensed, interruptible model, but the number of entrants is limited by licensing.

Each model could be further divided into fixed assignment and dynamic assignment. In fixed assignment, users take control of spectrum for a long time, e.g., 10 years, while in dynamic assignment, users use spectrum for a relatively short time, e.g., a few minutes, hours, or days.

To support more dynamic leases, policies have a notion of a *time-limited lease* (Chapin and Lehr 2007). This implies that each policy has a specified period over which it is valid. The specified period could be specific dates it is valid or short time intervals. For instance, a control channel for landing might be assigned in a policy valid for a 10-min period during final approach after which it would be released for other landing aircraft.

35.5.2 Control of Spectrum Access

Spectrum access is controlled by policies. What are the mechanisms to distribute and manage policies that underpin the control of spectrum access? To address this question, it is necessary to examine where the policies come from, where they are ultimately used, and how the process is mediated.

35.5.2.1 Where Do Policies Come From?

An important concept is the leasing and sub-leasing of spectrum through policies as illustrated in Fig. 35.14. Policies originate from base authorities. In the United States, this might be the FCC or NTIA. The NTIA through a policy grants the Federal Aviation Administration (FAA) control over a specific frequency range and set of locations (a specific 10-MHz block over the continental USA for 5 years in this example). This chain is extended further by the FAA providing policies to other entities. In the example, the FAA grants the Phoenix Sky Harbor International Airport (PHX) the rights over the 10 MHz in the vicinity of the airport (which, for simplicity, is described as Arizona). In turn, PHX can assign channels to specific aircraft.

The policies used to access spectrum must be valid in three ways. First, they must come from a source which is authorized to issue a policy. An end user needs to see not only the final policy but also the chain of policies tracing back to a trusted root source (in this case, the NTIA). Because policies might be corrupted or maliciously modified in transit, the policies need to be cryptographically protected with a digital signature so that the end user can verify that each policy originated

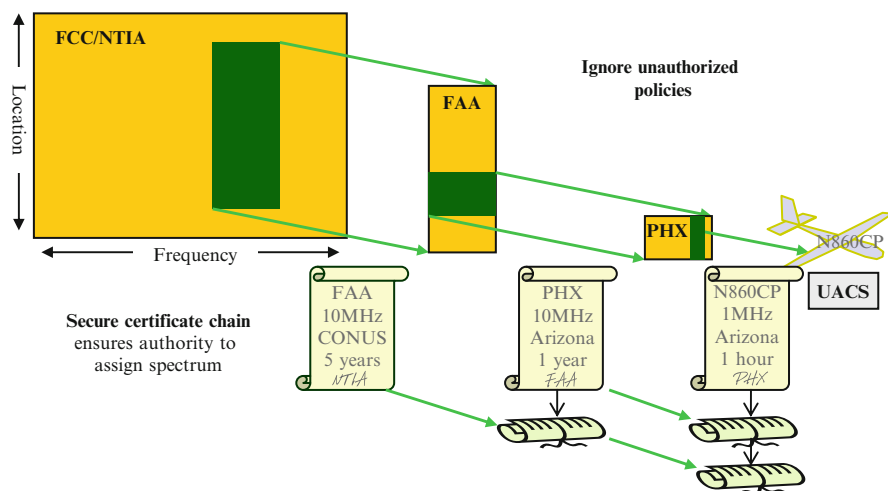

Fig. 35.14 Certificate chain

from the purported source (Stallings 2000). Second, they must be consistent and not contradict other policies. The characteristics of the policies such as the spectrum bands and time period for each subpolicy must be a subset of the higher-level policies. Further, there may be other prohibitive policies that exclude use in certain bands. The end user must validate the policy it uses against these other policies. To enable this validation and reasoning, the policies must be written in an appropriate machine-readable form (IEEE 1900.5). Third, the conditions of the policy must match the situation to which the policy will be applied. The end user must validate that it meets the location, type of communication, and other conditions of the policy before it uses the policy. In particular, the bands must be available according to the spectrum awareness function and the radio must be capable to transmit in the band.

Since the FAA/NTIA can grant such spectrum policies to multiple sub-entities which in turn can grant to multiple sub-subentities. This process produces a distributed policy tree with each node only required to (a) store the chain of policies to the root of the tree that validates its authority and (b) manage issuing policies to their direct child nodes. Policies can be issued in a chain architecture where a child policy includes the parent, grandparent, etc., policies. This simplifies the policy validation since every policy contains all the required information for the end user to validate the policy. However, in an environment where a child policy changes often, this increases the burden on the system since the entire chain has to be sent every time. In the above example, a plane that travels often to PHX would receive the entire three-policy chain every time it used the airport. An alternate approach is a web approach where the end user downloads the policies one by one. Here the challenge is that the end user needs to have access to and be able to find all the policies in the chain. This can be simplified by embedding short “resource locator” information about the needed higher-level policies. In this case, the parent policies

are stored and only the child policy changes. Note that the public keys required for the digital signatures can be distributed either embedded in the policies themselves or according to their own distribution chain.

35.5.2.2 Where Are Policies Used?

The end user of a policy could be the cognitive radio in the UA or the cognitive radio at the other side of the connection (in the control station, satellite, or network radio). In this cases the one side or the other that is receiving the policies would control the choice of frequency band used for communication. In using a policy, it is possible for the two cognitive radios to be widely separated. Thus, in applying the policy, the end user must consider the situation at both sides of the connection. In some cases, both sides of the connection may hold their own set of policies and neither is controlling the choice. Because they are widely separated, they may hold different spectrum awareness views. In the worst case, there may be no connection and the problem is for the radios to find a common spectrum band to *rendezvous* in order to start communication (Akyildiz et al. 2006).

Policies can also go to some other controlling entity. For instance, a policy might go directly to a UAS operator who performs all of the validation of a policy and then through a trusted link sends the frequency assignment to the UAS. Or, policies might go to another agent who similarly acts on behalf of the UAS.

Some policies are *open-ended*; anyone holding the policy that meets the conditions of the policy may use the policy. Other policies are assigned to use by *specific* end users.

35.5.2.3 How Are Policies Mediated?

In the above example, the policy's authority follows through specific organizations. More generally, these policies are mediated by a *spectrum manager*. The spectrum manager is responsible for gathering policies from appropriate agencies and distributing them to sublessees. A spectrum manager may be an agent within an organization or a separate designated third party.

There are several models for how spectrum policies can be distributed. In a *shared* model, policies may give access to a band of spectrum to a set of end users who must coordinate their access. At one extreme, the access is open-ended in terms of the number of users who are given access and as to the period that it is available. Like the ATC band at the airport, many users potentially have access for an extended period of time. There may be operational limits to the number of users on a band (only so many airplanes can use the airport) or other limits (a band that is busy will simply not be used). Such shared use works better when there are rules or etiquettes (e.g., listen before talk) to manage communication. To avoid channels from becoming overloaded and unusable, a *limited shared* model may be used where the set of users that have access are limited in number or time. At the other extreme is a *dedicated* model where a spectrum band may be given to only one end user at a time. The limited and dedicated models require the spectrum manager to track which users have active policies at any given time. To better control the access, the spectrum manager may flag a policy as being *terminal*, meaning that it cannot be subleased further.

Policies can be created on an *as-needed* basis. In this model, based on the operational situation, the spectrum manager issues policies to the end user as needed to fulfill specific needs. For instance, an airport may issue policies to UA on approach to provide them with a dedicated high-quality band for controlling the landing of the aircraft. Policies can be *negotiated*. In this model, the end user may make a request to a spectrum manager for a policy to fill a specific need. The spectrum manager responds with a policy that meets the request or with a message that the request cannot be met. In the latter case, the end user may make a revised request seeking to find the spectrum it needs. Policies can also be *premade* and warehoused in a database accessible to end users. Here a user visits the database, downloads suitable policies, and makes its own decision about which policy to use. The premade model works best for distributing shared policies and for storing higher-level policies that users can use to validate end-user policies.

A problem that is particular to UAS is being sure that there is spectrum available to control the aircraft throughout its flight plan. In a *real-time spectrum* model, the UAS dynamically selects policies over the course of the flight. For shorter-range and shorter-duration flights, this makes sense. Some UAs are large and costly and can fly for more than a day over distances spanning a continent. It would make sense for such a plane to have a spectrum plan to match its flight plan. In the *preplanned spectrum* approach, the UAS gathers policies not only for its current needs but also for its needs over the entire flight plan. The previous two models make the communication depend on the flight operations. A third model is a coordinated model that connects the communication and flight operations. In the *coordinated spectrum and flight* approach, the aircraft modifies its flight path as needed to ensure that spectrum is available. For instance, in the networked radio approach, if the UA flight path crosses a radio cell that is currently at capacity, the UA can modify its flight path. The flight path could be routed around the busy cell through cells that do have capacity. Or the aircraft could slow down to provide time for traffic in the cell to subside. If necessary, the plane might even loiter at the edge of the cell until the needed spectrum is available. Conversely, the spectrum manager for a cell can consider the flight plan, endurance, and other factors of incoming aircraft in prioritizing which aircraft are given a channel.

Note that spectrum access interacts with spectrum awareness. In the case of the geolocation and database approach, the spectrum availability in the database can be expressed directly in policies similar to this section. For sensing, the policies can specify how often sensing is necessary, the sensitivity levels for detection, and the consequences of positive detection. For beacons, the policies can specify how often beacons must be received and other conditions. So, in this way, policies can mediate the interaction between different spectrum awareness schemes. For instance, some bands may be allowed without any sensing. In this way entrants without sensing can still access spectrum. Other spectrum will specify sensing or beacon requirements that will allow radios with these capabilities further access to the spectrum.

This section emphasizes the flexibility with which spectrum access can be managed through the use of policies. A summary of all the choices in a UAS cognitive radio design are given in Table 35.4.

Table 35.4 UAS cognitive radio architecture choices

| Property | Design choices |
|---------------------------------------|---|
| UAS C3 architectures | Direct Satellite Ground network Mesh |
| Spectrum awareness | Geolocation Geolocation pooling External sensing network Sensing on some entrant radios Sensing on all entrant radios Sensing on all entrants pooling area beacon per radio beacon Incumbent signaling Hybrid approach |
| Spectrum access | Unlicensed Licensed |
| Entrant response to incumbent | Uninterruptible Interruptible |
| Policy authentication | Embedded-entire chain in every policy Web-chain assembled from multiple policies |
| Public key distribution | Embedded in policies Separate infrastructure |
| Frequency choice | Assigned by UA CR Assigned by other CR Assigned by third party Rendezvous |
| Policy assignment | Open-ended Specific end users |
| Spectrum exclusivity | Open shared (unlicensed) Limited shared Dedicated |
| Policy creation | As needed Negotiated Premade |
| Spectrum interaction with flight plan | Real-time spectrum Preplanned spectrum Coordinated spectrum and flight |

35.6 Example

In this section, an example is given of a cognitive radio-enabled UAS. In this fictitious example, a medium altitude long-endurance unmanned aircraft operated by the U.S. Customs and Border Protection Agency (CBP) is tasked with flying along

a coast to monitor marine traffic. The aircraft is controlled from a remote ground control station. The example follows the aircraft through different phases of flight.

Flight Planning: As the plane is prepared for its mission by the ground crew, the autopilot indicates that the plane is in the flight planning phase of flight. For this phase, any spectrum (e.g., unlicensed interruptible) can be used. To exchange flight plan data, update maintenance records, and upgrade onboard software, the plane needs high bandwidth. Delays are tolerated and higher-layer (i.e., TCP) protocols compensate for packet losses. Therefore, based on its location, phase of flight, and a long-term premade policy, the UA identifies the 2.4-GHz ISM band as acceptable. This is a shared unlicensed band. The policy chain is direct from the FCC. However, the policy was downloaded months before from an intermediate CBP policy database. The policy is validated using a well-known public key for the FCC. Also at this time, the UAS negotiates a policy for the spectrum used during the en route and aerial work phases of flight.

Start and Taxi: Control of the plane is passed to a distant UA control station. A ground-based network communicates with a transmitter located at the airport that communicates directly with the plane. At this point the UA chooses a premade policy for UA ground operations issued by the local airport and stored in a public database. This is a policy specifying a shared unlicensed uninterruptible band that is restricted to aircraft in start and taxi operations. However, the spectrum is allocated to an incumbent for a future different but, as yet, unneeded purpose. Every week, the incumbent user issues a policy good from the time of issue until a month into the future. During this month, the incumbent revokes its right to interrupt and use the spectrum. When the incumbent wishes to regain use of the spectrum, it stops issuing new policies. Since this policy is downloaded infrequently (twice a month would be sufficient), the entire policy chain is embedded in the policy along with the public key chain.

Takeoff and Departure: The pilot indicates that the plane is ready for departure. At this point the plane is assigned a policy that is valid for 15 min using a spectrum appropriate for this airport. If the plane should be delayed on the runway, additional policies would be assigned that extend the time period. The spectrum is a dedicated licensed uninterruptible spectrum allocated for this purpose, and the UA is assigned a policy for one of the channels in the allocation. Communication is direct between the UA and a radio at the airport. To simplify policy assignments, only the last link of the policy chain is sent. The plane must have stored the higher links in the policy chain. The plane separately downloads public key information.

En route: As the plane gains altitude, the autopilot indicates that the plane has entered the en route phase and the plane switches to its preplanned en route frequencies. The policy used for departure is released. While en route, the plane uses a network of ground radios as it flies from inland toward the ocean. Each ground radio uses spectrum in its area on a secondary basis from unused white space. The spectrum is a mix of interruptible and uninterruptible spectrum. There is, in fact, a surplus of spectrum for this purpose, and statistically, the plane has enough preplanned policies such that the likelihood of having its entire spectrum interrupted is negligible. Further, though spectrum is shared with other UAS, the preplanning

ensures that each ground node always has sufficient spectrum to serve all aircraft in its cell. If planning would have revealed an overload, then alternate routes or times would have been suggested to the UA at the preflight stage. Much like a cellular mobile system, the ground cells direct the plane as to which channel it should use at any time. Through a network of sensors, the ground stations identify the presence of incumbents and guide the use of spectrum. En route communication traffic demands are small and sporadic so access to spectrum is shared for efficiency but limited to ensure good performance. Because of the potentially many sources of spectrum, the full policy chain and public keys are embedded in each policy.

Aerial Work: Reaching the ocean, communication switches to a licensed satellite channel to provide UA C3. The UA would also like to send video and sensor data back to the control station. Since the channels are limited and aerial work operations are difficult to preplan, the UA switches to a coordinated spectrum and flight operations mode. For instance, upon reaching the ocean, if no satellite channel is available, the UA might loiter until a channel becomes free. Once under the control of the satellite, the plane must negotiate periodically for how much spectrum it gets at any time. During some times it can backhaul all video and sensor data. At other times only basic C3 data can be sent. To simplify negotiations, since all but the last link of the policy chain is the same in each policy, the initial links are sent once and only modifications are sent at each renegotiation.

Emergency: While over the water, the UA engine loses power and must find a place to land within a 75-mile radius. The plane has a set of preloaded policies for this situation. Initially, it uses the dedicated satellite channel. But as it approaches the airport, it needs to switch to a more responsive ground-based architecture. It has a premade policy which directs it to use one of several unlicensed frequency channels but only as allowed by an area beacon located at the airport. Though unlicensed, it is only allowed for emergency operations. The beacon specifies which band is currently reserved for emergency operations and helps facilitate rendezvous with the control station radio should the emergency be communication related. With this frequency band, the emergency landing is successful.

The specific architecture choices made at each phase of flight are summarized in Table 35.5.

35.7 Conclusion

Cognitive radio is a flexible technology that supports different communication architectures and enables access to more spectrum for UAS operations. Fallow spectrum can be used through time-limited policies so that a spectrum manager can manage when and where spectrum can be accessed. Different spectrum awareness schemes ensure that UAS are aware of available spectrum and avoid causing harmful interference to incumbents. By resolving the static allocation issues, spectrum managers would be more willing to offer up spectrum, thus making more spectrum available and less spectrum left fallow.

Table 35.5 Summary of architecture choices made during example flight

| Property | Flight planning | Start and taxi | Takeoff and departure | En route | Aerial work | Emergency |
|-------------------------------------|--------------------|--------------------------|-----------------------|--------------------------|-------------------------|--------------------|
| Policy chain | FCC→all | NTIA→primary→airport→all | NTIA→airport→end user | Various→network→end user | NTIA→satellite→end user | NTIA→airport→all |
| UAS C3 architectures | Direct | Direct | Direct | Ground network | Satellite | Direct |
| Spectrum awareness | Geolocation | Geolocation | Geolocation | External sensing | Geolocation | Area beacon |
| Spectrum access | Unlicensed | Licensed | Licensed | Unlicensed | Licensed | Unlicensed |
| Entrant resp. to incumbent | N/A | Uninterrupt. | Uninterrupt. | Interruptible | Uninterrupt. | N/A |
| Policy authentication | Embedded | Embedded | Web | Embedded | Web | Embedded |
| Public key distribution | Separate | Embedded | Separate | Embedded | Separate | Embedded |
| Frequency choice | UA CR | UA CR | Third party | Other CR | Other CR | UA CR |
| Policy assignment | Open-ended | Open-ended | Specific end user | Specific end user | Specific end user | Open-ended |
| Spectrum exclusivity | Open shared | Open shared | Dedicated | Limited shared | Dedicated | Open shared |
| Policy creation | Premade | Premade | As needed | As needed | Negotiated | Premade |
| Spectrum interaction w/ flight plan | Real-time spectrum | Real-time spectrum | Real-time spectrum | Preplanned spectrum | Coordinated | Real-time spectrum |

The cognitive radio approach can also be used to increase flight safety. Spectrum arrangements can be made which can more easily be checked for consistency since they are explicitly coded in machine-readable form. Further, the cognitive radio enables appropriate spectrum to be used in each phase of the flight allowing more bandwidth to be safely used as illustrated in the extended example. Spectrum usage can be planned before flights to assure sufficient spectrum is available and the cognitive radio can more easily avoid channels with interference and other impairments increasing communication reliability.

Cognitive radios enable new spectrum allocation and business models. For instance, a spectrum owner can rent spectrum for individual UA flights. The UA operator based on its flight plans could get leases for specific time periods covering the flight. The spectrum can be rented long in advance (e.g., a month) and a policy issued immediately specifying the frequency for the period of the planned flight. The spectrum owner is ensured that the spectrum will be used only as planned and the UA operator can better prepare its flights.

UAV Architectures

***George J. Vachtsevanos and
Kimon P. Valavanis***

Kimón P. Valavanis and George J. Vachtsevanos

Complex engineered systems, like UAVs, combine a diverse grouping of hardware and software technologies for their performance and effectiveness. They must incorporate in their design and operation sophisticated hybrid architectures that integrate in a rather robust way and meet stringiest performance requirements. UAV Architectures presents and discusses UAV system concepts migrating from the individual UAV component technologies towards a “*system of systems*” view addressing and answering the question “*how do we put it all together?*”

► **HDRC3: A Distributed Hybrid Deliberative/Reactive Architecture for Unmanned Aircraft Systems** by Doherty, Kvarnstrom, Wzorek, Rudol, Heintz, and Conte presents a distributed UAS architecture, also extendable for use with multi-platform systems, providing full integration of both low and high autonomies. It covers the full spectrum of functionalities required for operation in missions requiring high autonomy. Specific interfaces and languages are introduced, which provide seamless transition between deliberative and reactive capability and reactive and control capability. Hierarchical Concurrent State Machines are introduced as a real-time mechanism for specifying and executing low-level reactive control. Task Specification Trees are introduced as both a declarative and procedural mechanism for specification of high-level tasks. Task planners and motion planners are described which are tightly integrated into the architecture. Generic middleware capability for specifying data and knowledge flow within the architecture based

on a stream abstraction is also described. Emphasis is placed on the robust integration and interaction between these diverse functionalities using a principled architectural framework. The architecture has been empirically tested in several complex missions, some of which are also described in this chapter.

► **Classification of Multi-UAV Architectures** by Maza, Ollero, Casado, and Scarlatti presents a classification of different schemes for multiple UAV cooperation considering the coupling between the vehicles and the type of cooperation. It also considers UAVs that are networked with other elements in the environment to support their navigation and, in general, their operation. The chapter provides a theoretical framework but also emphasizes practical field demonstrations involving aerial vehicles.

► **Operator Interaction with Centralized Versus Decentralized UAV Architectures** by Cummings starts from the fact that there are major attempts to streamline UAV operations and reduce staffing in order to invert the current many-to-one ratio of operators to vehicles. It then introduces architectural schemes in the context of optimizing operator workload and efficiency. In centralized multiple UAV architectures, a single operator, who requires significant cognitive resources, interacts with and oversees every UAV in the network. In decentralized multiple UAV architectures an operator interacts with an automated mission and payload manager, which coordinates a set of tasks for a group of highly autonomous vehicles. While a single operator can maintain effective control of a relatively small network of centralized UAVs, decentralized architectures are more scalable, particularly in terms of operator workload, and more robust to single points of failure. However, in terms of operator workload, the ultimate success of either a centralized or decentralized UAV architecture is not how many vehicles are in the network per se but rather how many tasks the group of vehicles generates for the operator and how much autonomy is onboard these vehicles. Task-based control of UAV architectures with higher degrees of autonomy (i.e., decentralized networks) can mitigate cognitive overload and reduce workload. Mutually exclusive boundaries for humans and computers in multiple UAV systems should not be the goal of designers for either centralized or decentralized architectures, but rather more effort needs to be spent in defining mutually supportive roles such that humans and computers complement one another.

Collectively, the reader is provided with information on single and multiple UAV architectural systems, hierarchical and hybrid architectures, centralized and decentralized ones, as well as architectures that optimize operator performance.
